PREFACE

This is a collection of summaries for more than 1200 research projects funded by the Office of Basic Energy Sciences (BES) in Fiscal Year 2014 at some 200 institutions across the U.S. This volume is organized based on the three BES divisions: Materials Sciences and Engineering (MSE); Chemical Sciences, Geosciences, and Biosciences (CSGB); and Scientific User Facilities (SUF). Within the MSE and CSGB divisions, the summaries are further organized by research program. For the SUF division, summaries are provided for the research projects in accelerator physics and x-ray and neutron detectors.

This is the third annual issue of BES research program summaries. The volume covers core research activities supported by BES. While every attempt was made to obtain a summary for each research project supported in FY 2014, there may be some omissions. Some specific activities are not covered, including the construction and operation of scientific user facilities, Energy Frontier Research Centers, the Fuels from Sunlight Energy Hub, the Batteries and Energy Storage Hub, and the Small Business Innovation Research (SBIR)/Small Business Technology Transfer (STTR) program. Each project summary includes: title, point of contact (to whom questions should be addressed), principal investigator, other senior investigators, postdoctoral fellows, graduate students, approximate funding given in FY 2014 (annual funding shows a single year; forward funding shows the entire award period), a brief description of the research project, and research highlights for FY 2014. For Experimental Program to Stimulate Competitive Research (EPSCoR) projects, the funding for the entire award period is shown. Many of these projects are jointly funded by other Department of Energy programs. A small number of awards are jointly funded by more than one BES research program. These entries are duplicated in both research programs and show the full funding amount.

This collection is complementary to the *Basic Energy Sciences 2014 Summary Report*, which describes in detail how BES is structured and managed and provides overviews of each of the three BES divisions and special research activities.

Tracing and Controlling Ultrafast Dynamics in Molecules

Institution:	Colorado, University of
Point of Contact:	Andreas Becker
Email:	andreas.Becker@colorado.edu
Principal Investigator:	Andreas Becker
Sr. Investigator(s):	
Students:	0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$140,000 (2014)

PROGRAM SCOPE

The emergence of attosecond technology has shifted our perspective in ultrafast science from the time scales intrinsic to nuclear dynamics to that of electron dynamics. With our projects we seek to provide theoretical support to establish new ultrafast concepts and optical techniques to obtain an advanced understanding and interpretation of electron dynamics in atoms and molecules.

FY 2014 HIGHLIGHTS

1. Finite-range time delays in numerical streaking experiments

The attosecond streak camera technique enables the retrieval of temporal information of ultrafast processes on the attosecond time scale. Based on our quantum simulations as well as a classical trajectory analysis, we have shown that the observed time delay can be written as a sum or integral of piecewise field-free time delays weighted by the instantaneous streaking field strength, relative to the streaking field strength at the instant of transition of the electron into the continuum. This led us to the intuitive interpretation that - for single photoionization - the observed time delay depends on the finite time between the transition of the photoelectron from the initial bound state into the continuum and the end of the streaking pulse.

2. Generation of isolated ultrashort pulses using long driving wavelengths

We have examined an alternative path of generating isolated ultrashort pulses by multi-cycle driving laser pulses at midinfrared wavelengths. Our calculations are based on a numerical model, in which harmonic generation is computed via an extension of the strong-field approximation on the microscopic level. Macroscopically, the gas medium is then discretized into elementary radiators and the radiation (harmonic emission) of each of these sources is propagated to the detector and calculated as coherent sum. Our results indicate, in support of corresponding experimental observations, that a temporal gating of the harmonic emission down to one optical cycle can be achieved.

3. Multiple rescattering dynamics at the single atom level

We have studied a control scheme based on the interrogation of the process of HHG by application of a second color of light. We have demonstrated selective generation of electrons into trajectories

which revisit the parent nucleus several times and have examined the signatures of multiple rescatterings in the temporal and frequency domain of the radiation.

Structure and Dynamics of Atomics, Ions, Molecules and Surfaces

Institution: Kansas State University

Students: 7 Postdoctoral Fellow(s), 22 Graduate(s), 2 Undergraduate(s)
Funding: \$2,500,000 (2014)

PROGRAM SCOPE

A wide range of experimental and theoretical projects have been conducted at the J.R. Macdonald Laboratory (JRML), Kansas State University, which fall into the category of observing and controlling single atoms and molecules on short time scales. The underlying goal is to eventually make this time scale the natural one on which electrons move in matter. These projects revolve around two themes, "Attosecond Physics" and "Control". There is, in reality, no sharp boundary between the two. In fact, we expect considerable cross-fertilization to enrich both efforts. The JRML laser sources, namely the Kansas Light Source (KLS), the newly-installed high power tunable wavelength HITS laser, and the high repetition rate PULSAR, provide a broad range of laser capabilities and ample beam time for research and development. Shorter, more intense attosecond pulses of radiation from harmonic generation, for instance, have been used to investigate electronic motion in the time domain and are constantly being developed further. The JRML theorists continue developing analytical and computational approaches, in addition to building and refining models for complicated processes, to analyze the interaction of femto- and atto-second pulses of light with atoms, molecules, and surfaces. Most JRML group members additionally participate in experiments in various labs around the world, provide theoretical support for such experiments, and otherwise actively pursue collaborations outside of JRML. Moreover, JRML continues to host several outside investigators for their experiments. All of these activities build towards the ultimate goal of understanding the dynamical processes of reactions well enough to control them while positioning JRML to be a leading center for ultrafast AMO physics.

FY 2014 HIGHLIGHTS

The Lab has seen many upgrades during this year. One of the more significant is the addition of a world-class 1 kHz ultrafast intense laser system funded partly by DOE. The HITS laser, which was delivered and installed by KMLabs in the spring, is rapidly being incorporated into our research, extending our capabilities by providing higher pulse energy (20mJ), tunable mid-IR wavelengths using a white-light-seeded optical parametric amplifier, and long term (better than 300 mrad RMS over 9 hours) carrier-

envelope phase (CEP) stability. We have been involved in a variety of projects this past year. Some of the most significant are: Imaging charge transfer in iodomethane upon x-ray photoabsorption, waveforms for optimal sub-keV high-order harmonics with synthesized two- or three-color laser fields, sub-femtosecond steering of hydrocarbon deprotonation through superposition of vibrational modes, Optical damage threshold of Au nanowires in strong femtosecond laser fields, multi-pulse three-dimensional alignment of asymmetric top molecules, and enhancing the intense field control of molecular fragmentation.

Probing Complexity using the LCLS and the ALS

Institution: Connecticut, University of
Point of Contact: Nora Berrah
Email: nora.berrah@uconn.edu
Principal Investigator: Nora Berrah
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$630,000 (2014-2016)

PROGRAM SCOPE

The goal of our research program is to investigate fundamental interactions between photons and molecular systems to advance our quantitative understanding of electron correlations, charge transfer and many body phenomena. Our research investigations focus on probing on femtosecond time-scale multi-electron interactions and tracing nuclear motion in order to understand and ultimately control energy and charge transfer processes from electromagnetic radiation to matter. Most of our work is carried out in a strong partnership with theorists. Our current interests include: 1) The study of non-linear and strong field phenomena in the x-ray regime using free electron lasers (FELs), and in particular, the ultrafast linac coherent light source (LCLS) x-ray FEL facility at the SLAC National Laboratory. 2) Time-resolved investigations of molecular dynamics using pump-probe techniques. Our experiments probe physical and chemical processes that happen on femtosecond time scales. This is achieved by measuring and examining both electronic and nuclear dynamics subsequent to the interaction of molecules and clusters with LCLS pulses of various fluence and fs (4-500) pulse duration. 3) The study of dynamics and correlated processes in select molecules as well as anions with vuv-soft x-rays from the Advanced Light Source (ALS) at Lawrence Berkeley Laboratory.

FY 2014 HIGHLIGHTS

1) Buckyball Explosion by Intense Femtosecond X-Ray Pulses: A Model System for Complex Molecules. We have carried out an experimental and theoretical study of C₆₀ molecules interacting with intense x-ray pulses from the LCLS X-ray free electron laser, revealing the influence of processes not previously reported. This work presents an essential step for the rigorous, quantitative understanding of femtosecond molecular dynamics. Measurements guided the development of molecular dynamics simulations suitable for large molecules exposed to intense XFEL pulses. Experimental and simulation data on C₆₀ ion dynamics reveal that a complex variety of physical and chemical processes are present in these interactions. Our model demonstrates that full atomic fragmentation of C₆₀ occurs at the highest fluence while molecular fragments are generated at medium fluence. We show that ionization suppression occurs for very short pulses (4 fs). Furthermore, our experiment provided evidence that the charged particles produced by exposing an extended quantum system, C₆₀, to high-fluence x-rays behave as if they were classical particles. At high fluence, the parent molecule explodes within few tens

of fs, giving rise to fragment ions and highly charged state of C atom including fully stripped C fragments. Scientific American, 310, 64, (2014); Nature Comm., 5, 4281 (2014); Faraday Discuss. 171, 471 (2014); J. Phys. B: At. Mol. Opt. Phys. 47 124006 (2014); J. Elec. Spect and Rela. Phen, 196, 34 (2014).

2) Advanced Instrumentation for LCLS-Based Research. We have built and commissioned a multi-user facility that consists presently of two instruments located at the LCLS and available to any user. They are: 1) the X-Ray Split and Delay (XRSD) to carry out time-resolved experiments utilizing x-ray pump x-ray probe technique and 2) the LAMP instrument which presently houses two imaging detectors and two VMI spectrometers. These instruments have already been used for experiments.

EARLY CAREER: Ultrafast Electron Diffraction from Aligned Molecules

Institution: Nebraska, University of
Point of Contact: Martin Centurion
Email: martin.centurion@unl.edu
Principal Investigator: Martin Centurion
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The aim of this project is to record time-resolved electron diffraction patterns of aligned molecules and to reconstruct the 3D molecular structure. This will allow us to investigate, on a fundamental level, the conversion of light into mechanical and chemical energy at the molecular level. Femtosecond laser pulses are used to excite the molecules and to align them, and an electron pulse is used to record the structure at a specific time after the interaction with the laser. The molecular alignment increases the information content of the diffraction patterns, and allows for retrieval of 3D structures. This method will allow for capturing structures of intermediate states in ultrafast photoreactions with sub-Angstrom spatial resolution.

FY 2014 HIGHLIGHTS

In this past year, we have experimentally investigated the interaction of a strong femtosecond laser pulse with molecules in order to determine the limits of the impulsive laser alignment method. We have investigated the effect of laser pulses using a linear molecule, carbon disulfide. It was observed that the degree of alignment increases with laser intensity until it reaches a saturation at an intensity below the ionization threshold. At intensities beyond the saturation level there is a deformation of the molecular structure. Using ultrafast electron diffraction we can characterize the structural changes with sub-Angstrom spatial resolution, and we were able to characterize the alignment, deformation and breakup of the molecules as a function of laser intensity. While we had previously shown that 3D structures of symmetric top molecules can be retrieved from diffraction patterns of aligned molecules, we have now extended the retrieval algorithm to work also for asymmetric molecules. We achieved this by using a two-step retrieval process. In the first step, two diffraction patterns are combined using a genetic algorithm to recreate a diffraction pattern corresponding to perfect 1D alignment. In the second step, we use an iterative phase retrieval algorithm that works with multiple cylindrical harmonics to retrieve the position of the atoms. We have successfully tested the algorithm with simulated diffraction patterns of trifluorotoluene ($C_6H_5CF_3$), an asymmetric molecule.

Atomic and Molecular Physics in Strong Fields

Institution: Kansas, University of
Point of Contact: Shih-I Chu
Email: sichu@ku.edu
Principal Investigator: Shih-I Chu
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$115,000 (2014)

PROGRAM SCOPE

In this research program, we address the fundamental physics of the interaction of atoms and molecules with intense ultrashort laser fields. The main objectives are to develop new theoretical formalisms and accurate computational methods for *ab initio* nonperturbative investigations of multiphoton quantum dynamics and very high-order nonlinear optical processes of one-, two-, and many-electron quantum systems in intense laser fields, taking into account detailed electronic structure information and many-body electron-correlated effects. Particular attention will be paid to the exploration of the effects of electron correlation on high-harmonic generation (HHG) and multiphoton ionization (MPI) processes, multi-electron response and underlying mechanisms responsible for the strong-field ionization of atoms, and diatomic, and small polyatomic molecules, time-frequency spectrum, and coherent control of HHG processes for the development of shorter and stronger attosecond laser pulses, etc.

FY 2014 HIGHLIGHTS

The major research highlights of our DOE project in 2014 are briefly summarized as follows: (1) Coherent Phase-matched VUV Generation by Field-controlled Bound States. Recently in collaboration with the experimental group led by Dr. Z. Chang in UCF, we extend our self-interaction-free TDDFT and generalized Floquet formalism and uncover a new regime of phase-matched below-threshold harmonics generation, for which the generation and phase matching is enabled only near Stark-shifted resonance structures of the atomic target. This work opens the door to the future development of compact, high flux and ultrafast VUV light sources without the need for cavity or nanoplasmonic enhancement. (2) Sub-optical-cycle HHG Dynamics and Ultrafast Spectroscopy in the Attosecond Time Domain. We performed the first *ab initio* study of the subcycle HHG dynamics of He atoms in near-infrared (NIR) laser fields subject to excitation by a single extreme ultraviolet (XUV) attosecond pulse (SAP). We explored the dynamical behavior of the subcycle high harmonic generation (HHG) for transitions from the excited states to the ground state and found oscillation structures with respect to the time delay between the SAP and NIR fields. Our analysis reveals several novel features of the subcycle HHG dynamics and we identify the mechanisms responsible for the observed peak splitting in the photon emission spectra. (3) Subcycle Transient Structures in Time-Dependent Multiphoton-Ionization (MPI) Rate. We perform an accurate exploration of the subcycle transient MPI dynamics of atomic and molecular systems subject to intense near-infrared laser fields on the subfemtosecond time scale. MPI bursts within a single optical cycle are found in the time-dependent ionization rates. The analysis of the electron density reveals that several distinct density portions can be shaped and detached from the target within a half cycle of the laser field.

Formation of Ultracold Molecules

Institution: Connecticut, University of
Point of Contact: Robin Côté

Email: rcote@phys.uconn.edu
Principal Investigator: Robin Côté
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$102,000 (2014)

PROGRAM SCOPE

The main aims of this Research Program are to identify efficient approaches to obtain ultracold molecules, and to understand their properties. To that end, we often need to calculate the electronic properties (energy surfaces, dipole and transition moments, ro-vibrational states, etc.), as well as the interaction of the molecules with their environment (surrounding atoms, molecules, or external fields).

FY 2014 HIGHLIGHTS

We have made progress on 4 main axes of research: 1) Rydberg interactions: we have recently started to investigate how interactions can be affected by dressing atoms with a Rydberg state. We have shown that Rydberg-dressed interactions could be used to tune ultracold chemical reactions. We illustrated the concept with benchmark system, namely $H_2+D \rightarrow HD+H$. We also investigate a possible new chemical bound between ground state atoms using Rydberg dressing of the atoms. The molecular bound states would be extremely long-range, roughly 500 bohr radii, and very weakly bound. 2) Energy surfaces and reactions: We recently computed the surfaces for $RbOH^-$ and $RbOH$ to model the associative detachment reaction, paying special attention to the angular dependence of the Potential Energy Surface (PES). We also extended our study of atom-diatom reactive scattering to H_2+Cl to investigate the effect of resonances near the scattering threshold. We found a new universal behavior of the inelastic cross section in the s-wave regime scaling as $1/k^3$, which can be explained by the proximity of a pole in the complex k-plane. Finally, we are in the process of completing the computation of PES of two other systems: Mg^{+2} and Sr^{+2} . More recently, we helped analyzing experimental results on $NaCa^+$. 3) Long-range interaction between diatomic molecules: We summarized some of our previous work in a book chapter on ultracold molecules for quantum information processing. 4) Formation of dimers and tetramers: We recently started to explore how Feshbach resonances could enhance the pump-dump scheme to produce ground state molecules, and we are using the same approach to investigate the possible formation of tetramers. In fact, by controlling the long-range interaction between polar diatomic molecules using external DC electric field, we could increase the shorter-range overlap of the continuum and excited states (as in FOPA: Feshbach Optimized Photo-Association), and thus the formation rate of tetramers.

Optical Two-Dimensional Spectroscopy of Disorder Semiconductor Quantum Wells and Quantum Dots

Institution: Colorado, University of
Point of Contact: Steven Cundiff
Email: cundiffs@jila.colorado.edu
Principal Investigator: Steven Cundiff
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$120,000 (2014)

PROGRAM SCOPE

We are using two-dimensional coherent spectroscopy to study electronic excitations, mainly excitons, in semiconductor nanostructures. During the next grant period, we plan to focus on using the ability of 2D coherent spectroscopy to make size resolved measurements in an ensemble sample to study size dependent phenomena in epitaxially grown self-organized quantum dots and in colloidal quantum dots. Typically the size dependence can only be determined by making a series of single dot measurements, whereas it can be extracted from a single two-dimensional spectrum. In addition, two-dimensional coherent spectroscopy can measure energetic shifts and splittings that are small compared to the inhomogeneous width, as long the fluctuations in the energies are correlated. In the self-organized InAs dots, we will use 2D coherent spectroscopy to 1) study the exciton-phonon interactions of both the ground-state and excited state transitions, 2) study the coherent and incoherent interaction between the ground-state and excited-state transitions and 3) to observe Rabi flopping due to a prepulse. We plan to use two-dimensional coherent spectroscopy to study three types of colloidal quantum dots. For CdSe/ZnS dots we will study the low temperature dephasing to determine underlying physical mechanism. For Ge dots we will determine the excitonic dephasing time, the fine structure and the biexciton binding energy. In PbSe/CdSe dots, we will make similar measurements. Both the Ge and PbSe/CdSe dots are quite new, thus very little is known about them, so these measurements will help establish their properties. In addition both are technologically relevant for solar energy applications.

FY 2014 HIGHLIGHTS

During the most recent grant period we used two-dimensional coherent spectroscopy to 1) measure the size dependence of the biexciton binding energy in self-organized InAs quantum dots, 2) observe contributions due to the $\chi^{(5)}$ terms and trions in the same sample, 3) measure the dephasing of excitons in 110 oriented GaAs quantum wells, 4) observe many-body induced coupling in asymmetric InAs double quantum wells, 5) observe exciton-trion coupling in an n-doped CdTe quantum well and 6) make preliminary measurements of the low-temperature dephasing of CdSe/ZnS colloidal quantum dots.

Understanding and Controlling Strong-Field Laser Interactions with Polyatomic Molecules

Institution: Michigan State University
Point of Contact: Marcos Dantus
Email: dantus@chemistry.msu.edu
Principal Investigator: Marcos Dantus
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

When intense laser fields interact with polyatomic molecules, the energy deposited leads to fragmentation, ionization and electromagnetic emission. The objective of this project is to determine to what extent these processes can be controlled by modifying the phase and amplitude characteristics of the laser field according to the timescales for electronic, vibrational, and rotational energy transfer. Controlling these processes will lead to order-of- magnitude changes in the outcome from laser-matter interactions, which may be both of fundamental and technical interest. The proposed work is unique because it seeks to combine knowledge from the field of atomic-molecular- optical physics with knowledge from the fields of analytical and organic ion chemistry. This multidisciplinary approach is

required to understand to what extent the shape of the field affects the outcome of the laser-molecule interaction and to which extent the products depend on ion stability. The information resulting from the systematic studies will be used to construct a theoretical model that tracks the energy flow in polyatomic molecules following interaction with an ultrafast pulse.

FY 2014 HIGHLIGHTS

This year we developed two different methods for determining electronic coherence in large molecules in solution using shaped laser pulses. These findings will eventually speed up and make possible single molecule coherent spectroscopies. Two publications have resulted from this work and a third one is pending. We completed a significant theory/experiment collaborative project on the behavior of polyatomic molecules under intense femtosecond laser irradiation. These findings are now published as a Feature Article in the Journal of Physical Chemistry. We have been completing a project on the study of electronic coherence mediated quantum control of chemical reactions in polyatomic molecules.

Production and Trapping of Ultracold Polar Molecules

Institution: Yale University
Point of Contact: David DeMille
Email: david.demille@yale.edu
Principal Investigator: David DeMille
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

Our goals are to produce and trap a gas of polar molecules in the ultracold regime, and to study novel physical effects associated with the low temperatures and/or the polar nature of the molecules. Using the technique of photoassociation, we form RbCs molecules by binding together laser-cooled Rb and Cs atoms. We previously created a gas of rovibrationally-excited RbCs in an optical trap, and studied the collisional properties of the molecules. Our focus since has been on the production of RbCs molecules in their absolute rovibronic ground state, where they will be stable against inelastic collisions and hence suitable for precisely controlled study and manipulation. Once a large trapped sample is formed, we will study chemical reactions at ultracold temperatures, dipolar effects in collisions, and similar phenomena.

FY 2014 HIGHLIGHTS

In Fiscal Year 2013, we have continued our study of a recently-discovered, simple method to produce ultracold RbCs in its absolute ground state. We drive photoassociation (PA) transitions from free Rb and Cs atoms into tightly-bound RbCs molecular states that can decay to the absolute ground state. We observe high rates of formation of RbCs into low-lying vibrational levels, including the vibrational ground state, through intermediate PA resonances that are well-characterized from previous spectroscopy. In the latest Fiscal Year, we used a new high-resolution spectroscopic technique to measure the distribution of rotational levels formed via PA. With this data, we were able to further characterize the decay process that leads to formation of ground state molecules. We also verified that, as expected, a large fraction ($\sim 1/3$) of the vibrational ground state molecules are formed also in their rotational ground state. We have subsequently gone on to apply this method to form molecules in an optical trap, and to verify that we are trapping significant numbers of ultracold, rovibrational ground-state molecules, as has

long been our goal. We have now begun to study the collisional properties of these absolute ground-state RbCs molecules. RbCs in its ground state should be immune to inelastic collisions with itself and with Cs atoms. Hence, molecule production in the presence of dense Cs vapor should make it possible to use Cs atoms as a “scrubber” to remove, via inelastic collisions, residual rovibrationally-excited RbCs molecules that otherwise would accumulate in the trap. We are exploring the dynamics of the scrubbing process in an optical trap now.

Attosecond Ultra-Fast X-Ray Science

Institution: Ohio State University
Point of Contact: Louis DiMauro
Email: dimauro@mps.ohio-state.edu
Principal Investigator: Louis DiMauro
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014-2015)

PROGRAM SCOPE

The new frontier of attophysics aims at visualizing and controlling in real time the motion of electrons composing matter. In the new millennium the generation of attosecond XUV pulses became a laboratory reality. A primary goal of this grant is to apply these light pulses in a series of time-resolved experiments in order to understand correlated electron dynamics, and by doing so provide a new perspective on elementary atomic processes. These studies will be enabled by the unique technology developed at The Ohio State University (OSU) for attosecond science that utilizes long wavelength lasers and the OSU attosecond beamline/end-station. Several key attosecond measurements were achieved in the previous grant cycle and provide a firm foundation for continued progress in the renewal. A second thrust will continue to explore fundamental aspects of high harmonic generation and the ability to utilize this spectroscopy to access some fundamental atomic parameters. The second scope of this grant is the continued implementation of AMO science program using the ultra-fast, intense x-rays available at LCLS XFEL. The objective is the study of fundamental atomic processes involving multiple inner-shell ionization, x-ray nonlinear optics and the development of unique methods for time-resolved x-ray physics. These investigations will also enable novel metrological methods for the characterization of the LCLS beam and the foundation for understanding more complex matter-x-ray interactions, e.g. biological imaging. In addition this grant allows the development of experimental and intellectual competency using different 4th generation platforms whether on laboratory attosecond sources or the larger facilities available at the LCLS. The OSU program has already trained graduate students and post-doctoral research associates that are now contributing to x-ray science as staff members at DOE laboratories.

FY 2014 HIGHLIGHTS

Attosecond pulse shaping around a Cooper minimum. One signature of atomic structure, first discussed by Cooper, is a local minimum in the photoionization (PI) probability at a specific photon energy. This Cooper minimum (CM) is caused by a sign change, equivalent to a π -phase jump, in the bound-free transition dipole of one angular momentum channel. The CM has been extensively studied using traditional photoionization spectroscopy but the phase of the total transition dipole is not directly accessible, although it strongly influences the measured electron angular distribution and spin polarization. Consequently the Cooper minimum in argon became an excellent candidate for examining the viability of high harmonic spectroscopy. We have investigated the phase modification in the high

harmonic emission induced by the 3p Cooper minimum of argon, over a wide spectral range. In the experiment, the derivative of the spectral phase, the group delay (GD), is measured using the resolution of attosecond beating by interference of two-photon transitions (RABBITT) method. The measured RDM phase and amplitude agrees well with predictions based on the scattering phases and amplitudes of the interfering s- and d-channel contributions to the complementary photoionization process.

RABBITT measurement and the interpretation of the Wigner delay in photoionization. Photoionization by an XUV attosecond pulse train in the presence of an infrared pulse (RABBITT method) conveys information about the atomic photoionization delay. By taking the difference of the spectral delays between pairs of rare gases (Ar,He), (Kr,He) and (Ne,He) it is possible to eliminate in each case the larger group delay (“attochirp”) associated with the attosecond pulse train itself and obtain the Ar, Kr and Ne “effective” Wigner delays referenced to calculated He delay. Our extracted delays have been compared with several theoretical predictions and the results are consistent within 30% as over the energy range.

Spatial - Temporal Imaging during Chemical Reactions

Institution: Ohio State University

Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$222,000 (2014)

PROGRAM SCOPE

This grant is an experimental program designed to develop and demonstrate the tools for directly “watching and clocking” both the nuclear and the electronic motion during chemical bond making/breaking and other comparable processes. Our program is built around two facets of the molecule self-probing paradigm, derived from the strong-field rescattering model scaled to long wavelength. The first one is laser-induced electron diffraction in which the molecular structure is retrieved from the photoelectron momentum distribution with sufficient space-time resolution to observe the motion of the nuclei as directly as conventional electron diffraction measures equilibrium nuclear positions. The second is based on high harmonic generation from aligned molecules and the tomographic reconstruction of the Dyson orbitals pushed to higher precision by virtue of our mid-infrared driver lasers, combined with a pump-probe scheme. Both approaches will be benchmarked and applied to the resolution of unimolecular dissociation reactions. Both techniques allow us to exploit fundamental principles of strong-field scaling and combined they have the potential to visualize both the nuclear and electronic dynamics in chemical and material processes.

FY 2014 HIGHLIGHTS

In Nature Communication we introduced fixed-angle broadband laser-driven electron scattering (FABLES) as an alternative to fixed-energy, angle-swept LIED. FABLES is analogous to white light interferometry in optics, and this is the first experimental confirmation that broadband electron wave packet (EWP) can be used for imaging. In FABLES, the energy-dependent DCS is retrieved as compared to the angle-dependent DCS of the LIED method. The main benefit of FABLES is a trivial retrieval of molecular structure via a simple Fourier transform (FT) with no theoretical fitting or modeling, e.g. no *a priori* knowledge of laser ionization. Furthermore, the method “visualizes” only bonds parallel to the laser polarization and has the potential for routine, real-time imaging in a pump-probe configuration.

This unique aspect combined with molecular alignment was shown theoretically to offer a full molecular tomographic reconstruction.

High Intensity Femtosecond XUV Pulse Interactions with Atomic Clusters

Institution: Texas-Austin, University of
Point of Contact: Todd Ditmire
Email: tditmire@physics.utexas.edu
Principal Investigator: Todd Ditmire
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The goals of our experiments are to extend experiments on the explosion of van der Waals bonded atomic and molecular clusters irradiated at 800 nm to the short wavelength regime (1 to 50 nm). Our studies with XUV light are designed to illuminate the mechanisms for intense pulse interactions in the regime of high intensity but low ponderomotive energy by measurement of electron and ion spectra. This regime is very different from the IR where the ponderomotive potential is significantly greater than the binding potential of electrons in the cluster. We perform these studies by converting a 1.5 J, femtosecond laser to short wavelengths by high order harmonic generation (HHG) in a gas jet. We are working to confirm a hypothesis about the origin of the high charge states seen in XUV irradiated exploding clusters. We assessed from our first experiments that the photo-ionization of the atoms and ions in each cluster is strongly affected by plasma continuum lowering (ionization potential depression) in a cluster nano-plasma. This effect, which is well known in plasma physics, leads to a depression of the ionization potential enabling direct photo-ionization of ion charge states which would otherwise have ionization energies which are above the photon energy employed in the experiment. In our present work, we intend to confirm this hypothesis by performing experiments in which XUV pulses of carefully chosen wavelength irradiate clusters composed, on one hand, of only low-Z atoms and, on the other hand, clusters with a mixture of this low-Z atom with higher Z atoms. The latter clusters will exhibit higher electron densities and will see greater ionization potential lowering than in the clusters composed only of low Z atoms. By measuring the charge state distribution, we can see if direct single photon photo-ionization channels open for higher charge states when there is a higher plasma density in the cluster.

FY 2014 HIGHLIGHTS

We completed the characterization of a long focal length, HHG beamline on a 1.5 J, 30 fs, 10 Hz Ti:sapphire laser. This new beam has produced XUV laser pulse energies at 38 nm which are twenty times that of our previous experiments. We made direct comparison of ion charge states observed in large Xe clusters in the new apparatus. We observed a dramatic drop in ion intensities above Xe⁶⁺ as observed previously. With the higher XUV intensity now available we see production up to Xe¹¹⁺ in the new experiments compared with Xe⁸⁺ in previous ones. We have also completed the measurement of ion charge state distributions, ion energies, and the electron emission spectra in Xe, Ar, N₂, CH₄, and Xe doped CH₄ clusters formed in a cryo-cooled, supersonic cluster source in the new target chamber. Some of the new clusters measured can be compared directly with experiments previously complete using the LCLS laser at much shorter wavelengths. We have now tested the LAM production of clusters of Ag on a

source which will be soon mounted on the new target chamber. We will then study ion production from XUV pulses in oxide clusters (like SiO₂ and SnO₂).

Atomic and Molecular Electron Correlation in Strong Fields

Institution: Rochester, University of
Point of Contact: Joseph Eberly
Email: eberly@pas.rochester.edu
Principal Investigator: Joseph Eberly
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$100,000 (2014)

PROGRAM SCOPE

We are interested to understand how very intense and very short laser pulses excite electrons in atoms and molecules, with intensities in the range above one-tenth PW per square centimeter. The combination of phase-coherent character and short-time nature of laser pulses in related experimental use creates substantial challenges to theoretical study in this domain. The intensities are high enough to mandate development of non-perturbative approaches. We have discussed the theoretical successes and listed the still-existing challenges in a recent article in *Reviews of Modern Physics*. Challenging complications of great interest arise when more than one electron is dynamically active in response to the laser excitation.

FY 2014 HIGHLIGHTS

In the current grant year we have undertaken two projects. First, we will extend the method we introduced last year that combines quantum and classical time-dependent descriptions of atomic electron evolution, labeled the SENE approach. The goal is to overcome the extreme demands made on computational resources by more conventional methods. Second, we have begun to calculate the degree of electron-electron correlation that develops during short-pulse ionization. Our method will allow the first distinction to be made between classical and quantum origins of correlation, a question of fundamental interest for which no answers are currently known.

Image Reconstruction Algorithms

Institution: Cornell University
Point of Contact: Veit Elser
Email: ve10@cornell.edu

Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Digital image processing has played a significant role in microscopy for decades. Removing noise, enhancing contrast, identifying features and constructing 3D models are now routine operations that the microscopist relies on to extract the maximum information from his instrument. These now standard forms of data manipulation are in a sense refinements in that they begin with something that

is already recognizable as an image. However, with the development of techniques such as diffractive imaging the scope of digital processing in microscopy has expanded considerably. The data delivered by the new instruments are often very indirectly related to actual images and sophisticated algorithms are increasingly an integral component of the actual microscope. One of the most ambitious plans for algorithmically enabled microscopy is the proposal to image individual biological particles such as proteins and viruses with X-ray free electron lasers. The incentive for the development of this capability is strong, given that many of the most interesting targets of study resist crystallization, the necessary first step in the standard crystallographic approach to structural biology. But while the brilliance of free-electron lasers such as LCLS is higher by orders of magnitude than synchrotron sources, so too is the amplification effect of crystals. Single-particle imaging at LCLS will not only be very indirect, as diffraction images, but extremely noisy because of the weak signal. The main project described in this proposal is the further development of the expand-maximize-compress (EMC) algorithm for obtaining 3D structure from millions of noisy diffraction data. This algorithm has been very successful in simulations, at building accurate models in the standard setting where the particle orientation is unknown in each frame of data. The new studies will address various forms of background in the data and assess the effects of particle heterogeneity.

FY 2014 HIGHLIGHTS

No FY14 Highlights received.

Collective Coulomb Excitations and Reaction Imaging

Institution: California State University-Fullerton
Point of Contact: James Feagin

Principal Investigator: James Feagin
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$96,000 (2014)

PROGRAM SCOPE

Innovations in few-body science at molecular nano levels will be a critical component of ongoing international efforts to establish sustainable environmental and energy resources. The varied research paths to be taken will require the development of basic science on broad fronts with increasingly flexible views to crossover technologies. Although the work described and performed in this project is theoretical, our interest in these topics remains motivated by the recent surge in and success of experiments involving few-body atomic and molecular fragmentation and the collection of all the fragments. We accordingly continue two parallel efforts with (i) emphasis on reaction imaging while (ii) pursuing longtime work on collective Coulomb excitations. As in the past, we continue to place priority on research relevant to experiment.

FY 2014 HIGHLIGHTS

Three papers have been published this past year as a culmination of efforts on this project to track the origins of classical trajectories in an otherwise fully time-independent quantum reaction event. In the first of these papers, we have analyzed the so-called imaging theorem (IT) to establish an asymptotic relation for macroscopic times between coordinate and momentum wavefunctions describing the

many-particle state of an arbitrary fragmentation reaction. In the second paper, we extended the IT to electric- and magnetic-field extraction and position-sensitive detection as widely used in modern reaction microscopes. In the third paper, we derived a multi-fragment generalization of the IT and emphasized an alternative point of view relevant to quantum imaging that fully establishes a link to the classical trajectories without wavepackets or wavefunction collapse.

Studies of Autoionizing States Relevant to Dielectronic Recombination

Institution: Virginia, University of
Point of Contact: Thomas Gallagher
Email: tfg@virginia.edu
Principal Investigator: Thomas Gallagher

Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$148,000 (2014)

PROGRAM SCOPE

In this DoE sponsored program we have worked on two major areas. The first is understanding the response of atoms to simultaneously applied low and high frequency fields which are harmonically related. Experiments done with a combined xuv attosecond pulse train (APT) and an intense infrared laser field showed a clear phase dependence of the ionization of He atoms on the phase of the infrared field at which the attosecond pulses arrived. The phase dependence arises because the energy transfer from the low frequency field to the He electron excited by the APT depends on the phase of the infrared field at which the excitation occurs. The accompanying theoretical analysis showed that the magnitude of the phase dependent signal depended on the coherent effect of the train of attosecond pulses. We are conducting analogous experiments having using a microwave field as the low frequency field and a near infrared laser as the high frequency field. With previous DoE support we used a single ps infrared laser pulse which could be moved temporally relative to the microwave field. We were able to observe a clear dependence on the phase of the microwave field at which the ps pulse, but the signal was very small, less than 0.1%. The present effort has been focused on extending our work to match the APT, as opposed to a single attosecond pulse. We have replaced the ps infrared laser with two diode lasers whose beat note is phase locked to the second harmonic of the microwave source generating the microwave field. The two lasers generate a 100% amplitude modulated infrared field, analogous to the APT, which has maxima every half microwave cycle. These maxima can be phase shifted relative to the microwave field, mimicking the APT and the near infrared laser. If the coherent effect of the multiple pulses in an APT is important we should see a corresponding increase in the magnitude of the phase dependent energy transfer signal. The second area in which we have worked is to measure

FY 2014 HIGHLIGHTS

The most striking advance was that we observed phase dependent energy transfer using our amplitude modulated laser, which was phase locked to the microwave field. Unlike the single ps infrared pulse, the magnitude of the phase dependent signal was enormous, 10%. This observation verified the theoretical claim that the coherent effect of the APT was important in the earlier experiments. Depending on how we tune the frequencies of the diode lasers we are able to see the transfer of population to both higher and lower energy, as expected theoretically. In much of the literature on the interactions of strong electromagnetic fields with atoms or molecules the coulomb potential is ignored. While this approximation is excellent in some cases, in problems involving near threshold electrons it is wrong, as

these experiments clearly demonstrate. We have completed a series of microwave measurements of the intervals between the high angular momentum states of Ca. Ca^+ is a most promising candidate for an optical clock, and its dipole polarizability was not known to 10%. Our experimental value for the dipole polarizability of Ca^+ is in good agreement with the recently calculated value, providing confidence that the black body radiation shift can be calculated with sufficient accuracy to correct for temperature shifts of the clock. The Ca^+ clock transition has a measurement uncertainty of 1 Hz, and the black body shift at 300K is 0.4 Hz. Since the shift has a T^4 temperature dependence, the temperature shift is quite important. While our value of the dipole polarizability agree with the calculations, the quadrupole polarizability does not, although the source of the discrepancy is not apparent. If it can be identified, we shall be able to extract more precise values from our measurements.

Experiments in Ultracold Molecules

Institution: Connecticut, University of
Point of Contact: Phillip Gould
Email: plg@phys.uconn.edu
Principal Investigator: Phillip Gould
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$125,000 (2014)

PROGRAM SCOPE

This project is currently focused on the production of molecules at sub-millikelvin temperatures via the process of photoassociation. Our experiments begin with ultracold Rb atoms confined at high density in a magneto-optical trap. We then apply pulses of frequency-chirped light to form excited-state molecules by long-range photoassociation of the colliding atoms. Normally, ground-state molecules are produced by spontaneous emission of these excited molecules. However, by manipulating the frequency and amplitude of the pulses on the nanosecond time scale, we can coherently control the molecular formation process. The resulting ground-state molecules are detected using state-selective ionization with a pulsed dye laser. In conjunction with the molecular experiments, we are developing the technology to enable production of pulses and frequency chirps on nanosecond and subnanosecond time scales. Diode laser light is manipulated by fiber-optic-based electro-optical phase and intensity modulators that are driven by a fast arbitrary waveform generator. The resulting chirped pulses are then amplified by a tapered semiconductor amplifier or by injection locking a slave diode laser. The output pulses are diagnosed using heterodyne analysis. Overall goals of the program include the development of techniques to control the interactions of ultracold atoms, improved schemes for ultracold molecule production, and application of the techniques of coherent control to ultracold systems. Ultracold molecules have many potential uses, including precision measurements, quantum degeneracy, quantum computing and ultracold chemistry. Understanding, controlling, and optimizing their formation is important to many of these applications.

FY 2014 HIGHLIGHTS

We have extended our work on the production of ground-state rubidium molecules with frequency-chirped light. We previously found a dramatic difference in the production rate for positive and negative chirps and identified, via quantum simulations, the mechanism for this difference. The formation of ground-state molecules takes place in two-steps. First, a colliding pair of atoms absorbs a photon and forms an excited molecule. Then, this excited state makes a transition to the ground state, either by

incoherent spontaneous emission or by coherent stimulated emission. For the coherent process, a positive chirp provides the proper time ordering of the two steps and thus enhances the formation rate. We are currently using faster chirps and shorter pulses, as well as higher intensities, in order to enhance the coherent contribution and diminish the role of spontaneous emission. We are also implementing a novel double-pass configuration with a tapered semiconductor amplifier in order to achieve even higher intensities of the chirped light.

Physics of Correlated Systems

Institution: Purdue University
Point of Contact: Chris Greene
Email: chgreene@purdue.edu
Principal Investigator: Chris Greene
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

The focus of this project is the theoretical quantum mechanical description of systems having two or more strongly coupled degrees of freedom. While diverse topics come under investigation, the unifying theme connecting all of the supported research is the goal of overcoming existing limitations in the quantitative and qualitative understanding of nonperturbatively interacting atomic and molecular systems, in which energy and angular momentum is exchanged between different coordinates or modes of the system. We have continued our efforts in recent years to understand the interaction of very short pulsed lasers with atomic and molecular systems. A second thrust is in the area of electron-molecule collisions, where there are frequently strong correlations between the incident electron motion and other electrons in the molecular target, or with the nuclear motion degrees of freedom. In one new direction for this project, we have begun an investigation into the connection between quantal and classical theories of three-body recombination in collisions of three neutral atoms. The resulting sharper understanding of the borderline between quantal and classical regimes has led to the realization that ion-atom-atom three-body recombination can be accurately treated using the techniques developed for collisions of three neutral atoms. These systems are all representative of nonperturbative energy transfer processes, in the sense that energy from one degree of freedom becomes coupled or transformed into another degree of freedom in a microscopic system. Another area of continuing development has been an extension and application of theoretical techniques that allow a systematic separation of short-range interaction effects and long-range evolution of a fragmented quantum system.

FY 2014 HIGHLIGHTS

Three-body recombination and its time-reversed process have historically been some of the most difficult types of energy transfer processes to describe using the standard toolkits of theoretical atomic and molecular physics. Our project has made strides over the years in advancing this theoretical capability, and the past year has seen encouraging progress in extending the range of systems for which three-body recombination processes such as $A+B+C \rightarrow AB+C$ can be quantitatively described. Calculations this year have helped to delineate the energy range above which classical Newtonian methods can be safely utilized instead of the far more expensive and complicated quantal treatments that are required in the low energy limit. A new direction that followed up this better understanding has been an initial treatment of three-body recombination processes for which one of the three incident

collision partners is ionized. This has already generated some encouraging results such as the classical threshold law for this process, apparently not previously derived. Further extensions to four interacting atoms have been of interest for some time, although the computational capabilities are far more limited for the four-body problem than they are for three-body systems. As a prototype four-body system, we have conducted a first exploration of the positronium dimer molecule, consisting of two positrons and two electrons. This intriguing system has some of the same topological features as the hydrogen molecule, such as a mix of ionized and neutral fragmentation channels, but with a mass ratio that makes the usual Born-Oppenheimer picture inappropriate. Our study has shown the feasibility of developing a coupled-channels hyperspherical representation of dynamical processes such as charge exchange. Finally, progress has been achieved this year in reformulating the frame transformation theory of photoionization microscopy for a nonhydrogenic atom in an external electric field.

Using Strong Optical Fields to Manipulate and Probe Coherent Molecular Dynamics

Institution: Virginia, University of
Point of Contact: Robert Jones
Email: bjones@virginia.edu
Principal Investigator: Robert Jones
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

This project focuses on the exploration and control of dynamics in atoms and small molecules driven by strong laser fields. Our goal is to exploit strong-field processes to implement novel ultrafast techniques for manipulating and probing coherent electronic and nuclear motion within atoms, molecules, and on surfaces. Ultimately, through the application of these methods, we hope to obtain a more complete picture of correlated multi-particle dynamics in molecules and other complex systems.

FY 2014 HIGHLIGHTS

During the current funding year we have: (i) continued our investigation of transient, field-free orientation of polar molecules induced by combinations of intense optical and THz pulses; (ii) extended our studies of strong-field ionization by intense single-cycle THz pulses, moving from Rydberg atom targets to nano-structured metals; (iii) examined the role of multi-electron dynamics in enhanced multiple-ionization of diatomic molecules; and (iv) begun a collaboration with the DiMauro/Agostini group at the Ohio State University to characterize the influence of the electronic binding potential on energy transfer between an optical dressing field and near-threshold attosecond photo-electrons.

Molecular Dynamics Probed by Coherent Soft X-rays

Institution: Colorado, University of
Point of Contact: Henry Kapteyn
Email: kapteyn@jila.colorado.edu
Principal Investigator: Henry Kapteyn
Sr. Investigator(s): Margaret Murnane; Colorado, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014)

PROGRAM SCOPE

The goal of this project is to develop novel short wavelength probes of molecules and nanosystems, and to understand the response of atoms and molecules to strong laser fields, in particular mid-infrared (mid-IR) laser fields. Several recent breakthroughs from the Kapteyn-Murnane group in tabletop soft x-ray sources have dramatically expanded the photon energy range over which bright femtosecond-to-attosecond high harmonic (HHG) beams can be generated. Using tabletop mid-infrared (IR) femtosecond lasers, bright soft x-ray supercontinua can be generated that span from the VUV to the keV regions of the spectrum (to below 8 Å), with sufficient flux for applications. Moreover, high harmonic soft x-ray pulses are unique because they are perfectly synchronized to the driving laser, with $\approx \mu\text{W}$ average powers required for advanced chemical spectroscopies.

FY 2014 HIGHLIGHTS

Photoelectron spectroscopy and charge transfer dynamics of isolated quantum dots [1]:

In 2013 work, we reported the first studies of isolated quantum dots. In FY 2014, we expanded on this work by studying dye-quantum dot charge transfer, comparing charge transfer rates of free quantum-dot dye systems with those in solution. Our findings support the hypothesis that reorganization energy of nonpolar solvents plays a minimal role in charge transfer. This work has been submitted.

First isolated attosecond soft X-ray pulses [2]:

Until recently, attosecond pulses were confined to the EUV, limiting the range of molecular/materials systems that could be explored. Here, we experimentally demonstrated a remarkable convergence of physics: when mid-IR lasers are used to drive HHG, the conditions for bright phase-matched soft X-ray generation naturally coincide with the generation of isolated attosecond pulses.

First bright soft x-ray harmonics at kHz repetition rates [3]:

We demonstrated bright soft x ray harmonics at kHz repetition rates driven by 1.3 and 2 μm tabletop lasers. This represents a $> \times 1000$ increase in HHG flux beyond other work.

Exploiting Non-equilibrium Charge Dynamics in Polyatomic Molecules to Steer Chemical Reactions

Institution: Wayne State University

Point of Contact: Wen Li

Email: wli@chem.wayne.edu

Principal Investigator: Wen Li

Sr. Investigator(s): Raphael Levine; California-Los Angeles, University of
Henry Kapteyn; Colorado, University of

H. Bernhard Schlegel; Wayne State University
Students: 4 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014)

PROGRAM SCOPE

The main objectives of this proposal are to achieve two major research goals of ultrafast science: 1. Creating and probing photo-induced charge migration dynamics of pure electronic origin on the attosecond to few femtoseconds time scales and studying the role of non-equilibrium charge distributions in inducing selectivity of chemical reactions in polyatomic molecules. 2. Achieving mode-selective chemistry in polyatomic molecules using intense ultrashort mid-infrared pulses. For the first goal, coherent electronic wave packets due to the superposition of a few electronic states in molecular cations will be created with strong field photoionization by ultrashort optical pulses and the subsequent charge migration along the molecular backbone will be monitored by various advanced methods including a photoionization probe implemented with intense attosecond pulse trains (APT) coupled with ion-electron coincidence measurements and attosecond transient absorption with high energy attosecond pulses. Because our theoretical models simulate both the pump and the probe steps with minimum approximations, they will provide realistic experimental parameters and are also well suited to extract electronic dynamics from experimental observations. In the transient absorption experiments, the time-resolved spectra reflect the instantaneous electron density with element and site specificity and thus charge migration dynamics will be captured in real time. For the second goal, we have recently shown in models that mode-selective chemistry can be achieved using intense mid-IR laser excitation through charge polarization on the ground electronic state. The study will be carried out in molecular ions to minimize complications from competing strong field ionization. Mid-IR laser pulses at 3-4 μm will be focused to reach strong field intensity to achieve mode-selectivity in aligned polyatomic molecules. Systems of interest include iodobenzene dication and formyl chloride cation.

FY 2014 HIGHLIGHTS

This is a newly funded project. The starting date was Sept. 1, 2014. We provide no highlights at this point.

Time-Resolved Imaging of Molecules by High-Order Harmonics and Ultra Short Rescattering Electrons

Institution: Kansas State University
Point of Contact: Chii-Dong Lin
Email: cdlin@phys.ksu.edu
Principal Investigator: Chii-Dong Lin
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

When a molecule is exposed to an intense ultrashort infrared laser pulse, electrons that were ionized earlier may be driven back by the oscillating electric field of the laser to recollide with the parent ion. If the returning electron recombines with the ion, high-order harmonics are generated. If the returning electron is backscattered elastically by the ion, high energy photoelectrons are emitted. In both cases, the emitted radiation or the scattered electrons contain information on the target molecule. Since laser

pulses of duration of a few femtoseconds are readily available, they can be used to probe the dynamics of molecules with femtosecond timescales. In this project, we established how to extract the spectral behavior of the target molecules from the emitted harmonics. From the photoelectron spectra, our method is called laser-induced electron diffraction. The latter allows us to extract the bond lengths and bond angles of molecules. If the molecule under study is first perturbed by a pump laser, another probe laser can be used to extract the dynamics of molecules as they are under transformation. In this respect, short infrared lasers can be used to probe the evolution of molecules with femtoseconds resolution.

FY 2014 HIGHLIGHTS

In this past period, we demonstrated a new method to analyze electron diffraction patterns from which bond lengths are accurately retrieved. We also studied how to increase the fluence of the returning electrons to enhance diffraction images by combining two- or three-color lasers. In collaboration with an experimental group in Spain, we have been able to extract the C-C and C-H bond lengths of acetylene molecules from the photoelectron spectra generated using 3.1 micron lasers.

Probing electron-molecule scattering with HHG: Theory and Experiment

Institution:	Texas A&M University
Point of Contact:	Robert Lucchese
Email:	Lucchese@Mail.Chem.Tamu.Edu
Principal Investigator:	Robert Lucchese
Sr. Investigator(s):	Erwin Poliakoff; Louisiana State University
Students:	0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding:	\$465,000 (2014-2016)

PROGRAM SCOPE

This project is a combined experimental and theoretical study of high harmonic generation (HHG) in molecular systems. Additionally we are developing accurate quantum mechanical descriptions of such interactions that involve one continuum electron. The HHG process can be modeled within the three-step picture that consists of tunnel ionization of an electron, then electron wave propagation, followed by the recapture of the electron by photorecombination. This last step, photorecombination, is our particular interest since it involves the same transition matrix elements as the corresponding photoionization process that would be obtained by time reversal. The goal is to probe how resonant and non-resonant processes in electron-ion collisions affect the HHG process. Experimentally, we will consider studies of HHG on a series of polyatomic molecules for which we will map out the behavior as a function of power, focal position, and ellipticity. The objective is to explore the structure found in the HHG spectra as a function of harmonic order. By a comparison with computed cross sections we should be able to identify the processes in the electron continuum that lead to the observed features in the HHG spectra. Specific systems that will be studied include, initially, SF₆, SiCl₄, and CF₄ with later investigation being extended to CS₂, CCl₄, and various substituted benzenes. These systems have known resonant features that may lead to corresponding features in the HHG spectra. Theoretically, we will consider how different levels of approximation for computing the photorecombination matrix elements affect the computed HHG spectra. To enhance our ability to compute the needed matrix elements, we will investigate alternative grid based methods for computing the wave functions for the scattered electrons. The goal will be to overcome the limitations of our current numerical methods which are based on the use of rather slowly convergent single-center expansions.

FY 2014 HIGHLIGHTS

We have completed a study of the high-resolution photoelectron spectrum with partial vibrational resolution of a series of pyrimidine-type nucleobases: thymine, uracil and cytosine. Improved resolution allowed us to identify the electronic origins for the outermost valence electronic states. Striking similarities in the spectral features of all three pyrimidine-type nucleobases lead us to conclude that the features in the cytosine photoelectron spectrum are not due to contributions from multiple tautomers but instead are from unresolved vibrational progressions. We have also completed a study of vibrationally resolved photoionization of acrolein. In our experimental and theoretical study of the non-Franck-Condon behavior in acrolein we found evidence of two localized low energy sigma anti-bonding resonances, which interact to form two resonant states. Excitation of these states leads to significant non-Franck-Condon effects in the excitation of C-C vinyl stretch. We have made considerable progress, in collaboration with Profs. Trallero and Lin at the McDonald Laboratory in the study of molecular HHG. Preliminary work on the HHG spectrum SF₆ found noticeable structure in the experimental spectrum. We varied the gas jet position to change the macroscopic propagation and the effective trajectories of the returning electron. The one feature that is consistently present in the experimental data is the minimum in the HHG spectrum at the 17th harmonic. In the theory we have applied the quantitative rescattering (QRS) theory to isolated molecules and considered the ionization of the electrons from the three most weakly bound orbitals, which have ionization potentials that are all within 1.5 eV of each other. We have examined limitations of the current calculations and found that the asymmetric nuclear vibrations and interchannel coupling may be important to understand the observed spectra.

Properties of Actinide Ions from Measurements of Rydberg Ion Fine Structure

Institution: Colorado State University
Point of Contact: Stephen Lundeen
Email: lundeen@lamar.colostate.edu
Principal Investigator: Stephen Lundeen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

This project determines certain properties of chemically significant Uranium and Thorium ions through measurements of fine structure patterns in high-L Rydberg ions consisting of a single weakly bound electron attached to the actinide ion of interest. The measured properties, such as polarizabilities and permanent moments, control the long-range interactions of the ion with the Rydberg electron or other ligands. The ions selected for initial study in this project, U⁶⁺, U⁵⁺, Th⁴⁺, and Th³⁺, all play significant roles in actinide chemistry, and are all sufficiently complex that a-priori calculations of their properties are suspect until tested. The measurements planned under this project serve the dual purpose of 1) providing data that may be directly useful to actinide chemists and 2) providing benchmark tests of relativistic atomic structure calculations. In addition to the work with U and Th ions, which takes place at the J.R. Macdonald Laboratory at Kansas State University, a parallel program of studies with stable singly-charged ions takes place at Colorado State University. These studies are aimed at clarifying theoretical questions connecting the Rydberg fine structure patterns to the properties of the free ion cores, thus directly supporting the actinide ion studies. In addition, they provide training for students who can later participate directly in the actinide work.

FY 2014 HIGHLIGHTS

We have successfully completed the studies of Rn-like and Fr-like Th ions, but have so far been unable to learn anything about the properties of the isoelectronic U ions. The difficulties are two-fold: very small resolved signals, and large background rates. During the past year, we have shown that both difficulties are traced to the presence of metastable ions in the U beams extracted from the ECR ion source. As a by-product of these studies, we managed to measure the metastable fraction of the U beams, and achieve a substantial reduction in the background rate. However, despite these advances, we have still been unable to extract any useful information about the U ions.

Theory of Atom Collisions and Dynamics

Institution: Tennessee, University of
Point of Contact: Joseph Macek
Email: jmacek@utk.edu
Principal Investigator: Joseph Macek
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$126,000 (2014)

PROGRAM SCOPE

The transfer of angular momentum in atomic collisions is the subject that we have investigated in the last year of the project. Our investigations find that angular momentum is transferred to both excited and ionized states of targets and projectiles in the collisions of ions and target atoms. The transfer to excited states produces aligned and oriented atomic states. The oriented atomic states are the most important since they have non-zero mean values of the vector angular momentum and are typically understood in semi-classical terms. We find that in quantum terms the most significant transfer of vector angular momentum occurs near the united atom limit where target and projectile interact strongly to deflect the incident projectile. The transferred angular momentum is observed as orientation of excited states. Some of the angular momentum is transferred to ionized states of the target and projectile as the two species separate. We have shown that this angular momentum produces vortices in the velocity fields of the ejected electrons. A search for such vortices has been successfully completed by our experimental collaborators using an improved COLTRIMS apparatus. This confirms that vortices appear in the velocity field of ionized electrons.

FY 2014 HIGHLIGHTS

The highlight of our work has been the experimental discovery of isolated zeros in the spectrum of electrons ejected in the transfer ionization process. Theory confirms that such isolated zeros are indicative of vortices in the velocity field of ejected electrons.

Photoabsorption by Free and Confined Atoms and Ions

Institution: Georgia State University
Point of Contact: Steven Manson
Email: smanson@gsu.edu
Principal Investigator: Steven Manson
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$80,000 (2014)

PROGRAM SCOPE

The goals of this research program are: to provide theoretical support to, and collaboration with, various experimental programs that employ latest generation light sources, particularly ALS, APS and LCLS; to further our understanding of the photoabsorption process; and to study the properties (especially photoabsorption) of confined atoms and ions. Specifically, calculations are performed using and upgrading state-of-the-art theoretical methodologies to help understand the physics of the experimental results; to suggest future experimental investigations; and seek out new phenomenology, especially in the realm of confined systems. The primary areas of programmatic focus are: nondipole and relativistic effects in photoionization; photoabsorption of inner and outer shells of atoms and atomic ions (positive and negative); dynamical properties of atoms endohedrally confined in buckyballs, primarily C₆₀; studies of time delay on the attosecond scale in photoionization of free and confined atomic systems. Flexibility is maintained to respond to opportunities.

FY 2014 HIGHLIGHTS

Confinement resonances, oscillations that occur in the photoionization cross section of an endohedral atom owing to the interference of the photoelectron wave function for direct emission with those scattered from the surrounding shell have been predicted in a broad range of cases; recently, their existence has been confirmed experimentally. Further, the photoionization of endohedral atoms within nested fullerenes, has shown that, as a result of the multi-walled confining structures, the confinement resonances become much more complicated. And we have shown that confinement resonances induce resonances in the time-delay of photoelectron emission. Also a Xe atom endohedrally confined in C₆₀ exhibits a new type of atom-fullerene hybrid which arise from the near-degeneracy of inner levels of the confined atom and the confining shell, in contrast to the known overlap-induced hybrid states around the Fermi level of smaller compounds, and are found to occur in confined noble gas, alkali-earth atoms and the Zn series. The photoionization cross sections of these hybrid states exhibit rich structures and are radically different from the cross sections of free atomic or fullerene states. This also occurs in buckyonions, nested fullerenes which suggests the possibility of creating buckyonions with plasmons of specified character, i.e., designer resonances. We have also explored the interatomic Coulomb decay (ICD) phenomenon in confined atoms and found, owing to hybridization between atomic and shell orbitals, that ICD occurs both ways, from atom to shell and shell to atom, and the rates (widths) are often much larger than the ordinary Auger rates. In addition, we have explained the significant structure in free atom subshell photoionization cross sections many keV above their thresholds found experimentally in Ag; the structure is nonresonant and about 50 eV wide. It was found to be induced by interchannel coupling with inner-shell ionization channels near threshold.

Combining High Level *Ab Initio* Calculations with Laser Control of Molecular Dynamics

Institution: Temple University
Point of Contact: Spiridoula Matsika
Email: smatsika@temple.edu
Principal Investigator: Spiridoula Matsika
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

We use intense, shaped, ultrafast laser pulses to follow and control molecular dynamics, and high level *ab initio* calculations to interpret the dynamics and guide the control.

FY 2014 HIGHLIGHTS

(1) Development of a VUV source: A main experimental development in the past year is a UV pump VUV probe apparatus for pump probe measurements of excited state dynamics and a comparison of weak and strong field ionization of excited states. The pump probe apparatus is almost completed and about to be tested.

(2) Velocity Map Imaging measurements of relaxation in excited molecular cations: We ionize the molecules using our strong field IR laser pulses. Ionization can proceed to a range of ionic states. By measuring the photoelectrons in coincidence with the fragment ions produced by ionization, we can determine the ionic state of the molecule immediately after ionization. Then, the velocity map imaging measurement of the fragment ion measured in coincidence with the photoelectron can be used to determine the kinetic energy release in dissociation for the case of ionization to a dissociative cationic state. A signature of relaxation prior to dissociation is the measurement of fragment ions with kinetic energy release equal to the energy difference between the initial ionic state and ground ionic state at the FC point minus the dissociation energy on the ground state.

(3) Ultrafast relaxation in molecular cations: In strong field dissociative ionization techniques several excited ionic states can be created during the ionization step followed by fragmentation, and it is not clear whether the fragments are produced directly in the excited ionic states or if fast relaxation to the ground ionic state occurs first and fragmentation follows. In order to better understand the processes occurring after ionization and interpret the experimental observables, we have theoretically investigated dynamics of excited radical cations. We have applied trajectory surface hopping molecular dynamics and the Multi-Configurational Time-Dependent Hartree approach to study the dynamics of the uracil radical cation as well as cyclohexadiene and hexatriene radical cations.

Electron-Driven Processes in Polyatomic Molecules

Institution: California Institute of Technology
Point of Contact: Vincent McKoy
Email: mckoy@caltech.edu
Principal Investigator: Vincent McKoy
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$375,000 (2014-2016)

PROGRAM SCOPE

The focus of this project is the development, extension, and application of accurate, scalable computational methods for studying low-energy electron-molecule collisions, with emphasis on larger polyatomic molecules relevant to electron-driven chemistry in biology and materials processing. Because the required calculations are numerically intensive, efficient use of large-scale parallel computers is essential, and the computer codes developed for the project are designed to run both on tightly-coupled parallel supercomputers and on workstation clusters.

FY 2014 HIGHLIGHTS

We developed computational procedures necessary to explore angle-resolved dissociative electron attachment processes while continuing to explore electron scattering processes in biologically relevant molecules. In collaboration with the Belkacem group (Lawrence Berkeley National Laboratory), who performed the relevant experimental measurements, we studied angle-resolved dissociative attachment to uracil, the simplest nucleobase and thus a prototype for studying electron-induced damage to DNA and RNA. We computed the quantum-mechanical entrance amplitudes that describe how the probability of attaching an electron during a collision varies depending on the direction from which it approaches the molecule. We find, consistent with the Belkacem group's measurements, that the energetic hydrogen anions formed via attachment of electrons with about 6 electron-volts of kinetic energy most likely result from breaking a specific nitrogen-hydrogen bond. These results were published in *Journal of Physical Chemistry Letters*. For some time we have been interested in electron collisions with alcohols, which are actual or potential biofuels. One fundamental issue that has arisen in our studies is the connection between the angular scattering pattern and the molecular structure. Specifically, in the 6 to 10 electron-volt range of collision energies, straight-chain alcohols tend to show one scattering pattern and branched alcohols a different pattern. To explore this further, we collaborated with the experimental group of M. Khakoo (California State University, Fullerton) and the theoretical group of M. Bettega (Federal University of Parana, Brazil) on a study of alcohols and alkyl amines. We found that the trends identified in the alcohols persist in the straight and branched amines. Our results were published in *Physical Review A*.

Electron/Photon Interactions with Atoms/Ions

Institution: Clark Atlanta University
Point of Contact: Alfred Msezane
Email: AMsezane@cau.edu
Principal Investigator: Alfred Msezane
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$80,000 (2014)

PROGRAM SCOPE

To understand the physical mechanism underlying low-energy electron attachment and trapping and creation of new exotic molecules three interwoven and interrelated subprojects have been investigated. Subproject-1 uses our recent novel Regge-pole methodology to: 1) Explore in the near-threshold energy region through the calculation of the elastic total cross sections (TCSs) possible electron attachment to selected atoms resulting in the formation of weakly bound ground and excited anions as resonances; and 2) Demonstrate that the Os^- anion shows dramatic improvement on the catalysis of H_2O to H_2O_2 over recent results obtained using Au^- and Pd^- anions and in the oxidation of CH_4 to methanol using the Au^- anion without the CO_2 emission. Also, recent fundamental anionic, cationic, and neutral atomic metal predictions utilizing density functional theory calculations validate the recent discovery identifying the interplay between Regge resonances and R-T minima as the fundamental atomic mechanism underlying nanoscale catalysis.

In Subproject-2 the CAM method is also being extended to investigate the energy region between the first and the second atomic excitation thresholds where interchannel coupling was found to split degenerate Regge trajectories.

Subproject-3 evaluates the absolute differential oscillator strengths for the photoabsorption of the Xe atoms encapsulated inside the C₆₀, C₁₈₀ and C₂₄₀ in the energy regions both inside and outside the C₆₀ giant resonance, using the time-dependent density-functional theory (TDDFT). These proposed research projects constitute the intellectual contributions to knowledge of the fundamental underpinnings of AMO science.

FY 2014 HIGHLIGHTS

No FY14 Highlights provided.

Theory and Simulation of Nonlinear X-Ray Spectroscopy of Molecules

Institution: California-Irvine, University of
Point of Contact: Shaul Mukamel
Email: smukamel@uci.edu
Principal Investigator: Shaul Mukamel
Sr. Investigator(s):
Students: 6 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$512,000 (2014-2016)

PROGRAM SCOPE

Nonlinear X-ray spectroscopy experiments, which use sequences of coherent broadband X-ray pulses, are made possible by new X-ray free electron laser (XFEL) and high harmonic generation (HHG) sources. These provide a unique window into the motions of electrons and nuclei in molecules and materials. This program is aimed at the design of novel X-ray pulse sequences for probing valence electronic excitations, the development of computational approaches for describing core-excited states, and the application of these techniques to specific molecular systems. Nonlinear spectroscopy techniques widely used in the visible and infrared regimes (e.g. time-resolved photoelectron spectroscopy, time-resolved broadband stimulated Raman, coherent control and frequency combs) are extended to the X-ray regime. Applications are made to energy transfer in metalloporphyrin heterodimers, effects of electronic coherence in nanostructured photovoltaics, charge and energy transfer between different metal centers in mixed-valence complexes, and delocalized carbon core excitations in conjugated hydrocarbons. Signatures of vibrational motions and nonadiabatic dynamics in photo-excited molecules are identified via two-dimensional X-ray correlation spectroscopy of multiple core states, time-, frequency-, and wavevector- resolved X-ray diffraction from single molecules as well as photon coincidence detection of multidimensional attosecond X-ray scattering. Other applications include probing electronic and vibrational dynamics in molecules by time-resolved photoelectron, auger-electron, and x-ray photon scattering spectroscopy and three-dimensional attosecond resonant stimulated x-ray Raman spectroscopy of electronic excitations triggered by core ionization.

FY 2014 HIGHLIGHTS

Multiporphyrin arrays are good candidates for artificial photosynthesis and molecular electronics applications. Understanding the excitation energy transfer (EET) pathways in these systems is of considerable interest. Stimulated X-ray Raman spectroscopy (SXRS) signals of various porphyrin heterodimers with different linkers, bonding structures, and geometries were predicted. The time-domain one and two color SXRS signals show coherent excitonic motions, which can be directly mapped into the excited state doorway wavepacket created by the pump pulse, which probes the EET. SXRS

signals are demonstrated to be very sensitive to the chemical bonding and local geometrical environment, and offer a novel window for photophysical and photochemical processes that could help the design of efficient solar energy devices. The SXRS technique was further extended to study multiple core excitation states of the same element. Carbon K-edge signals was simulated for the furan molecule. We also investigated the influence of vibronic coupling on SXRS signals by using the linear coupling exciton-phonon model and the cumulant expansion. Fine-structure features were obtained and analyzed. The nuclei act as a bath for electronic transitions which accelerates the decay of the time-domain signal. Our previously-developed description of time- and frequency-resolved detection of spontaneous emission was extended to the detection of diffracted X-rays. This extension showed the contribution of inelastic scattering events and provided a way to select them in the diffraction signal. We have shown that in elastic terms, they do not contribute to the diffraction from crystals, and must be taken into account for scattering from single-molecule samples. This work was further extended to multidimensional X-ray diffraction in which several X-ray pulses are scattered from the sample. X-ray photon coincidence detection then probes multipoint correlation functions of the electron charge density.

Nonlinear Materials Spectroscopies Probed By Ultrafast X-Rays

Institution: Massachusetts Institute of Technology
Point of Contact: Keith Nelson
Email: kanelson@MIT.EDU
Principal Investigator: Keith Nelson
Sr. Investigator(s): Margaret Murnane; Colorado, University of
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

In this project, ultrashort electromagnetic pulses in the visible, extreme ultraviolet (EUV), and x-ray spectral ranges are all used in complementary efforts to gain experimental access to elementary material excitations and fundamental condensed matter processes on ultrafast time scales and mesoscopic length scales. Of primary interest are heat transport, whose nondiffusive character at short length scales plays important roles in thermoelectric materials and nanoscale devices, and structural evolution in disordered media, which shows dynamics on wide-ranging time scales that have long eluded first-principles description. Central to these phenomena are acoustic phonons, which mediate both thermal transport and the compressional and shear components of structural relaxation. In addition to direct time-resolved observation of thermal transport, longitudinal, transverse, and surface acoustic wave generation and detection are key elements of our experiments in all spectral ranges. We develop and use a variety of methods to excite and monitor acoustic waves and thermal transport on a wide range of length and time scales. For length scales in the roughly 1-100 micron range and acoustic waves in the MHz to low GHz range, we use crossed optical pulses to form an interference or 'transient grating' pattern, directly generating thermoelastic responses with the grating period. The responses are monitored by diffraction of probe laser light. In order to reach higher acoustic frequencies and to monitor heat transport on submicron length scales, spatially periodic structures are deposited onto substrate surfaces so that optical irradiation produces thermoelastic responses at their nanometer periods. The responses are monitored by diffraction of EUV pulses produced by high harmonic generation. To excite GHz-THz acoustic waves, a thin layer or a superlattice structure is irradiated and the acoustic wave is detected by time-resolved optical reflectivity or interferometry.

FY 2014 HIGHLIGHTS

We generated and probed the shortest wavelength surface acoustic waves (SAW) to date, at 45 nm (frequency ~80 GHz), with corresponding penetration depths of ~10 nm. [1,2] This result is significant for nanoscale materials physics because it makes it possible to selectively probe the mechanical properties of very thin films and interfaces, as well as nanostructures deposited on or embedded within a surface. We characterized the acoustic velocity dispersion of 1D and 2D Ni nanostructures with periods 45 nm – 4 μ m. We conducted photoacoustic measurements spanning the 1 MHz - 100 GHz frequency range and combined the results with those of a collaborating group that conducted dynamic mechanical measurements in the mHz-kHz range to determine the complex elastic modulus over 13 decades of frequency, by many decades the most comprehensive study of viscoelastic dynamics ever performed on a single material. The results showed agreement with scaling predictions of mode-coupling theory of supercooled liquids. Finally, we made significant progress on GHz and even THz acoustic wave generation and detection on several fronts. We measured acoustic attenuation mechanisms for acoustic waves in the 0.5-THz frequency range, a step toward mapping the mean free paths of phonons and thereby determining their contributions to thermal transport. We also generated a frequency comb comprising seven acoustic modes spanning a range from 360 GHz to 2.5 THz, the highest coherent acoustic frequency seen to date.

Electron and Photon Excitation and Dissociation of Molecules

Institution: California-Davis, University of
Point of Contact: Ann Orel
Email: aeorel@ucdavis.edu
Principal Investigator: Ann Orel
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$95,000 (2014)

PROGRAM SCOPE

This program studies how energy is interchanged in electron and photon collisions with molecules leading to excitation and dissociation. Modern *ab initio* techniques, both for the photoionization and electron scattering and the subsequent nuclear dynamics are used to accurately treat these problems. This work addresses vibrational excitation and dissociative attachment following electron impact, and the dynamics following inner shell photoionization. These problems are ones for which a full multi-dimensional treatment of the nuclear dynamics is essential and where non-adiabatic effects are expected to be important.

FY 2014 HIGHLIGHTS

Core-level and some inner-valence level photoionization can lead to double ionization that can populate dissociative dication states. Coincident measurement of photoelectrons and fragment ion momenta allows one to study photoelectron angular distributions in the molecular-frame (MFPAD). We have computed MFPADs for the isomerization of acetylene and ethylene and for carbon 1s core ionization of neutral acetylene. We have substituted hydrogen for fluorine, computing the MFPADs for FCCF and lithium for the hydrogen, studying the LiCCLi MFPAD to see the effect of electronegativity on the distributions. Our previous studies of dissociative electron attachment (DEA) of HCCH showed a barrier to reaction in linear geometry. Bending the molecule allowed coupling between the ground and the

excited state of the anion which lowered the barrier so the reaction could proceed. The calculated cross sections and isotope effects were in good agreement with experiment. Recent experiments have produced ion-momentum imaging of the products of DEA in HCCH. The entrance amplitude for this process was calculated to obtain an attachment probability which was integrated over the angle azimuthal to the recoil axis to produce an observable angular distribution. This coincides with the measured angular distribution if the overall rotation of the molecule is slow compared to dissociation and if the fragments recoil at a given angle in the molecular frame, i.e., if the molecular frame recoil axis R is constant over the Franck-Condon region of the neutral. As expected, since theory predicted significant bending during dissociation, this was not found to be the case. However, if the recoil axis was rotated by a fixed amount before averaging the attachment probability over the azimuthal angle the effect of bending can be included. The results with a bending angle around 27 degrees was found to be in good agreement with the observed experimental fragment angular distribution.

Low-Energy Electron Interactions with Liquid Interfaces and Biological Targets

Institution: Georgia Institute of Technology
Point of Contact: Thomas Orlando
Email: thomas.orlando@chemistry.gatech.edu
Principal Investigator: Thomas Orlando
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

The primary objectives of this program are to investigate the fundamental physics and chemistry involved in low-energy (1-250 eV) electron and soft x-ray interactions with complex targets. There is a particular emphasis on understanding correlated electron interactions and energy exchange in the deep valence and shallow core regions of the collision targets. The energy loss channels associated with these types of excitations involve ionization/hole exchange and negative ion resonances. Thus, the energy decay pathways are extremely sensitive to many body interactions and changes in local potentials. Our proposed investigations should help determine the roles of hole exchange via inter-atomic and intermolecular Coulomb decay (ICD) and energy exchange via localized shape and Feshbach resonances in the non-thermal damage of biological interfaces.

FY 2014 HIGHLIGHTS

Low-energy electron induced damage of DNA-We have used a sensitive chemical vapor deposited graphene platform for controlled and enhanced sequence dependent DNA damage studies. The use of p-doped graphene substrates enhances DNA breakage due to phosphate mediated parallel adsorption geometries and direct ballistic electron transfer to phosphate sigma* levels. Graphene adsorbed on Au-thin films also provides enhanced electric fields for Surface Enhanced Raman micro-spectroscopy. The combination of these effects allows direct and fast assessment of ≤ 5 eV electron induced DNA damage as a function of base sequence without separations and amplification steps. We have examined LEE induced damage of nucleotides that have a minor change in the sugar structure. Specifically, we examined the LEE induced damage of deoxyadenosine monophosphate (dAMP) and adenosine monophosphate (rAMP) using the graphene Raman micro-spectroscopy. There is no observable change in the Raman spectra after 1 eV electron irradiation. However, significant damage of dAMP occurs after 2 eV electron bombardment. The situation is not the same for the rAMP. There is limited damage even

at 2 eV. Remarkably, the simple addition of an OH^- group to the 2'-C site dramatically changes the stability of the nucleotide with respect to glycosidic bond cleavage and base damage. This is likely related to the nature of the sugar shape resonances and decay products and the ability of charge to be transferred to the phosphate σ^* levels. Our collaboration at Argonne National Laboratory focused on examining x-ray damage of DNA adsorbed on Au in two different conformations. The first is a thiolated form which binds via an S bond and the other is direct adsorption via the bases. The damage cross section was found to be significantly higher for the thiolated DNA, probably resulting from the LUMO initially being less populated and hence more effective in capturing of low energy secondary electrons.

Structure from Fleeting Illumination of Faint Spinning Objects in Flight

Institution: Wisconsin-Milwaukee, University of
Point of Contact: Abbas Ourmazd
Email: ourmazd@uwm.edu
Principal Investigator: Abbas Ourmazd
Sr. Investigator(s): Russell Fung; Wisconsin-Milwaukee, University of
Peter Schwander; Wisconsin-Milwaukee, University of
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

It is now possible to interrogate molecules and their assemblies “in flight” with intense short pulses of radiation, and record “snapshots” before they are destroyed. We are developing a new generation of powerful algorithms to recover structure and dynamics from such ultra-low-signal random sightings. Combining concepts from differential geometry, general relativity, graph theory, and diffraction physics, these techniques promise to revolutionize our understanding of key processes in biological machines, such as enzymes, and ultrafast breaking of bonds in molecules.

FY 2014 HIGHLIGHTS

We have developed a new generation of algorithms capable of determining the structure and conformations of nanomachines from large noisy ensembles of heterogeneous snapshots, and demonstrated this capability in the context of simulated XFEL diffraction snapshots from discrete conformations, and experimental cryo-electron microscope (cryo-EM) image snapshots for continuous conformational changes.

Control of Molecular Dynamics: Algorithms for Design, Analysis, and Implementation

Institution: Princeton University
Point of Contact: Herschel Rabitz
Email: hrabitz@princeton.edu
Principal Investigator: Herschel Rabitz
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

The control of quantum dynamics is accomplished by seeking a tailored electromagnetic field to meet a posed objective. A search for an optimal control, both in simulation and in the laboratory, occurs over a landscape, which is the physical observable as a function of the control. The topology and general features of these landscapes are important for assessing the ease of identifying optimal controls, the robustness to field noise, and other properties. Optimizing the pulse shape corresponds to climbing the landscape in the control function space. The direct nature of these optimal control trajectories can be quantified by the metric R , defined as the ratio of the length of the control trajectory to the Euclidean distance between its end points. An important, practical assumption underlying landscape analysis is free access to all necessary control resources (i.e., unconstrained laser fields). In practice, constraints will always be present and a basic concern is the control performance achieved upon working with increasingly limited resources. The landscape principles have a universal character and should apply to complex situations including molecular fragmentation, molecular isomerization, ion-atom collisional charge exchange reaction, open quantum systems, and nonlinear many-body dynamical problems involving, for example, ultra-cold Bose-Einstein condensates, etc. One of the main stumbling blocks, both in simulations and in complex laboratory scenarios, is the lack of efficient algorithms to identify optimal control fields. Although the control landscape concepts were developed as a basis to understand quantum control principles, there are emerging practical consequences of this knowledge. A broad variety of research topics was pursued in the general area of controlling quantum dynamics phenomena. The research is theoretical and computational in nature, aiming at developing a deeper understanding of quantum control to extend the laboratory control capabilities.

FY 2014 HIGHLIGHTS

Exploring the impact of resource constraints: We laid out the mathematical foundation for developing practical algorithms to assess the impact of control constraints. Control principles in the chemical sciences: We examined control principles for different families of molecules, all related through various moieties bonded to a common scaffold, utilizing NMR and IR spectral data as the properties of interest. Control landscapes for molecular fragmentation: We examined the landscape principles for laser-driven molecular fragmentation, enabling a series of experimental studies of the landscapes for molecular dissociative ionization of halo-methane molecules. Invariance of quantum optimal control fields to experimental parameters: We utilized landscape principles to demonstrate that an optimal field at one temperature will remain optimal at other temperatures in the laboratory. Control of charge transfer in ion-atom collisions and isomerization: We showed that charge transfer between $H^+ + D$ collisions and ozone isomerization process can be significantly manipulated by shaped pulses. Control landscapes for nonlinear quantum systems: We extended the analysis of control landscape topology to nonlinear quantum dynamics, including the Gross-Pitaevskii equation. Minimal time population transfer for two-level systems by two bounded controls: We analyzed the minimum time population transfer problem for a two level quantum system driven by two external fields with bounded amplitude. Selectively addressing optically nonlinear nanocrystals by polarization-shaped ultrafast lasers: We theoretically studied second-harmonic generation and sum-frequency generation signals produced by nanocrystals driven with broad-bandwidth laser pulses. Exploring quantum control landscape structure: We investigated whether there is a relationship between the control mechanism and the complexity of the trajectory taken through the control space reflected in the value of R .

Atoms and Ions Interacting with Particles and Fields

Institution: Purdue University
Point of Contact: Francis Robicheaux
Email: robichf@purdue.edu
Principal Investigator: Francis Robicheaux
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 4 Undergraduate(s)
Funding: \$107,053 (2014)

PROGRAM SCOPE

This theory project focuses on the time evolution of systems subjected to either coherent or incoherent interactions represented by fields and particles, respectively. This study is divided into three categories: (1) coherent evolution of highly excited quantum states, (2) incoherent evolution of highly excited quantum states, and (3) the interplay between ultra-cold plasmas and Rydberg atoms. Some of the techniques we developed have been used to study collision processes in ions, atoms and molecules. In particular, we have used these techniques to study the correlation between two (or more) continuum electrons and electron impact ionization of small molecules.

FY 2014 HIGHLIGHTS

(1) We modified our time dependent Schrodinger equation programs to perform calculations of attosecond laser-atom interactions for laser intensities where interesting two- and three-photon effects become relevant. (2) We were involved in an experimental/computational project to image a part of the wave function inside an atom. (3) We performed classical calculations of one of the iconic effects of Rydberg atoms in electric fields to study classical-quantum correspondence. (4) We were involved in an experimental/theoretical study of how atoms can have resonance states in extremely strong microwave fields. (5) We performed calculations to investigate the way that many simultaneously excited atoms can exchange energy and ionize. (6) We performed calculations of single and double photoionization of Ne⁸⁺ by direct solution of the time-dependent Dirac equation. (7) We performed calculations of elastic and inelastic scattering of neutral molecules and cold ions in a magnetic field.

Generation of Bright Soft X-Ray Laser Beams

Institution: Colorado State University
Point of Contact: Jorge Rocca
Email: rocca@enr.colostate.edu
Principal Investigator: Jorge Rocca
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This research addresses the challenge of the efficient generation of bright x-ray laser beams. The widespread interest in the use of high intensity soft x-ray and x-ray light that has motivated the commissioning of free electron lasers also inspires the development of more compact and more readily accessible sources of intense soft x-ray laser light for applications. Table-top experiments are conducted at Colorado State University to study the fundamental aspects of the dynamic of soft x-ray plasma

amplifiers and advance the development of gain-saturated, high repetition rate, table-top plasma lasers towards shorter wavelengths. X-ray pump–x-ray probe measurement of the non-linear response of atomic soft x-ray laser plasma amplifiers perturbed by a strong ultrashort soft x-ray pulse are conducted in combination with model simulations to study the ultrafast gain. The linewidth of atomic soft x-ray lasers an important parameter that determines the gain, the saturation behavior, and the shortest pulse width that can be obtained, is measured using a new interferometric single-shot technique. In table-top experiments we extended gain-saturated table-top lasers down to $\lambda=8.8$ nm, and demonstrated 100 Hz repetition rate soft x-ray laser operation generating a record average power of 0.15 mW at $\lambda=18.9$ nm. Experiments in collaboration were also conducted at LCLS to demonstrated strong stimulated x-ray Raman scattering by resonantly exciting a dense gas target with high-intensity femtosecond x-ray free-electron laser pulses.

FY 2014 HIGHLIGHTS

We completed the first x-ray pump–x-ray probe measurement of the non-linear response of an atomic soft x-ray laser plasma amplifier perturbed by a strong ultrashort soft x-ray pulse. A sequence of two time-delayed spatially-overlapping high harmonic (HH) pulses was seeded into an 18.9 nm wavelength nickel-like Mo plasma amplifier to measure the rapid regeneration of the population inversion that follows the gain depletion caused by the amplification of a strong seed pulse. Although such gain recovery time is one of the most fundamental parameters for soft x-ray lasers, it had never been measured. The measured fast gain recovery time of ~ 1.75 ps supports the possibility to generate ultra-intense fully phase-coherent soft x-ray laser by chirped-pulse-amplification in plasma amplifiers. This first x-ray pump- x-ray probe experiment in a soft x-ray plasma amplifier not only uncovers the gain recovery dynamics due to electron collisions but also serves as a diagnostic of the ionization mechanisms in the hot dense plasma with a resolution for a few hundred fs. The results were published in Nature Photonics (8, 381, 2014). In a separate experiment the linewidth of a $\lambda=14.7$ nm Ni-like Pd soft x-ray laser was measured in a single shot using a soft x-ray diffraction grating interferometer that uses the time delay introduced by the gratings across the beam to measure the temporal coherence. The linewidth of atomic soft x-ray lasers is an important parameter that determines the gain, the saturation behavior, and the shortest pulse width that can be obtained. The spectral linewidth of the $4d^1S_0-4p^1P_1$ Ni-like Pd lasing line was measured to be $\Delta\lambda/\lambda=3\times 10^{-5}$ from the Fourier transform of the fringe visibility. This new single shot linewidth measurement technique can contribute to the development femtosecond plasma-based soft x-ray lasers.

Spatial Frequency X-Ray Heterodyne Imaging of Micro and Nano Structured Materials and Their Time-Resolved Dynamics

Institution: Brown University
Point of Contact: Christoph Rose-Petruck
Email: Christoph_Rose-Petruck@brown.edu
Principal Investigator: Christoph Rose-Petruck
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$420,000 (2014-2016)

PROGRAM SCOPE

Materials are organized in hierarchical structures. Atoms combine to molecules, molecules and atoms combine to nano-scale structures, which, in turn are often embedded in microscopic media. The time

scales of processes vary accordingly from femto and picoseconds for the chemical dynamics of molecules, to hundreds of picoseconds for the transformations of nanoparticles. The goal of this research program is the study of the complex interplay between processes at their varying length and time scales. The kinetics of nanometer-sized materials is studied using Spatial Frequency Heterodyne Imaging (SFHI) an imaging modality that is specifically sensitive to the nano-structure of samples. Ultrafast dynamics of the solvation environment for molecules is studied with picosecond x-ray absorption fine structure (XAFS) spectroscopy using a streak-camera endstation that we developed in collaboration with Bernhard Adams at 7ID-C of the Advanced Photon Source, Argonne National Laboratory. The SFH-imaging studies on the nanoscale focus on the phase transitions of water in nano-confinement. Water in confined spaces can show unusual properties that are not observed in the bulk. For instance, Carbon Nanotubes (CNTs) are made of hydrophobic graphene sheets. Despite the hydrophobic nature of the grapheme sheets, experimental studies have revealed that water can be confined in CNTs. We observe the phase transitions of water and its removal from the external surfaces and inner cavities of CNTs as a function of temperature and time. Ultrafast studies on solvated anions in aqueous solution are studied with picosecond temporal resolution. The goal is not to study the detailed atomic motions of the solutes but rather to study the response of the solvation shells to sudden changes of the solute charge.

FY 2014 HIGHLIGHTS

We used SFHI to observe the removal of water from the outer and inner surfaces of CNTs, establishing the modality's ability to probe nanoscale systems in an aqueous environment over a relatively large temperature range. The capacity for observing macroscopic systems with SFHI was highlighted in this study by imaging multiple macroscopic samples within a single image. The results of this study suggest the potential of SFHI for *in situ* observation of nano-chemical reactions, and possible use of CNTs as high pressure nano-scale reaction vessels. The continuation of this projects aims at measuring the internal pressure of water inside of CNTs. This pressure has been calculated but never measured. Simulations show that a temperatures well-below the water boiling point the pressure inside the CNTs reaches the 0.1GPa regime. The picosecond response of $[\text{Fe}(\text{CN})_6]^{4-}$ and MnO^{4-} in aqueous solution after 266 nm photo excitation has been measured by picosecond XAFS. The results for both complexes show coherent oscillations of the x-ray absorption cross section with a period of approximately 33ps. Coherent molecular motions that modulate the XAFS signal after excitation are conceivable. However, one expects such motions to be on the much faster time-scale of the normal modes of the excited molecule and its immediate solvation shell. On the other hand, classic microwave spectroscopy of water shows a strong absorption band around 30 GHz which has been attributed to librational motions of networks of water molecules. Such motions modulate the dielectric constant of the medium, which in turn modulates the energies of high-lying molecular orbitals of the excited solute. The XAFS oscillations we observe here are the consequence of such dielectric constant modulations in the immediate vicinity of the solute molecule. Thus, to our knowledge for the first time, we observe the concerted motions of the first few solvation shells after excitation of a solute.

Time Resolved High Harmonic Spectroscopy: A Coherently Enhanced Profile of Charge Migration

Institution: Louisiana State University

Point of Contact: Kenneth Schafer

Email: schaffer@phys.lsu.edu

Principal Investigator: Kenneth Schafer

Sr. Investigator(s):

Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)

Funding: \$674,999 (2014)

PROGRAM SCOPE

This project is a collaboration between Louisiana State University (LSU), The Ohio State University (OSU) and the University of Virginia (UVa) that intends to meet the challenge of measuring electron dynamics down to the attosecond time scale by initiating and following ultrafast charge migration in a series of carefully chosen molecules. The collaboration aims at establishing a focused theory and computational program at Louisiana State University to guide experiments at OSU and UVa focused on exploring ultrafast electron dynamics in molecules. Individual members of the team have substantial experience in theory and experiment related to high-harmonic and attosecond pulse generation and characterization, including coherent macroscopic propagation, and advanced quantum chemistry methods. The effort will rely heavily on theory to guide the development and interpretation of experiments that will probe dynamics in complex systems, where intuition developed with simpler systems may fail. The measurements will be performed with apparatus currently available (or readily adaptable) at the University of Virginia and The Ohio State University. To encourage cross-fertilization between theory and experiment and, accordingly, to enhance productivity of the collaboration, we will create an active visitors program at each site. We anticipate that students, postdocs, and faculty from the principal (theory) hub at LSU, and the (experiment) nodes at OSU and UVa will spend time at the other sites, with experimentalists visiting LSU during preliminary planning for experiments and post-measurement analysis, and theorists at the laboratories during experimental runs.

FY 2014 HIGHLIGHTS

This grant was funded August 1st, 2014 and so is only few months old at this point. Our first priority has been to find qualified researchers to fill out the roster of approximately 4 postdoctoral and 4 graduate student positions spread over the three institutions. This is very challenging, especially at the post-doc level and beginning late in the calendar year. At present one postdoc has been hired in physics at LSU, with a start date of March 2015. Another in Chemistry at LSU is to be interviewed shortly. Two graduate students are funded at LSU, and the three LSU PIs and these students meet weekly. At OSU a graduate student has begun work on the grant, and one student is to be employed at UVa beginning in the Spring. Both OSU and UVa have active postdoc searches underway. Our second priority has been to organize the collaboration kickoff meeting at LSU. This meeting is scheduled for March 1-3, 2015 and will be hosted at the Center for Computational Technologies (CCT) at LSU. In addition to the six PIs, several postdocs and graduate students, we will also have several outside speakers to provide additional perspectives. Confirmed speakers are Robert Lucchese, Lenz Cederbaum, Catarina Vozzi, Bridgette Cooper, Pascal Salaries, and Erwin Poliakoff. All of the outside speakers are actively involved in high harmonic spectroscopy. Research highlights include the adaptation of the NWChem code to treat strong field ionization, undertaken by Ken Lopata and his student. Mette Gaarde and her student have written a first generation classical trajectory code to evaluate strong field trajectories in elliptically polarized fields. Taken together, these are the first two 'steps' in the three step model which we will use for the theoretical description of high harmonic spectroscopy with an eye towards defining a first set of experiments to be carried at OSU.

Transient Absorption and Reshaping of Ultrafast Radiation

Institution: Louisiana State University
Point of Contact: Kenneth Schafer
Email: schafer@phys.lsu.edu

Principal Investigator: Kenneth Schafer
Sr. Investigator(s): Mette Gaarde; Louisiana State University
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

Our program is centered around the theoretical study of transient absorption of ultrafast extreme ultraviolet (XUV) radiation by atoms and materials interacting with a precisely synchronized near-to-mid infrared (IR) laser pulse. Transient absorption spectroscopy can in principle provide high spectral resolution and high (attosecond) time resolution simultaneously, by spectrally resolving the light transmitted through a sample as a function of delay between the dressing laser pulse and the broadband attosecond XUV probe. As in all transient absorption calculations/measurements, one of the main challenges we confront is the extraction of time-dependent dynamics from delay-dependent information. In addition, we must also account for the reshaping of the broadband XUV light in the macroscopic medium. We study attosecond transient absorption (ATA) using a versatile theoretical treatment that takes account of both the strong laser-atom interaction at the atomic level via the time-dependent Schrodinger equation (TDSE), as well as propagation of the emitted radiation in the non-linear medium via the Maxwell wave equation (MWE), in the single-active electron (SAE) approximation up to now. We are also extending our SAE treatment in atoms to fully-active two electron calculations in helium, in both full and reduced dimensions. These tools allow us to treat the interaction of ultrafast radiation with laser-field dressed atoms down to the single cycle limit with sub-cycle time resolution. Our first principles approach allows us to make close contact with experiment, both explaining existing experiments and identifying fruitful areas for future experiments.

FY 2014 HIGHLIGHTS

We have explored a variety of issues in ATA. Four of these projects were in collaboration with experimental groups, (i) Leone and Neumark, UC Berkeley, (ii) Gallmann and Keller, ETH, Zurich, (iii) Sansone and Nisoli, Politecnico di Milan, and (iv) Sandhu, U. Arizona. (i) "Attosecond transient absorption probing of electronic superpositions of bound states in neon: detection of quantum beats", Beck *et al.*, New J. Phys. 16, 113016 (2014). This study finds that the transient absorption spectra of an IR-laser-dressed neon gas excited by a broadband XUV pulse exhibit oscillations with IR-XUV delay characteristic of superpositions between pairs of spin-orbit split states. (ii) "Multiphoton transitions for delay-zero calibrations in attosecond spectroscopy", Herrmann *et al.*, NJP (2015). We propose a new method for calibrating delay-zero between an IR and an attosecond XUV pulse to within 1 fs, something which has not previously been achieved. (iii) "Polarization control of absorption of virtual dressed states in helium", Reduzzi *et al.*, submitted to PRA (2014). This study explores the dependence of XUV absorption on the relative polarizations of the XUV field and a dressing IR field, and finds that in particular the light-induced features in the ATA spectrum are very sensitive to the relative polarization. (iv) "Beyond the single-atom response in absorption lineshapes: Probing a dense, laser-dressed helium gas with attosecond pulse trains", Liao *et al.*, submitted to PRL (2014). This work explores the interplay between different effects that can change the absorption line shape in an ATA experiment: a microscopic effect due to an IR-induced phase on the time-dependent dipole moment, and a macroscopic effect due to resonant pulse propagation. (v) Postdoc X. Guan has developed an ab-initio two-electron TDSE solver and is exploring ATA in He. This work (in prep. for PRA) focuses on the (surprisingly many) light-induced states which can be seen in the absorption spectrogram.

Strong Field Coherent Dynamics and Control. From Alignment to High Harmonic Generation in Complex Systems

Institution: Northwestern University
Point of Contact: Tamar Seideman
Email: t-seideman@northwestern.edu
Principal Investigator: Tamar Seideman
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our BES-supported research can be broadly categorized into two conceptually and practically related topics: (1) the design and control of complex material system with strong field concepts, including alignment, 3D alignment, torsional alignment and molecular focusing; and (2) the physics, implications, and potential applications of high harmonics generated from aligned molecules. Whereas the first topic is a generalization of the thrust of our original application, the second has been motivated by the intense interest of the Atomic, Molecular and Optical Science (AMOS) Program in attosecond science and rescattering electrons physics, and has been carried out in collaboration with AMOS experimentalists colleagues. Laser alignment is an approach to control over the spatial properties of molecules wherein a moderately intense laser field excites a broad superposition of rotational levels through sequential Rabi-type cycles, in each of which another one or two units of angular momentum is exchanged between the molecule and the field. In the limit of rigid, isolated diatomic molecules, this approach matured, during the past 15 years from a theoretical dream into a large field of theoretical and experimental research with a growing range of applications in optics and physics. The goal of our research has been to extend the alignment concept from the domain of physics and optics to make a tool in solution chemistry, material research and possibly biology and engineering. High harmonic generation is an approach to producing high frequency radiation through the interaction of atoms or molecules with an intense IR laser pulse. Combined with laser alignment, this method provides a view of the orbitals of molecules. Our research developed a theoretical approach that takes into account both the rotational and the electronic motions of molecules and applied the theory in collaborative work with two AMOS experimental groups.

FY 2014 HIGHLIGHTS

Our work during the past year within the first of the above two components includes two theory development projects and two collaborative research projects with different experimental laboratories. Specifically, we studied: 1. dissipation and rotational quasi-revivals in asymmetric-top molecules - joint theoretical and experimental work with AMOS colleagues; 2. strong field multiple ionization as a route to electron dynamics in a van der Waals cluster - joint theoretical and experimental work with international collaborators; 3. the use of pulling to influence the optical controllability of molecular junctions - theory and computation; and 4. the dissipative dynamics of laser-induced torsional coherences - numerical research. Within the second part of our BES-supported research during the past year, we combined joint research with several AMOS colleagues with a theory of rotational wavepacket imaging via high harmonic generation. In particular we explored: 5. the axis-dependence of molecular high harmonic emission in three dimensions - joint theoretical and experimental work with AMOS colleagues; 6. ultrafast elliptical dichroism in high-order harmonics as a probe of molecular structure and electron dynamics - joint theoretical and experimental work with a second group of AMOS colleagues;

and 7. the application of high harmonic spectra as a rotational wave packet imaging - theoretical research.

Inelastic X-ray Scattering Under Extreme and Transitional Conditions

Institution: Washington, University of
Point of Contact: Gerald Seidler
Email: seidler@u.washington.edu
Principal Investigator: Gerald Seidler
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal of this program is to expand the scope and scientific potential of time-resolved inelastic x-ray scattering (IXS) and closely related x-ray techniques. First, we are using x-ray spectroscopies, soon to include resonant inelastic x-ray scattering, to gain new insight into the energy transfer mechanisms of lanthanide-based phosphors and related luminescent materials and to study the time dynamics of the electronic and structural changes at metal-insulator transitions. Second, we are performing combined theoretical and experimental work to critically test, and substantially improve, the use of IXS methods in the study of dense plasmas, such as in the transitional, 'warm dense matter' regime. Third, we are continuing several collaborations based on IXS instrumentation and methods developed by the PI, including studies of the time-dynamics of energy transfer in photosynthetic proteins and of the f-electron physics of lanthanide elements and compounds at high pressures. Finally, our side-project for laboratory-based XAFS and XES is showing high promise for impact in DOE mission-driven research on electrical energy storage, catalysis, and actinide materials. This new generation of lab-based advanced x-ray spectrometers serves as an important complement and supplement to the DOE synchrotron light sources.

FY 2014 HIGHLIGHTS

FY2014 has seen three major accomplishments under this award: (1) In October 2013 we commissioned a new type of inexpensive lab-based spectrometer for high-resolution x-ray studies, including x-ray absorption fine structure (XAFS) and x-ray emission spectroscopy (XES). We now regularly achieve data that is in perfect agreement with synchrotron-based results. (Seidler, *et al.*, <http://dx.doi.org/10.1063/1.4901599>) The startling performance of this modest instrument has garnered significant interest and has immediately led to the construction at the UW of a mid-scale lab XAFS user facility that emphasizes long-baseline studies of electrical energy storage that cannot, due to the long experimental duration, be frequently performed at synchrotron beamlines. (2) The recent LD67 campaign at LCLS/MEC was led by the PI. While this beam run emphasized laser-shock heating of multicomponent targets (supported by a grant from DOE/FES), complementary x-ray heating experiments were also performed as part of the WDM research under the present award. The results are still under analysis, but show interesting effects in the electronic structure of metallic and metal oxide targets. These results have led to new ideas for multicomponent target designs for x-ray heating studies. (Hoidn, *et al.*, in preparation). (3) Finally, lanthanide compounds and coordination complexes are responsible for a wide range of light-gathering and light-emitting applications. Our recent work at the Advanced Photon Source on luminescent lanthanide complexes demonstrates an unexpected but clear expression of the long-lived 4f intrashell photo-excitation in the time-resolved XAFS of the

lanthanide ion. (Pacold, *et al.*, JACS 2014) Our leading explanation requires a surprisingly dynamic coupling between the 4f and 5d orbitals of the lanthanide ion, a hypothesis that could have broad implications for the correct microscopic understanding of energy transfer in several families of phosphors.

Dynamics of Few-Body Atomic Processes

Institution: Nebraska, University of
Point of Contact: Anthony Starace
Email: astarace1@unl.edu
Principal Investigator: Anthony Starace
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$364,250 (2014-2016)

PROGRAM SCOPE

The goals of this project are to understand, describe, control, and image processes involving energy transfers from intense electromagnetic radiation to matter as well as the time-dependent dynamics of interacting few-body quantum systems. Investigations of current interest are in the areas of strong field (intense laser) physics, attosecond physics, high energy density physics, and multiphoton ionization processes. Nearly all proposed projects require large-scale numerical computations, involving, e.g., the direct solution of the full-dimensional time-dependent or time-independent Schrödinger equation for two-electron (or multi-electron) systems interacting with electromagnetic radiation. In some cases our studies are supportive of and/or have been stimulated by experimental work carried out by other investigators funded by the DOE AMOS physics program. Principal benefits and outcomes of this research are improved understanding of how to control atomic processes with electromagnetic radiation and how to transfer energy optimally from electromagnetic radiation to matter.

FY 2014 HIGHLIGHTS

Four projects were completed in FY 2014: (1) By solving the two-electron time-dependent Schrödinger equation (TDSE), we studied carrier-envelope-phase (CEP) effects on ionization plus excitation of He to He⁺ (n=2) states by a few-cycle attosecond pulse. The asymmetries in the photoelectron angular distributions with excitation of He⁺(2s) or He⁺(2p) have opposite signs and are two orders of magnitude larger than for ionization without excitation. Thus attosecond pulse CEP effects are significantly amplified in correlated two-electron ionization processes. (2) The CEP dependence of electron angular distributions in double ionization of He by a few-cycle, intense XUV pulse was formulated using perturbation theory in the pulse amplitude. Owing to the broad pulse bandwidth, interference of first and second order perturbation amplitudes produces asymmetric angular distributions sensitive to the CEP. Our perturbation theory parametrization agrees with two-electron TDSE results. (3) The Be harmonic generation spectrum was investigated by solving the two-electron TDSE in an intense laser field. As the laser frequency ωL varies from 1.7 to 1.8 eV, the 7th harmonic becomes resonant sequentially with transitions between the ground state and two doubly-excited autoionizing states. At each resonant frequency, the HHG power spectrum increases by an order of magnitude over a range of harmonics that form a plateau, extending up to the 25th harmonic. (4) Resonance-like enhancements of generalized three-photon cross sections for XUV ionization of Ar, Kr, and Xe were demonstrated using a central-potential model. The resonant-like behavior originates from potential barriers experienced by intermediate- and final-state photoelectron wave packets corresponding to absorption of one, two, or

three photons. Such potential barrier effects are general features of multiphoton ionization processes in most atoms with occupied p- and d-subshells.

Femtosecond and Attosecond Laser-Pulse Energy Transformation and Concentration in Nanostructured Systems

Institution: Georgia State University
Point of Contact: Mark Stockman
Email: mstockman@gsu.edu
Principal Investigator: Mark Stockman
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$300,003 (2014-2016)

PROGRAM SCOPE

The program is aimed at theoretical investigations of a wide range of phenomena induced by ultrafast laser-light excitation of nanostructured or nanosize systems, in particular, metal/semiconductor/dielectric nano-structured composites (metamaterials) and nano-clusters. Among the primary phenomena are processes of energy transformation, generation, transfer, and localization on the nanoscale and coherent control of such phenomena. Ultrafast processes in superstrong laser fields in nanostructures recently have received major research attention.

FY 2014 HIGHLIGHTS

During the current grant period of 2013-2014, the following articles with this DOE support have been published [1-7]. The major results are highlighted below:

1.1 Attosecond Control of Dielectrics

[5] We have established the feasibility of manipulating the electronic structure and electric polarizability of a dielectric reversibly with the electric field of light. The established ultrafast reversibility of the effects implies that the physical properties of a dielectric can be controlled with the electric field of light, offering the potential for petahertz-bandwidth signal manipulation.

1.2 Metal Nanofilm in Strong Ultrafast Optical Fields

[1] We have predicted that a metal nanofilm subjected to an ultrashort (near-single oscillation) optical pulse of a high field amplitude $\sim 3 \text{ V/\AA}$ at normal incidence undergoes an ultrafast (at subcycle times $\sim 1 \text{ fs}$) transition to a state resembling semimetal. 1.3 Hot-Electron Nanoscopy Using Adiabatic Compression of Surface Plasmons

[3] We have shown that adiabatic nanofocusing of surface plasmons on a Schottky diode-terminated tip of nanoscale dimensions allows for a plasmon-to-hot-electron conversion efficiency of $\sim 30\%$.

X-rays with Femtosecond Duration and Angstrom Wavelength from a Laser Synchrotron

Institution: Nebraska, University of
Point of Contact: Donald Umstadter
Email: dpu@unlserve.unl.edu
Principal Investigator: Donald Umstadter
Sr. Investigator(s):
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

X-ray synchrotrons and x-ray free-electron lasers have proven to be transformational technologies for physical and biological sciences. As part of this project, we developed a new type of x-ray source, one which—by virtue of its unique characteristics—may have similar transformational potential. Not only does its x-ray peak brightness and photon energy rival that of 3rd generation x-ray synchrotrons, but its femtosecond x-ray pulse duration is comparable to x-ray free-electron lasers. Moreover, the device is small enough to fit in a university laboratory. The new light source is based on inverse Compton back-scattering, driven by two intense light pulses, each of which are amplified by a single high-power laser system. One laser pulse rapidly accelerates electrons (~ 3 GeV/cm) by means of the laser-wakefield mechanism; and the other laser pulse Thomson-backscatters from the relativistic electrons. The scattered light Doppler upshifts relativistically to high photon energy. The new source has advantages for x-ray science in general, and for the study of ultrafast phenomena in particular. Its exceptionally large x-ray-energy tuning range facilitates probing of almost any element's inner-shell atomic structure. Its femtosecond x-ray pulse duration, coupled to high photon energy, enables ultrafast time-resolved studies with atomic-scale spatial and temporal resolutions. Its synchronization with ultra-high-intensity laser light pulses ($\leq 10^{22}$ W/cm², $a_0 \sim 100$) can merge ultrafast science with high field science; for example, ultrafast dynamics of either highly stripped atoms or extreme states of matter can be investigated. Several of our near-term project objectives include: (i) reduction of the x-ray spectral width, (ii) measurement of the x-ray pulse duration (inferred to be < 10 fs), and (iii) demonstration of an x-ray pump-probe capability.

FY 2014 HIGHLIGHTS

Several novel and unique features of a compact laser-driven Thomson x-ray source were demonstrated at the University of Nebraska, Lincoln [Powers *et al* (2014)]. These include: quasi-monoenergetic spectral width (energy spread $\sim 40\%$), large energy-tuning range (50 keV $\leq E \leq 10$ MeV), and small angular divergence (10-mrad). This is the first demonstration of an all-laser-driven x-ray source with a synchrotron spectrum. It is also a demonstration of the widest tuning range of x-ray source of any type. These attributes, coupled with femtosecond x-ray pulse duration make the source ideal for ultrafast AMO x-ray science. Two other improvements to the x-ray source were also recently implemented. First, the phase distortions of both laser beams used in the system were corrected by means of a novel dual pulse-compressor laser design. This allowed independent control and optimization of the separate laser pulses used to drive the electron accelerator and Thomson scattering [Liu *et al* (2014b)]. Second, a frequency-doubling crystal was used in the scattering beam-line to convert the incident 800-nm light to 400 nm. Doubling the scattering-pulse photon energy reduces the electron energy required to produce x-rays of given energy.

Cold and Ultracold Polar Molecules-Dipolar Collisions and Anisotropic Quantum Gas

Institution: Colorado, University of
Point of Contact: Jun Ye
Email: Ye@jila.colorado.edu
Principal Investigator: Jun Ye
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

Following the demonstration of a two-dimensional magneto-optical trap for molecular YO, we have been working on the implementation of a three-dimensional MOT. Collaborating with John Doyle's group in Harvard, we have prepared a slow YO molecule beam with a center velocity of 70 m/s from a dual stage buffer gas cooled laser ablation source. We have successfully demonstrated the slowing and cooling of this molecular beam to 20 m/s, and are working now to further cool this beam for loading into a 3D MOT. We expect to achieve this result soon. Evaporation of the hydroxyl radical (OH) remains an exciting prospect for further cooling of chemically interesting molecules and increasing their phase space density. Thus far evaporation efficiency has been limited by collision rate and vacuum lifetime, prompting an investigation of possible improvements. We have designed a new permanent magnetic trap with a factor of 2 steeper gradient and a more favorable loading geometry. Using this trap, we show an order of magnitude increase in the initial density and in collision rate of OH molecules. We are currently working on a detailed investigation of the inelastic and elastic collisions of OH free radicals.

FY 2014 HIGHLIGHTS

On the front of dipolar molecules in the quantum regime, we have recently realized a lattice spin model. By encoding spin in rotational states, we have observed spin exchanges of ultracold polar KRb molecules that are confined in a deep three-dimensional optical lattice. The interactions manifest as a density dependent decay of the spin coherence of the system. In addition to decaying, the spin contrast oscillates, with frequency components that are consistent with the dipolar interaction energies. We have studied these spin exchanges for two different pairs of rotational states, which differ by a factor of two in interaction strength, and find the decay and oscillations to be roughly twice as fast in the case of stronger interactions. A theory comparison based on a cluster expansion agrees quantitatively with our data. These observations were made in a regime where the lattice filling is quite dilute. Our current experimental efforts are focused on increasing the filling fraction. Higher lattice fillings will enable the study of richer physics, such as transport of excitations in an out of equilibrium long-range interacting system. While we have used dipolar interactions of polar molecules pinned in a three-dimensional optical lattice to realize the spin exchange model, the absence of an external electric field precludes the study of the full spin-1/2 Hamiltonian that includes the Ising interaction. Moreover, advanced manipulation of dipolar properties of a bulk molecular gas is also strongly desired. In the near future we will commission the second generation of our KRb polar molecule apparatus that allows large electric fields with the flexibility to apply gradients of the field in arbitrary directions. The same electrodes that supply large DC electric fields also provide AC fields for driving rotational transitions to encode spin.

PROGRAM SCOPE

The AMOS program at LBNL is aimed at understanding the structure and dynamics of atoms and molecules using photons and electrons as probes. The experimental and theoretical efforts are strongly linked and are designed to work together to break new ground and provide basic knowledge that is central to the programmatic goals of the Department of Energy as formulated in the “Grand Challenges”. The current emphasis of the program is in three major areas with important connections and overlap: inner-shell photo-ionization and multiple-ionization of atoms and small molecules; low-energy electron impact and dissociative electron attachment of molecules; and time-resolved studies of atomic processes using a combination of femtosecond x-rays and femtosecond laser pulses. This latter part of the program is folded in the overall research program in the Ultrafast X-ray Science Laboratory (UXSL). The experimental component at the Advanced Light Source makes use of the Cold Target Recoil Ion Momentum Spectrometer (COLTRIMS) to advance the description of the final states and mechanisms of the production of these final states in collisions among photons, electrons and molecules. Parallel to this experimental effort, the theory component of the program focuses on the development of new methods for solving multiple photo-ionization of atoms and molecules. This dual approach is key to break new ground and provide a new understanding of how electronic energy channels into nuclear motion and chemical energy in polyatomic molecules as well as unravel unambiguously electron correlation effects in multi-electron processes.

FY 2014 HIGHLIGHTS

Applying our COLTRIMS scheme at the ALS to nitrogen and carbon monoxide dimers we could experimentally verify for the first time how energy between molecules can be transferred (10x) more efficiently (resonantly) on an atomic level and ultrafast time scale in a theoretically predicted so-called Resonant Auger Inter Coulombic decay (RA-ICD). We performed experimental measurements and theoretical calculations for the photoionization of CH₄ at the carbon K-edge. The measurements performed with our COLTRIMS method at the ALS combined with the complex Kohn variational calculations of the photoelectron in the molecular frame demonstrated the surprising result that the low energy photoelectrons (~4eV), when averaged over all photon polarization directions, effectively image the geometry of the molecule. We have since found that the situation with molecules containing more than one central heavy atom can be more complicated, with multiple scattering effects leading to additional structure in the MFPADs. The origin of these imaging effects is still not well understood. For

example, we have found that carbon 1s ionization from CF₄ produces an MFPAD that actually anti-images the molecule, that is, the electron is preferentially ejected in directions between the CF bonds, producing a six-lobed octahedral figure. The fundamental importance in electron-driven chemistry provides an impetus for understanding the mechanism of DEA. Our earlier studies of DEA to water, CO₂ and methanol have shown that the topology of the transient anion surfaces relevant to DEA can be quite complicated, with conical intersections between shape resonances, Feshbach resonances and virtual states that can play a role in the dissociation dynamics. We have found that with polyatomic targets, studies of the total dissociation cross sections can belie the complexity of the dissociation dynamics, which is only revealed in angular distribution of the product anions.

Ultrafast Chemical Sciences

Institution: SLAC National Accelerator Laboratory
Point of Contact: Jens Norskov

Markus Guehr; SLAC National Accelerator Laboratory
Students: 8 Postdoctoral Fellow(s), 8 Graduate(s), 0 Undergraduate(s)
Funding: \$3,758,000 (2014)

PROGRAM SCOPE

The Ultrafast Chemical Science program has a particular emphasis on ultrafast chemical physics research at SLAC that is enabled by LCLS, the world's first hard x-ray free-electron laser, which began operations at SLAC in 2009. There are three major themes in this program: (1) Imaging on the nanoscale. X-ray imaging using LCLS allows structure determination. (2) Light conversion chemistry. We are particularly interested in the process of photocatalysis within coordination complexes and similar materials. (3) The eV scale in time, space, and field strength. This is the fundamental scale that determines structure and dynamics of electrons in molecules, and motivates advances in sub-femtosecond time-resolution and Angstrom spatial resolution in theory and experiments.

FY 2014 HIGHLIGHTS

The Ultrafast Chemical Science Program made significant progress, with highlights in each of its subtasks during FY 2014. In Attosecond Science, our discovery that multiple electron orbitals can contribute to high harmonics is now used to investigate electronic structural symmetries and sub-femtosecond dynamics in molecules. In our task on non-periodic imaging, we focused on high-speed optical imaging, sample preparation and low-flow electrokinetic microjets for sample delivery. We are developing fluid mixing techniques for time-resolved chemical and biological studies, and development of our electrokinetic microjet resulted in a version that will be used as a standard technique in crystal screening at the Coherent X-Ray Imaging endstation and for future experiments at the LCLS. High-speed imaging schemes developed in our lab will be implemented at the LCLS as well. In strong-field science, we have probed electron delays in above threshold ionization, extending our capability of velocity map imaging in ions to electrons combined with interference techniques, so we can view the quantum evolution of electrons in strong fields with resolution of ten attoseconds or better during strong field ionization. In

solution phase chemistry, key results included using hard x-ray fluorescence to demonstrate that spin crossover in photoexcited Fe compounds occurs stepwise through a triplet intermediate, and using hard x-ray fluorescence to demonstrate that Fe complex spin crossover can be manipulated by ligand and solvent modifications, and anisotropic hard x-ray scattering to study photo-induced bond isomerization. In our nonlinear x-ray optics activity, we published the first paper on phase-matched x-ray frequency doubling and have compared high-harmonic generation in solids and gas phase argon. And in ultrafast theory, we have implemented methods to compute Auger spectra as a probe for excited state dynamics.

EARLY CAREER: Ultrafast X-Ray Studies of Intramolecular and Interfacial Charge Migration

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Oliver Gessner
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Key intramolecular and interfacial charge-transport mechanisms in novel molecular devices for sustainable energy solutions will be studied on their natural timescales and with atomic specificity by means of a new class of ultrafast x-ray experiments. The central motivation is to derive an accurate description not only of the complex electronic structure that emerges from extended molecular and interfacial assemblies, but in particular of the dramatic changes in these electronic structures that, by definition, have to occur in order to enable, for example, long-range charge transfer and/or catalytic function. The combination of different x-ray techniques will provide the capability to test molecular level models of intramolecular and interfacial charge migration by a new set of molecular level probes. Charge migration in porphyrin dyads after photoexcitation will be probed with atomic accuracy by a transient change in atom-specific inner shell photoemission spectra. The arrival of charge carriers on dye-sensitized semiconductor surfaces will be timed with femtosecond precision by the transient change of Auger cascades. Electronic dynamics at bulk-heterojunction interfaces will be observed from different sides of the interface by time-resolved near-edge coherent diffractive imaging experiments. Laboratory based experiments in LBNL's Ultrafast X-ray Science Laboratory (UXSL) will be combined with studies at 4th generation light sources such as the Linac Coherent Light Source (LCLS) and complementary measurements at 3rd generation synchrotrons such as the Advanced Light Source (ALS).

FY 2014 HIGHLIGHTS

In a concerted effort of femtosecond time-resolved x-ray photoelectron spectroscopy (TRXPS) performed at the Linac Coherent Light Source (LCLS) and constrained density functional theory (CDFT) calculations, an interfacial charge-transfer state has been identified as the intermediate electronic configuration that precedes free charge carrier generation upon photoexcitation of a film of ZnO nanocrystals sensitized with N₃ dye molecules. The results provide an important benchmark for the long-standing quest to identify the fundamental mechanisms underlying the performance differences of TiO₂ and ZnO-based hybrid molecule-semiconductor systems for photo-induced charge generation. The LCLS based femtosecond time-resolved experiments have been complemented by picosecond time-resolved experiments at the Advanced Light Source (ALS). A novel TRXPS technique has been developed that provides an electron bunch-length limited temporal resolution of ~70 ps (FWHM) and that can be

applied in all operating modes of the ALS (2-bunch and multi-bunch) while making use of a large fraction of the total ALS X-ray flux. The new capability has been employed to characterize the transient surface photovoltage (SPV) response of a nanoporous, N₃-sensitized ZnO semiconductor substrate due to photoinduced interfacial charge-injection and recombination dynamics. The measurements demonstrate a substantial SPV response of the sintered nanocrystal film and provide direct insight into the dynamics induced in the electron acceptor of the dye-semiconductor interface. The development of a new *in operando* picosecond time-resolved x-ray absorption spectroscopy (TRXAS) technique has been initiated at the ALS to study interfacial electron dynamics in photoelectrochemical devices under application-like conditions. Preliminary *in operando* TRXAS spectra have been recorded for a photoelectrochemical cell based on a thin film hematite (α -Fe₂O₃) working electrode exposed to an aqueous NaOH electrolyte.

EARLY CAREER: Strongly-Driven Attosecond Electron-Dynamics in Periodic Media

Institution: SLAC National Accelerator Laboratory
Point of Contact: Jens Norskov
Email: norskov@stanford.edu
Principal Investigator: Shambhu Ghimire
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Fundamental strong-field response in crystalline solids involves attosecond electron dynamics. High-density and periodicity of the solid-state make these dynamics markedly different from those in the gas phase. Observation of non-perturbative high-order harmonics in bulk crystals subjected to strong mid-infrared laser fields has been attributed to these sub-cycle electron dynamics. Unlike in a gas, the solid-state exhibits many body problems making these dynamics very rich, and consequently the mechanism for high-order harmonic generation in high-density periodic system is of current debate. The scope of this program is to initiate, control and measure attosecond electron dynamics in periodic media by using strong, waveform controlled mid-infrared laser pulses. This research will advance our understanding of fundamental high-intensity laser interactions in transparent solids particularly focusing on the fundamental differences to the gas phase attosecond AMO.

FY 2014 HIGHLIGHTS

This program began in August 2014. We are setting up a high-intensity, mid-infrared laser system and an experimental chamber for measuring temporal characteristics of high-order harmonics in crystals. In this setup, we will be able to measure the phase of individual harmonics with respect to the laser phase, so called atto-chirp. In analogy to the gas phase attosecond AMO, these time-domain measurements test the suitability of solid-state harmonics for the synthesis of attosecond pulses.

EARLY CAREER: Understanding Photochemistry using Extreme Ultraviolet and Soft X-Ray Time Resolved Spectroscopy

Institution: SLAC National Accelerator Laboratory
Point of Contact: Jens Norskov
Email: norskov@stanford.edu
Principal Investigator: Markus Guehr

Sr. Investigator(s):

Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)

Funding: \$502,000 (2014)

PROGRAM SCOPE

The scientific scope of this early career program is a better understanding of photochemistry using ultrafast spectroscopy with high photon energies. Reactions driven by sunlight power nearly all biological functions and are thus responsible for most of the energy resources available on earth. The key question in the matter-light interaction is about the conversion of light energy into other forms of energy. Some molecules transform a large fraction of the light energy into changes in chemical bonds or into a charge transfer. Others distribute the photon energy over many vibrational modes leading to heating without bond change. This selectivity and the efficiency of the light induced processes in matter is the great question in light-matter interaction.

To obtain a better understanding of the light-energy conversion, we combine optical femtosecond photoexcitation with extreme ultraviolet (EUV) and soft x-ray (SXR) femtosecond pulses that serve to probe the molecular dynamics related to nuclear-, electronic- or spin-relaxation. This spectral range provides two crucial advantages. First, the high photon energy probe pulses accomplish to monitor the full molecular relaxation via the emission of photoelectrons. This is in contrast to optical probes that generally accomplish only the photoemission from un- or weakly relaxed molecules. Second, the EUV and SXR pulses provide element and site specificity due to the spectrally distinct absorption and emission features of core electrons. In the EUV domain, we are able to observe the 3d-3p resonance features of 3d transition metals. In the SXR domain, the carbon, nitrogen and oxygen K edges are of particular importance for our work. We use laboratory based femtosecond high harmonic generation (HHG) sources in the range of 20-100 eV; synchrotrons with a wide spectral range from the EUV to the high SXR and the Linac Coherent Light Source (LCLS) providing high pulse energy femtosecond pulses in the soft and hard x-ray range.

FY 2014 HIGHLIGHTS

During this past year we fully commissioned and performed first experiments with our extreme ultraviolet photoelectron/photoion spectrometer. We use pulses of 14 eV photon energy to probe the dynamics on photoexcited molecular states via photoelectron and photoion spectroscopy. We compared the transient photoelectron spectra with multiphoton ion-spectra of perylene after UV excitation of the S_1 state. We found a stark discrepancy in the two different transient signals reflecting the same molecular dynamics. The EUV probe directly leads from the S_1 to the cationic states; the multiphoton probe process involves several neutral resonant states in between the S_1 and cationic states, as we know from signal vs. IR intensity measurements. These intermediate states play a crucial role in shaping the observed transient. Our study shows systematically that intermediate resonances in multiphoton transitions can enhance the sensitivity to molecular dynamics but at the same time are also much more difficult to interpret.

Furthermore, we studied the optically induced insulator-to-metal transition (IMT) of a VO_2 film with EUV diffraction in the range of the vanadium 3p-3d resonance (M-edge). The sample was excited by two optical pulses creating an excitation grating. Performing the experiment above and below the critical temperature for the IMT allowed to separate the effect of the IMT from the acoustic response of the

sample. The IMT creates an ultrafast increase in the diffraction near the vanadium M-edge at very short times.

EARLY CAREER: the Multiconfiguration Time-dependent Hartree Fock (MCTDHF) Method for Interactions of Molecules with Strong Ultrafast High-energy Laser Pulses

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Daniel Haxton
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Recent advances in laser technology have made accessible a range of experiments involving short laser pulses. Using such pulses we can excite molecules in various ways and then watch how the energy flows within the molecule, in real time. Doing so permits us to understand and design systems like quantum computers and photosynthetic complexes. We would like to be able to calculate what will happen in a given experiment; theoretical results are always important for designing experiments and explaining the results. However, it is difficult to calculate what happens to a molecule exposed to an arbitrary laser pulse and there are no established methods to do so, even with a supercomputer. Recently the Multiconfiguration Time-Dependent Hartree-Fock (MCTDHF) method has been shown to be viable for this purpose. To be the most useful tool, the method must be able to calculate the dynamics of larger molecules, including the effects of nuclear motion. The goals of this research problem are to apply the MCTDHF method to small systems (atoms and diatomic molecules) that are currently being studied, and to develop the additional capabilities needed to apply the method to larger systems.

FY 2014 HIGHLIGHTS

The program consists of three interlocking thrusts: code development, method development and applications. We made major progress in all areas. Most of the effort in 2014 was spent on code development. We compiled separately the software for three coordinate systems; others may easily be added. We are implementing nonadiabatic rotational motion and improving the treatment of nonadiabatic vibrational dynamics, for diatomics. Methods development was enabled by synergy with the SciDAC project, and the polyatomic capability is now implemented for fixed nuclei without exterior complex scaling. We are calculating valence absorption cross sections for methane. Also in this area, it is necessary to go beyond full configuration interaction. In the publication accepted 12/23/2014 to Phys Rev A, 'Two methods for restricted configuration spaces within the MCTDHF method,' we completed the derivation of MCTDHF for arbitrary configuration spaces. Many authors have published papers on the subject, all with specialized treatments. We derived the general equations for arbitrary spaces, showing that most treatments fall within the simplest category. In the applications area, our primary focus is on wave mixing. We applied Domcke's method to transient absorption of Helium and O₂. The next step in transient absorption experiments is to move to a perpendicular geometry and use several identical XUV pulses in a fan arrangement. We calculate the corresponding signals to make a prediction for the generalization of Chen, Bell, Neumark, Leone *et al*, PRA 86, 063408. I have implemented nonphysical, complex-valued, 'rotating' wave pulses. Issues of gauge invariance notwithstanding, it is clear that the method accomplishes a decomposition of the signal that can be used to chart the paths through which

energy flows in molecules. Preliminary results will be submitted for publication in early 2015. A paper on stimulated Raman in NO, submitted 9/17/2013, was published 11/21/2014.

Engineered Electronic and Magnetic Interactions in Nanocrystals

Institution: Los Alamos National Laboratory
Point of Contact: David Morris

Principal Investigator: Victor Klimov
Sr. Investigator(s): Jeff Pietryga; Los Alamos National Laboratory
Scott Crooker; Los Alamos National Laboratory
Istvan Robel; Los Alamos National Laboratory
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$776,000 (2014)

PROGRAM SCOPE

Chemically synthesized semiconductor nanocrystals (NCs) have been extensively studied as both a test bed for exploring the physics of strong quantum confinement as well as a highly flexible materials platform for the realization of a new generation of solution-processed optical, electronic and optoelectronic devices. Due to readily size-tunable emission, colloidal NCs are especially attractive for applications in light-emitting diode (LED) displays, solid-state lighting, lasing, and single-photon sources. It is universally recognized that the realization of these and other prospective applications of NCs requires a detailed understanding of carrier-carrier interactions in these structures, as they have a strong effect on both recombination dynamics of charge carriers and spectral properties of emitted light. A unifying theme of this project is fundamental physics of electronic and magnetic interactions involving strongly confined carriers/spins with focus on control of these interactions via size/shape manipulation, doping/heterostructuring, and “interface engineering.” Our goals in this project include: the development of high-efficiency NC-based LEDs free from detrimental effects of Auger recombination such as efficiency “roll-off” at high currents; realization of electrically pumped single-NC light sources; the achievement of NC lasing under continuous-wave excitation; and demonstration of ferromagnetic behavior in optically-active NCs doped with magnetic impurities.

FY 2014 HIGHLIGHTS

- Clear demonstration of the effect of Auger recombination (AR) on the performance of quantum dot (QD) light-emitting diodes (LEDs). [Nature Commun. 4, 2661, 2013; featured as DOE/BES highlight, May 2014] When LEDs are fabricated from alloyed core/shell QDs with suppressed AR, we observe a ca. two-fold improvement in the absolute external quantum efficiency, and a marked reduction in efficiency “droop” at high currents, compared to devices made with conventional core/shell QDs.
- Development of a new type of “dot-in-bulk” nanostructure for dual-color light emission. [Nano Lett. 14, 486, 2014] Heterostructures comprising a quantum-confined CdSe core and an ultra-thick (>25 monolayers) CdS shell separated by a thin interfacial barrier emit two-color light under both optical and electrical excitation with effective emission color that is tunable by excitation photon intensity or applied bias voltage.
- Single-QD spectroscopy produces new insights into the influence of the core/shell interface potential on the suppression of AR. [Nano Lett. 14, 396, 2014; ACS Nano 8, 7288-7296, 2014] Through time-resolved time-tagged single QD spectroscopy, we observe that while having essentially no effect on single-exciton decay, the interfacial alloy layer in a core/alloy/shell QD

heterostructure leads to a systematic increase in biexciton lifetimes, and biexciton emission efficiency as inferred from two-photon correlation measurements.

- Development of time-resolved spectro-electrochemistry for probing and controlling recombination processes in complex QDs. [Nano Lett. 14, 3855, 2014] A novel experimental apparatus allowed us to study the time resolved emission of QDs under an electrochemical bias. The result is unprecedented insight into the influence of charge-trapping processes QDs, and a means for activation and tuning of core- and shell-emission channels, including the tuning of the effective emission color from red to green in light-emitting devices based on dot-in-bulk QDs.

Ultrafast X-Ray Science Laboratory (UXSL)

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: C. William McCurdy
Sr. Investigator(s): Ali Belkacem; Lawrence Berkeley National Laboratory
Oliver Gessner; Lawrence Berkeley National Laboratory
Martin Head-Gordon; Lawrence Berkeley National Laboratory
Stephen Leone; Lawrence Berkeley National Laboratory
Daniel Neumark; Lawrence Berkeley National Laboratory
Students: 11 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$2,057,000 (2014)

PROGRAM SCOPE

The Ultrafast X-ray Science Laboratory (UXSL) exploits the use of short X-ray and XUV pulses to provide basic knowledge of ultrafast dynamics of photo-excited atoms and molecules from the natural time scale of electron motion to the time scale of the chemical transformations. There are five subtasks in the UXSL effort, reflecting the essential strategy of attacking these problems using an approach that applies an entire arsenal of ultrafast experimental and theoretical methodology spanning time scales from attoseconds to picoseconds to the study of systems that include atoms and molecules in the gas phase, clusters, nanodroplets and condensed phase transition-metal complexes. The set of experimental and theoretical projects that constitute the Ultrafast X-ray Science Laboratory are an integrated effort to develop novel applications of emerging ultrafast experimental techniques and to provide basic knowledge that is central to the programmatic goals of BES/DOE.

FY 2014 HIGHLIGHTS

- 1) Made first detection of quantum vortex lattices in rotating helium nanodroplets by X-ray coherent diffractive imaging. Isolated pure and Xe-doped nanodroplets imaged by single X-ray (1.5 keV) pulses at Linac Coherent Light Source. Vortices imaged by doping the droplets with Xe atoms, which are attracted to the vortex cores where they cluster and act as contrast agents for detection of elusive quantum phenomenon.
- 2) Refined and applied transient absorption spectroscopy to observe coherent superposition of Rydberg states below first ionization potential of neon. Attosecond pulse prepares the coherent superposition. Then NIR pulse interrogates initial excitation by perturbing induced polarization at varying time delay.
- 3) New reaction microscope completed and used in experiments on ethylene employing two photon processes generated from pump-probe schemes using femtosecond light pulses at 8 and

14 eV to break the C=C bond. Preferred emission of the CH_2^+ fragments along polarization direction found while fragments from higher-order excitation showed isotropic distribution. Surprising peak at zero kinetic energy release was discovered.

- 4) Completed first time-resolved X-ray absorption near edge spectroscopy and extended X-ray absorption fine structure spectroscopy studies of transient electronic and molecular structure of bimetallic $\text{Mn}_2(\text{CO})_{10}$ following photodissociation. This compound is a prototype for understanding solution photolysis of organometallic compounds with metal-metal bonds.
- 5) Using extensive computer simulations developed a new scheme for measurement of polarization of atoms and molecules above ionization threshold induced by intense IR or visible laser pulses using transient absorption methods. Also completed *ab initio* trajectory studies exploring post-electronic excitation dynamics of small helium clusters as a simulation counterpart to UXSL experiments.

Atomic, Molecular and Optical Physics

Institution: Argonne National Laboratory
Point of Contact: Emilio Bunel

Sr. Investigator(s): Norbert Scherer; Chicago, University of
Elliot Kanter; Argonne National Laboratory
Robert Dunford; Argonne National Laboratory
Students: 5 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$981,000 (2014)

PROGRAM SCOPE

The Argonne AMO physics program conducts experimental and theoretical research on x-ray interactions, inner-shell processes, and applications of x-ray methods at the Advanced Photon Source (APS) storage ring and at the LCLS and SACLA x-ray free-electron laser (XFEL) facilities. The APS is our primary source of intense, tunable, polarized x rays for time-resolved laser-pump/x-ray-probe experiments on the photochemical dynamics of solvated molecules. To exploit the full x-ray flux of the APS, we use high-repetition-rate lasers for pump-probe experiments at megahertz pulse rates. This enables high precision measurements of the electronic and atomic structures of laser-induced transient states. X-ray absorption and core-hole decay produces high charge states on the atomic sites of a molecule and the system Coulomb explodes. We use reaction microscopes to measure the breakup momenta of the fragment ions in coincidence. The APS measurements motivate the research performed at XFELs on the photo-dynamics of solvated molecules and on intense x-ray interactions with gas-phase atoms and molecules. Theory is a key component of the research program by predicting phenomena that motivate experiments and by simulating measured results. Optical lasers can trap, move, and orient nanoparticles and provide a new route towards the assembly of nanomaterials. The AMO program includes a collaboration with Professor Norbert Scherer at the University of Chicago to develop optical tweezers and traps for x-ray diffraction and coherent x-ray imaging of nanoparticles at the APS.

FY 2014 HIGHLIGHTS

By implementing high-repetition-rate lasers at the APS, time-resolved x-ray absorption (XAS) and x-ray emission (XES) spectra of laser-excited molecules in solution are recorded with high precision. The high statistical precision allowed the first observation of valence-to-core x-ray emission in short-lived

transient species. This capability was applied to characterizing transient electronic and atomic structures of:

- Ligand dissociation, ligand substitution, and electron detachment in aqueous ferrocyanide.
- The low-to-high-spin transient state of iron(II)-bis-terpyridine.
- Dynamics of charge carriers and trapping sites in aqueous zinc oxide nanoparticles.

The APS measurements on aqueous ferrocyanide and zinc oxide both motivated experiments in the femtosecond/few-picosecond regime at the SACLA XFEL. Inner-shell photoionization and core-hole decay in gas-phase xenon and xenon difluoride were compared to explore molecular effects. Total cross sections and partial ion yields were measured at the Wisconsin soft x-ray storage ring and compared with relativistic coupled-cluster calculations of the resonant states. These results guided subsequent measurements using two femtosecond x-ray pulses at the LCLS. The first pulse creates an inner-shell hole and the second pulse probes the molecular dynamics. A Monte Carlo rate equation method was developed to simulate the complex ionization dynamics of atoms exposed to an intense XFEL pulse. The calculations were the first to include resonances systematically and thus to identify resonance-enhanced x-ray multiple ionization pathways that play an essential role in ultraefficient production of high charge state ions in Ar, Kr and Xe. The code runs on advanced computational platforms. Future applications are planned on the interactions of intense x rays with molecules, clusters, and nanoparticles.

Principal Investigator: Mahdi Abu-Omar
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

Limited supply of nonrenewable crude oil and its impact on climate change necessitate a shift towards renewable resources. Plants are solar factories that utilize carbon dioxide, water, and sunlight to make lignocellulosic matter. However, biomass components, xylans, cellulose, and lignin are rich in oxygen. Therefore, the goal of this project is to develop efficient and selective catalytic processes that remove oxygen atoms from biomass derived compounds.

FY 2014 HIGHLIGHTS

We have shown that vicinal diols can be deoxygenated to alkenes using methyltrioxorhenium (MTO), water and air stable commercial catalyst, under reasonable conditions (140°C) with molecular hydrogen or secondary alcohols as the reductant. We have extended the MTO-catalyzed reaction to biomass derived glycerol and polyols to make alkenes and high value chemicals (HVCs) that can be used as drop in chemicals in polymer synthesis. The kinetics and mechanism of the MTO-catalyzed deoxydehydration (DODH) reaction has been elucidated revealing a previously unrealized rhenium(V)/rhenium(III) cycle. To explore rhenium complexes with various oxidation states and their potential in acceptorless dehydrogenation (AD) reactions, we synthesized and characterized several rhenium dicarbonyl complexes supported by PNN pincer ligation in three different oxidation states, rhenium (I), (II), and (III).

Structure-Reactivity Relationships in Multi-Component Transition Metal Oxide Catalysts

Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Cobalt-containing oxides are active for a wide range of reactions that typically require vastly more expensive Pt-group metals. The catalytic activity, however, is sensitive to the full range of effects seen in heterogeneous catalysis, including particle size dependence, support effects, sensitivity to preparation

conditions, and doping and impurity effects. Even for the binary oxide, the active phase of the material is an open question. Therefore, we have been working on determining how the geometric and chemical structures of Co oxide surfaces influence the catalytic properties of these materials. We use a surface science approach involving atomic resolution scanning probe microscopy coupled with macroscopic spectroscopic and reactivity measurements.

FY 2014 HIGHLIGHTS

We have focused on cobalt oxide clusters on Au. Although the O₂ pressures are orders of magnitude above the Co₃O₄ dissociation pressure, we find only CoO at low oxide coverages. The CoO surface exhibits a moiré pattern due to the lattice mismatch with Au. Interestingly, the moiré maxima, each with 220 atoms, become the building blocks that determine the cluster shape. The minimum number of maxima seen was three; no clusters containing four, six, or eight maxima were detected. The shapes of the stable clusters alternated between trapezoids and regular and elongated hexagons until the size approached 6,000 atoms, after which the clusters consistently displayed the expected asymmetric hexagonal shape due to the different energies of the alternating edges. The results highlight how even weak substrate interactions affect the stability and shape of catalytic clusters. The Co oxide clusters large enough to be oxidized to Co₃O₄ displayed “Y” defects due to CoO oxidation starting only at specific edges; since the Au determines the density of these edges, it plays a key role in determining the oxidation rate of the clusters. The Co₃O₄ could be reduced to CoO by CO, demonstrating that they are active for CO oxidation. We began to monitor the reduction of Co₃O₄ with STM video imaging. At 570 K in vacuum the Co₃O₄ clusters could be imaged; leaking in CO caused continual rapid restructuring of the clusters that made imaging difficult. Thus a phase transition was seen but obtaining atomic scale information will require fine tuning of the temperature and CO flux. To quantify the increased stability of small CO clusters and to characterize CO oxidation under catalytic conditions, Ambient Pressure XPS measurements were performed at Brookhaven National Laboratory. The results showed that the stability of even the large Co₃O₄ clusters was decreased by orders of magnitude compared to the bulk, and that the smaller Co oxide clusters could not be oxidized to Co₃O₄ even at 0.5 Torr O₂.

Modeling Catalyzed Growth of Single-Wall Carbon Nanotubes

Institution:	Texas A&M University
Point of Contact:	Perla Balbuena
Email:	balbuena@tamu.edu
Principal Investigator:	Perla Balbuena
Sr. Investigator(s):	
Students:	0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$110,000 (2014)

PROGRAM SCOPE

Single-wall carbon nanotubes have unusual physico-chemical properties that make them promising materials for a variety of electronics, biomedical, micro and nanofluidics, and other innovative applications. Such properties are mainly determined by the tubes diameter and by their degree of helicity, also known as chirality. Single-wall carbon nanotubes may be grown by decomposition of a carbon-containing species over nanocatalyst surfaces using chemical vapor deposition methods. Significant progress has been made in the last decade refining the synthesis process with the goal of obtaining a well-defined product useful for specific applications; however, a big challenge remains in trying to elucidate the reasons behind the chirality selectivity found under specific operation conditions,

nature of the precursor gas, and type of catalyst/support utilized in the synthesis. Thus, a large component of that challenge is associated with the catalytic process. In our previous work we used density functional theory and reactive molecular dynamics to demonstrate the existence of a structural correlation between the nanoparticle and the nascent nanotube at different growth stages. Such correlation can be dominated by either the nanotube (inverse template effect) or the nanoparticle (template effect). Thus achieving chirality control depends on determining synthesis conditions where crucial structural features of the nanoparticles are maintained during growth. The objective of this new work is to elucidate further aspects of the growth mechanism such as the nature of the active species being added to the nanotube rim, the influence of non-reactive gases, the role of surface and bulk carbon diffusion, the role of bimetallic surfaces, and the conditions for horizontal growth. These studies will allow a systematic search of nanotube growth conditions where the nanoparticle stability can be optimized thus allowing template effect and selective growth.

FY 2014 HIGHLIGHTS

A strong interaction between the catalyst surface and the graphitic lattice of the nanotube was found to be necessary for healing and formation of nanotube defects. Defects can be healed independently of their degree of embedment of the defective structure into the tube structure. Diffusion and catalytic events at the catalyst/tube interface are the main sources of nanotube structural recovery on the catalyst surface. Optimal growth conditions are identified that allow significant structural healing in nanotubes. Selective functionalization of low-coordinated surface sites on quartz surfaces cause exposure of low-coordinated Si atoms that bond strongly to nanotube walls. Saturation of low-coordinated oxygen also favors carbon nanotube adhesion to the substrate. A chirality preference was confirmed on functionalized surfaces towards zigzag over armchair nanotubes. Magnetization effects on the surface originated by the presence of adsorbed functional groups were found to enhance adsorption of arm-chair nanotubes compared to that on clean surfaces. Based on the findings, it was suggested that surfaces may be engineered to favor horizontal adsorption of specific chiralities along preferential directions. Analyses of atomic scale movies obtained with an environmental transmission electron microscope (Dr. R. Sharma, NIST) showed how carbon atoms assemble developing a graphene sheet that wraps around a catalyst nanoparticle forming a nanotube. It was found that the catalyst nanoparticles have adjacent surfaces with divergent work of adhesion for graphene. This difference is crucial for nanotube growth efficiency because it offers the required anchoring and lift-off sites. Our results indicate that the faceting geometry of the nanoparticles determines the nanotube cap structure, thus defining both the diameter and the chiral angle of the single-walled carbon nanotubes during their birth.

Chemoselective Oxidations Using Visible-Light Responsive Semiconducting Oxides

Institution: Michigan, University of
Point of Contact: Bart Bartlett
Email: BARTMB@UMICH.EDU
Principal Investigator: Bart Bartlett
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$400,000 (2014-2016)

PROGRAM SCOPE

This research program builds on our efforts in using sol-gel chemistry to generate alloyed compositions of solid-state materials that can be used as either direct photocatalysts or as visible light-absorbing

compounds to transfer charge carriers to tethered molecular catalysts. This inorganic chemistry research addresses the Catalysis Science mission of examining the elementary steps in chemical reactions occurring at homogeneous-heterogeneous (molecular/solid) interfaces. Moreover, we have expanded the reaction scope of our work beyond water oxidation (from the previous funding cycle) to include photo(electro)chemical oxidation of alcohols and amines to generate value-added chemicals.

FY 2014 HIGHLIGHTS

In this first year of funding, we have demonstrated that a known iron-based water oxidation catalyst can be modified synthetically to include a phosphonate tethering group that binds the complex to the semiconductor, tungsten oxide (J. Am. Chem. Soc. 2014, 136, 1694). On their own, semiconducting oxides have the drawback that their valence band holes are so oxidizing that the resulting chemical reactions are non-specific. Typically stable anions such as chloride and sulfate used in common electrolytes react faster than does water. The advantage of the tethered architecture is that embedding a molecular catalyst, even at the low loading of 1 nm per square cm, onto tungsten oxide gives rise to a nearly 50% enhancement in the photocurrent density, in the voltammetry, and a 30% increase in the Faradaic efficiency for oxygen evolution from water. This result sets the stage for carrying out other chemoselective oxidation reactions using visible light.

Nanoscale Surface Chemistry and Electrochemistry of Clean and Metal-Covered Faceted Substrates: Structure, Reactivity and Electronic Properties

Institution: New Jersey-Rutgers, State University of
Point of Contact: Robert Bartynski
Email: bart@physics.rutgers.edu
Principal Investigator: Robert Bartynski
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

During catalytic reactions the shape (morphology) and size of supported metal nanoparticles can vary and sometimes undergo reversible shape changes in response to variations in the reacting gases, which in turn can induce changes in their reactivity and selectivity. These changes are attributed to the strong interaction between adsorbates (e.g. reactants, intermediates) and metal nanoparticles, which is related to adsorbate-induced morphological evolution (i.e. faceting) of metal surfaces. The goal of this project is to explore new aspects of the relationship between nanoscale metallic features and (electro)chemical reactivity/selectivity. We focus on three research areas: 1) fabrication and characterization of adsorbate-induced nano-faceting of atomically rough metal single crystal surfaces such as hcp (11-21), hcp (12-31) and fcc (210); 2) reactivity and selectivity of the faceted metal surfaces in catalysis; 3) utilization of faceted metal surfaces as nanotemplates for growth of metallic nanoclusters with regular spacings and synthesis of nanostructured metallic monolayer electrocatalysts. The faceted metal surfaces, free of any support material, represent a unique type of nanoscale model catalysts which can bridge the material gap between metal single crystal surfaces and supported metal nanoparticles. The well-defined facets allow for detailed experimental and theoretical characterization that provides insights into structure–reactivity/selectivity relationships, which is crucial for improving reactivity and selectivity by controlling the nanoscale morphology and size distribution of heterogeneous catalysts and electrocatalysis.

FY 2014 HIGHLIGHTS

We have written an invited review article for a book entitled 'Catalysis by Materials with Well-defined Structures' (Elsevier B.V., ISBN: 978-0-12-801217-8, 2015). The detailed studies on N-, C- and O-induced nano-faceting of Re(11-21) have been completed. The surface morphology (e.g. two-sided ridges, three-sided pyramids, four-sided pyramids, etc.) of Re(11-21) can be tailored on the nanometer scale by careful control of adsorbate species (N, C, O), adsorbate coverage and surface temperature. The (2x1) reconstructed Re(11-21) surface acts as a precursor state for N-induced faceting of Re(11-21) (J. Chem. Phys. 2014). When C-induced faceting of Re(11-21) occurs C atoms prefer to bind at four-fold sites of the Re facets (Catal. Lett. 2014). We have found microscopic structural connections between the various morphologies on O-covered faceted Re(11-21), which provide a natural explanation to the pathways of mass transport in reversible morphological transformation on faceted O/Re(11-21) (Surf. Sci. 2015). We have detected formation of N₂O in oxidation of ammonia by co-adsorbed oxygen on clean planar Ir(210) and clean faceted Ir(210), which is the first observation of N₂O production in catalytic ammonia oxidation under UHV conditions (< 1x10⁻⁹ Torr) (Catal. Lett. 2015). The selectivity of the reaction to N₂, N₂O and NO on Ir can be tuned by oxygen pre-coverage, surface morphology and facet size.

Photocatalysis of Modified Transition Metal Oxide Surfaces

Institution: South Florida, University of
Point of Contact: Matthias Batzill
Email: mbatzill@usf.edu
Principal Investigator: Matthias Batzill
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The scope of this project is to establish a cause-effect relationship for structurally and compositionally modified photocatalysts. Gaining molecular scale understanding of how surface and bulk modifications alter the photocatalytic reactivity to aid the design for next generation photocatalysts

FY 2014 HIGHLIGHTS

The prototypical photocatalyst TiO₂ exists in different polymorphs, the most common forms are the anatase- and rutile-crystal structures. Generally, anatase is more active than rutile, but up to now no consensus existed to explain this difference. This year we have demonstrated that it is the bulk transport of excitons to the surface that contributes to the difference. Utilizing high-quality epitaxial TiO₂ films of the two polymorphs we evaluate the photocatalytic activity as a function of TiO₂-film thickness. We found that for anatase the activity increases for films up to ~5 nm thick, while rutile films reach their maximum activity for ~2.5 nm films already. This shows that charge carriers excited deeper in the bulk contribute to surface reactions in anatase than in rutile. Furthermore, we measure surface orientation dependent activity on rutile single crystals. The pronounced orientation-dependent activity can also be correlated to anisotropic bulk charge carrier mobility, suggesting general importance of bulk charge diffusion for explaining photocatalytic anisotropies.

Studies of Metal-Metal Bonded Compounds in Group Transfer Catalysis

Institution: Wisconsin-Madison, University of
Point of Contact: John Berry
Email: berry@chem.wisc.edu
Principal Investigator: John Berry
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

The overall goals of this research are (1) to define the fundamental coordination chemistry underlying successful catalytic transformations promoted by metal-metal bonded compounds, and (2) to explore new chemical transformations that occur at metal-metal bonded sites that could lead to the discovery of new catalytic processes. Transformations of interest include metal-promoted reactions of carbene, nitrene, or nitrido species to yield products with new C–C and C–N bonds, respectively. The most promising suite of transition metal catalysts for these transformations is the set of metal-metal bonded coordination compounds of Ru and Rh of the general formula $M_2(\text{ligand})_4$, where $M = \text{Ru or Rh}$ and ligand = a monoanionic, bridging ligand such as acetate. Development of new catalysts and improvement of catalytic conditions have been stymied by a general lack of knowledge about the nature of highly reactive intermediates in these reactions, the knowledge that is to be supplied by this work. Our three specific objectives for this year have been (A) to trap, isolate, and characterize new reactive intermediates of general relevance to catalysis, (B) to explore the electronic structure and reactivity of these unusual species, and how these two properties are interrelated, and (C) to use our obtained mechanistic knowledge to design new catalysts with a focus on Earth-abundant first-row transition metal compounds.

Ammonia and Hydrazine: Transition-Metal-Catalyzed Hydroamination and Metal-Free Catalyzed Functionalization

Institution: California-San Diego, University of
Point of Contact: Guy Bertrand
Email: guybertrand@ucsd.edu
Principal Investigator: Guy Bertrand
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

Nitrogen-carbon bonds are ubiquitous in products ranging from chemical feedstock to pharmaceuticals. Consequently, the so-called hydroamination reaction, the addition of an N-H bond across a carbon-carbon multiple bond, a process, which ideally occurs with 100% atom economy, has been widely studied. Various catalysts have been found to promote this chemical transformation, although many limitations still remain; one of the most prominent is the use of NH_3 and NH_2NH_2 as the amine partners. In fact, the utilization of ammonia in catalytic olefin hydroamination was listed among the ten greatest challenges for catalytic chemistry over a decade ago, and it remains unsolved today. More broadly speaking, apart from a few heterogeneous processes, examples of transition metal catalyzed functionalization of NH_3 are rare. The importance of these challenges is readily understandable since more than 100 million metric tons of NH_3 are produced per year, and the production of amines is similarly huge. Therefore the goal of this project is the development of novel ligands and types of transition metal complexes, which are efficient for transforming ammonia and hydrazine. In addition, we search for metal-free catalyzed processes for the functionalization of these amines. Indeed, the activation of NH_3 and NH_2NH_2 without transition metal centers offers an alternative paradigm in the continuing search for efficient catalytic systems, and should allow considerable reductions in the cost of important chemical processes.

FY 2014 HIGHLIGHTS

We have developed a novel synthetic route giving access to mesoionic carbene and cyclopropenyliene supported gold chloride complexes, which after chloride abstraction allow for the first transition metal-catalyzed functionalization of both nitrogens of parent hydrazine. We have shown that, similarly to transition metal nitrido complexes involved in the Haber-Bosch hydrogenation of N_2 into NH_3 , the first stable nitrene prepared in our laboratory acts as a nitrogen atom transfer agent. It also allows for the isolation of the first phosphoranimines, and copper- and silver-nitrene complexes, which are important intermediates in phosphazene polymerization, and in aziridination and amination reactions, respectively. Friedel-Crafts reactions typically require Lewis acid catalysts and are therefore generally unsuitable for basic substrates. Classical textbooks especially emphasize their incompatibility with amines, which is a major limitation due to the ubiquity of this organic functionality. We have found that cationic gold complexes, supported by our stable electrophilic carbenes, promote the hydroarylation of styrenes and norbornene, as well as enones, by dialkylanilines. Thanks to the peculiar properties of cyclic (alkyl)(amino)carbenes (CAACs), we have isolated the first complexes featuring gold, copper, cobalt and iron in the zero oxidation state. The stability of these complexes is not only a demonstration that CAACs are very efficient redox active ligands, but it might allow for new types of catalytic cycles. It has already been shown that the iron complex can activate N_2 at -78°C . We also found that CAACs allow for the preparation of mixed-valence gold(I)/gold(0) trinuclear clusters, the smallest members of the $(\text{LnAu}_m)_x^+$ family. Such gold clusters have attracted a great deal of interest due to their potential applications for nanoelectronic devices, medical science, and catalysis

EARLY CAREER: Catalyst Design for Small Molecule Activation of Energy Consequence

Institution: Harvard University
Point of Contact: Theodore Betley
Email: betley@chemistry.harvard.edu
Principal Investigator: Theodore Betley
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)

Funding: \$150,000 (2014)

PROGRAM SCOPE

Small molecule substrates can be interconverted as a mechanism for advanced energy storage in conjunction with renewable energy sources. The type of chemistry and catalysis necessary to develop alternative energy sources rely on small molecule (e.g. H₂O, N₂, CO₂) activation processes. Activation of these substrates relies on mediation of multi-electron, multi-proton reaction sequences. Stepwise delivery of these reagents can incur large overpotential costs as high-energy intermediates are encountered, evidenced by the strong chemical oxidants and reductants commonly employed to initiate reactivity in molecular-based catalysts. One possible method to circumvent these high-energy pathways is to mediate concerted multi-electron reaction pathways, bypassing high-energy intermediates altogether. This program seeks to develop a general approach for transforming ubiquitous small molecules (e.g., N₂, CO₂) into viable building blocks for synthetic fuels through the development of a new class of polynuclear catalysts. Our efforts in catalyst development will be described in the following contexts: (1) design ligand platforms to proximally accommodate multiple metal centers; (2) establish the ability of the polynuclear complexes to mediate multi-electron redox transformations, both electrochemically and via small-molecule activation processes; and (3) develop the multi-electron, stoichiometric reactivity discovered into viable catalytic processes to transform small molecule substrates into value-added chemicals (e.g. fuels).

FY 2014 HIGHLIGHTS

(1) Using our synthetic protocols for the assembly of cluster-based materials, we have prepared homotrimeric complexes of each 1st row metal from V to Zn. (2) Mixed-metal clusters are afforded via sub-stoichiometric substitution or metathetical routes from alkaline-earth metal based clusters. (3) Using this strategy we were able to understand the onset of high-spin electronic structure via magnetic metal ion doping. This was achieved by comparing the following clusters: Fe₂, Fe₂Mg, Fe₂Ca, Fe₂Sr, and Fe₃. We investigated this series by magnetometry and uncovered geometrical changes that influence the overall spin-states obtained. (3b) Using redox-neutral metal clusters we are able to stabilize late transition metal ions in unusually high-spin states. For example, a Co₂Zn cluster was able to support CoIV with concomitant capture of an imido linkage. (4) The onset of single molecule magnetism is enhanced via the materials which display a strong preference for direct-exchange magnetic interactions (e.g., direct, intracluster M-M orbital overlap). As a result, high magnetic spin ground states have been observed existing to room temperature (e.g., S = 10 persistent to 300 K). (5a) We have shown that cluster-based main-group aggregates showcase orthogonal chemistry as a function of molecular spin-state. A bridging Co₃(_{m3-N}) complex is classically nucleophilic as a diradical anion, but classically electrophilic as a neutral species. (5b) We have asserted that cluster spin-state is directly proportional to the reactivity of the cluster as a molecular unit. Through isolation of the diamagnetic Ni₃ cluster, we have shown it is remarkably stable against atom and group transfer reagents. Only via reduction to the mono-anion is the Ni₃ platform rendered reactive for nitrene or S-atom capture. Via subsequent oxidation, the Ni₃ cluster has been found to be stable across five discrete oxidation states, far exceeding the typical availability from mononuclear Ni-based molecules.

EARLY CAREER: One-Pot Catalytic Conversion of Biomass and Alkanes: Kinetically Coupling Deoxygenation and Dehydrogenation Pathways

Institution: Minnesota, University of
Point of Contact: Aditya Bhan
Email: abhan@umn.edu
Principal Investigator: Aditya Bhan
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This research focuses on developing kinetic and mechanistic understanding of heterogeneous catalytic process involved in the hydrodeoxygenation (HDO) of biomass-derived polyfunctional molecules using either CH₄ or molecular H₂ as hydrogen sources on non-precious metal catalyst formulations. The stoichiometric hydrogen deficiency of carbohydrate feedstock implies that all conversion processes must remove oxygen and concurrently increase hydrogen content to form liquid hydrocarbon products. We report that non-precious metal based carbide formulations are selective catalysts for oxygen-removal from lignin and cellulose-derived biomass monomers at atmospheric pressure.

FY 2014 HIGHLIGHTS

We report: (i) Mo₂C is a stable and highly selective catalyst for the low temperature (550 K) vapor-phase HDO of lignin-derived phenolics to form benzene, toluene, and xylene (BTX) - aromatics that are each amongst the 50 most produced chemicals worldwide. Oxygen modification of the surface prevents successive hydrogenation reactions. (ii) Acid site densities on metal carbide surfaces can be reversibly tuned by a factor of ~30 using an O₂ co-feed, which reversibly creates Brønsted acid sites on the carbide surface without altering bulk crystal structure as inferred from titration studies and reaction kinetics of isopropyl alcohol dehydration. The acid and metallic characteristics of carbidic formulations of highly oxophilic metals such as Molybdenum can therefore be systematically tuned by co-processing oxygen. (iii) The carbon-to-hydrogen effective ratio is a single value descriptor of oxygen removal pathways when co-processing C₁-C₃ oxygenates and CH₄ on Mo/ZSM-5 formulations reflecting the stoichiometric loss of oxygen as carbon monoxide when co-processing oxygenates and CH₄ at high temperatures (~950 K).

Single-Molecule Fluorescence Imaging for Studying Organic, Organometallic, and Inorganic Reaction Mechanisms

Institution: California-Irvine, University of
Point of Contact: Suzanne Blum
Email: blums@uci.edu
Principal Investigator: Suzanne Blum
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our laboratory has pioneered direct imaging techniques by fluorescence microscopy to study chemical reaction mechanisms and catalyst efficiencies by determining the location of reactivity with single-molecule and -particle sensitivity and spatial resolution. These studies have established our ability to characterize mechanisms, measure kinetics, and image single reactions at individual metal complexes with organic ligands similar to those used in homogeneous and supported-molecular heterogeneous catalysts in industrial- and research-scale synthesis. Improvement of catalytic reactions relies on accurate knowledge of the phase and structure of the active catalyst. Our program provides knowledge of the phase and partial structural information (with a long-term goal of additional structural information) of the active catalyst through sensitive microscopy techniques that are capable of deconvoluting multistep systems. One focus is the characterization of reactivity distributions of supported molecular catalysts under “normal” synthetic reaction conditions (e.g., ambient pressure and temperature, solution phase, and standard reagent concentrations). Supported molecular catalysts have the advantage of facilitating separations and recyclability and limiting reactor fouling while in theory retaining some of the uniformity of the environment around the active metal center possessed by homogeneous molecular catalysis. In part the difficulty in characterizing these heterogeneous systems arises from the measurement challenge of characterizing the reactivity distributions that are obscured by ensemble averaging in traditional bulk measurements. Our research program removes this ensemble averaging through the development of single-molecule and -particle microscopy technology.

FY 2014 HIGHLIGHTS

We overcame these measurement challenges via optical and SEM microscopy in studies of single resin beads of a commercial supported molecular ruthenium metathesis catalysts during the polymerization of norbornene. The major findings of these studies are: 1) over half of the support beads are fully inactive to the detection limits of the methods and lack active sites that contribute significantly to the generation of the polymer; 2) on the active beads, the majority of polymer forms at only a small number of locations; 3) the ruthenium is more evenly distributed across and within a catalyst bead than is distributed the catalytic reactivity; 4) polymer morphology is influenced by its growth from individual locations; and 5) this microscale, heterogeneous spatial reactivity suggests an untapped potential for substantially increased catalyst efficiency in this commercial system which was previously unrecognized. Tapping into this potential lead to improving the catalytic efficiency of the supported catalyst by deforming the resin support beads prior to the reaction, enabling 90% conversion to polynorbornene in 10 minutes, instead of the original 27% conversion with the unmodified commercial support as received from the manufacturer.

Novel Transport of Porous and Composite Nanostructures

Institution: New Mexico, University of

Funding: \$180,000 (2014)

PROGRAM SCOPE

This project is based on our unique abilities to synthesize model nanoscale architectures incorporating and interfacing monosized catalytic NPs and NP arrays with ultra-thin nanoporous membranes that are further 'adjustable' by conventional and plasma assisted atomic layer deposition (ALD) methodologies developed by our team in our prior grant cycle. Building on the concept of model nanoparticle catalytic reactors, the overall goal of our work is to fabricate catalytic systems with adjustable particle size, composition, spacing and accessibility along with tailorable NP/support interfaces and steric constraints. Additionally and importantly we have devised synthetic approaches to prepare these model systems in ultra-thin, electron transparent forms allowing direct TEM structural and chemical imaging of the parent system and its morphological and chemical evolution during the course of a realistic catalytic process. Also the 'thinness' of our systems, e.g. membranes or 2D-MoS₂, maximizes the catalytically accessible surface area per gram and guarantees short diffusion distances, minimizing contact times of desired products with active sites and enhancing flux of catalytic membrane reactor systems. A direct immediate goal is to use our model membrane reactors to investigate *in situ* TEM imaging of catalyst structure and chemistry during the oxidative dehydrogenation (ODH) of light alkanes. Based on the combination of ultrathin mesoporous silica membranes modified with ALD, we are also developing strategies for the synthesis of energy-relevant separation membranes with enhanced properties, e.g. CO₂ sequestration, resulting from well-defined chemical and dimensional asymmetry as inspired by natural biological systems and channels. Our research efforts are supported by molecular and atomic-level modeling and imaging of our membrane and catalytic architectures, with the goal of understanding the relationship between nanostructure and functional properties.

FY 2014 HIGHLIGHTS

During the past year, our research has refined the synthesis and characterization of nanoporous silica membranes, fabricated via evaporation-induced self-assembly (EISA) with Pluronic ethylene oxide/propylene oxide/ethylene oxide (PEO/PPO/PEO) triblock polymer templates, demonstrating for the first time truly variable pore size (4.5 to 20 nm) with controlled 3D pore network structure in porous silica films. We have also refined the atomic layer deposition (ALD) process for deposition of conformal vanadium oxide and nanoparticulate PdO and Pt into these silica membranes, and characterized material stability toward coarsening by heat, x-rays, and electron beam. Combining EISA and ALD, we fabricated an initial set of model reactors (Pt nanoparticles within 8 nm silica pores) on TEM transparent silicon nitride membranes (20 nm thick) for characterization of structure and reactivity in the laboratory of Robert Schlögl at the Fritz Haber Institute, Berlin, Germany. Using proton transfer reaction mass spectrometry coupled to a temperature controlled microreactor, we were able to measure catalytic activity in our model reactor architecture, even with a real active area of less than 1 mm², and determined the onset temperature of CO oxidation. On the same sample, we were able to image the Pt

nanoparticle/SiO₂ interface using high resolution TEM, demonstrating the capability of combining reaction measurements with detailed studies of active site morphology before and after catalytic testing. Other work in this year continued our efforts at using ALD modification of silica to create asymmetric biomimetic separation membranes, with the development of a nano-stabilized enzymatic membrane for CO₂ capture with unprecedented flux and selectivity. Finally, we used high resolution TEM to image exfoliated MoS₂ to develop correlations between atomic structure rearrangement and photocatalytic activity of this material during dye-sensitized H₂ evolution.

Supported Metal Nanoparticles: Correlating Catalytic Kinetics, Energetics and Surface Structure

Institution: Washington, University of
Point of Contact: Charles Campbell
Email: campbell@chem.washington.edu
Principal Investigator: Charles Campbell
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014-2016)

PROGRAM SCOPE

Most solid catalysts used for industrial chemical reactions that produce fuels and clean up pollution from the generation and use of fuels consist of transition metal nanoparticles dispersed across the surfaces of oxide and carbon supports. These materials also serve as electrocatalysts and photocatalysts for energy conversions. This experimental research program aims to provide the basic understanding needed to develop better catalyst materials for these applications. Well-defined model catalysts consisting of metal nanoparticles supported on single-crystal oxide and carbon surfaces are structurally characterized using surface spectroscopies, and the energies of the metal atoms in these particles, the metal/support adhesion energies (E_{adh}) and the energy of adsorbed intermediates on these particles are measured by calorimetry techniques we developed that are unique in the world. Our prior results proved that these energies depend strongly on the size of the particles and the nature of the support, and that they correlate with their catalytic properties, which correlate with the chemical potential of the metal atoms. This is measured by metal adsorption calorimetry and found to increase strongly with decreasing particle size below 6 nm and, for a given size and metal, with decreasing E_{adh} . We are seeking to develop predictive ability for E_{adh} on many metal/support combinations. This in turn will allow us to predict metal chemical potential versus particle size and support. We also seek to further refine the correlation of this chemical potential with their catalytic properties (chemisorption strengths, elementary-step rates, net catalytic reaction rates and sintering kinetics), and to utilize this to predict better catalyst materials. The energies of adsorbed intermediates are also measured by calorimetry, and their rates are measured by transient kinetics. These energies of metal atoms and adsorbates also serve as benchmarks for improving computational methods.

FY 2014 HIGHLIGHTS

We developed an improved adsorption calorimeter for metal atom adsorption energies on single-crystal surfaces, and applied it to study the energetics of Cu, Ag and/or Au nanoparticles on Fe₃O₄(111) and CeO₂(111). Comparing the resulting adhesion energies for Cu, Ag and Au on CeO₂(111) to our earlier results for many metals on MgO(100) show that E_{adh} for any one metal is larger by ~ 1.7 J/m² on CeO₂(111) than on MgO(100). We also developed the first crude ranking of adhesion energies of different supports to the same metal: MgO(100) \approx TiO₂(110) < Al₂O₃(0001) < CeO₂(111) \leq Fe₃O₄(111).

Metal chemical potential at small size ranks in the reverse. For different metals on the same oxide surface, Each scales with the heat of formation of the oxide of that metal from metal gas plus O₂. Taking advantage of this new understanding of metal / oxide bonding energies and their relationship to sintering rates, we developed a more sinter-resistant Pt catalyst in collaboration with Younan Xia at Georgia Tech. It involves a thin SiO₂ coating which completely surrounds the Pt nanoparticles on the TiO₂ nanofiber support. Xia developed a clever wet-chemical approach to synthesize this that is more applicable in industrial catalysis than alternative approaches that have been used to make similar structures. The average size and number density of supported metal nanoparticles is very important, and these can be estimated by electron microscopies. However, this is very time consuming and often impossible when the particle size is only 1-2 nm. However, electron spectroscopies (XPS and AES) provide quantitative information on both the total amount of adsorbed metal and the particle thickness in this size range. The Hemispherical Cap Model has been widely used to relate their signal intensities to the particles size and number density, but this only works for electron detection normal to the support surface. We derived a new algorithm that extends this model to other detection angles.

Catalytic Upgrading of Key Biorefining Building Blocks to Renewable Chemicals, Polymeric Materials, and Liquid Fuels

Institution: Colorado State University
Point of Contact: Eugene Chen
Email: eugene.chen@colostate.edu
Principal Investigator: Eugene Chen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The central objective of this project is to develop efficient, selective, and cost-effective catalytic systems for upgrading of key biorefining building blocks, derived from catalytic conversion of plant biomass, into value-added chemicals, polymeric materials, and liquid fuels. More specifically, the proposed work seeks to accomplish the following three specific objectives: (a) developing cost-effective and recyclable catalysts for selective upgrading of C₅-C₆ biorefining building blocks into C₁₀-C₁₂ intermediates and for integrating biomass conversion and upgrading processes; (b) transforming the upgraded intermediates into polyols, polyurethanes, polyesters, and diesel fuels; and (c) reforming the upgraded intermediates into high-grade C₁₀-C₁₂ liquid hydrocarbon transportation fuels via selective hydrodeoxygenation catalysis. The hypothesis-driven research described in this proposal employs combined experimental techniques for mechanistic, structural, and synthetic studies of catalysis as well as for polymer and nanoscale science. Building upon a key discovery that 5-hydroxymethylfurfural (HMF), an established biorefining building block or biomass platform chemical, can be selectively and quantitatively upgraded into the C₁₂ DHMF (5,5'-di(hydroxymethyl)furoin) in a catalytic and 100% atom-economical fashion, the research proposed for the current grant period will focus on the next-phase of the project: selective upgrading of HMF and two other related C₅ and C₆ biorefining building blocks into higher-energy-density C₁₀ and C₁₂ furoin intermediates and subsequent catalytic reforming of such intermediates into value-added chemicals, polymeric materials, and liquid fuels. The research described in this renewal proposal addresses one of the DOE-BES's priority research directions in Catalysis for Energy, particularly in terms of exploring new catalytic pathways for lignocellulosic biomass conversion and upgrading into chemicals and fuels.

FY 2014 HIGHLIGHTS

We have developed a highly effective new strategy for upgrading biomass furaldehydes to liquid fuels. This strategy consists of organocatalytic self-condensation (umpolung) of biomass furaldehydes into C₁₀–C₁₂ furoin intermediates, followed by hydrogenation, etherification or esterification into oxygenated biodiesel, or hydrodeoxygenation by metal-acid tandem catalysis into premium alkane jet fuels. We have developed an integrated catalytic process for conversion and upgrading of biomass feedstocks into 5,5'-dihydroxymethyl furoin (DHMF), through self-coupling of 5-hydroxymethylfurfural (HMF) via organocatalysis, and subsequently into n-C₁₂H₂₆ alkane fuel via metal-acid tandem catalysis. We have uncovered the role of N-heterocyclic carbenes in glucose conversion into HMF by Cr catalysts in ionic liquids, and introduced organocatalysis into biorefining for biomass conversion and upgrading.

Dedicated Beamline Facilities for Catalytic Research: Synchrotron Catalysis Consortium (SCC)

Institution: Columbia University
Point of Contact: Jingguang Chen
Email: jgchen@columbia.edu
Principal Investigator: Jingguang Chen
Sr. Investigator(s): Anatoly Frenkel; Yeshiva University
Jose Rodriguez; Brookhaven National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$369,451 (2014)

PROGRAM SCOPE

Synchrotron spectroscopies offer unique advantages over conventional techniques, including higher detection sensitivity and molecular specificity, faster detection rate, and more in-depth information regarding the structural, electronic and catalytic properties under in-situ reaction conditions. Despite these advantages, synchrotron techniques are often underutilized or unexplored by the catalysis community due to various perceived and real barriers, which will be addressed in the current proposal. Since its establishment in 2005, the Synchrotron Catalysis Consortium (SCC) has coordinated significant efforts to promote the utilization of cutting-edge catalytic research under in-situ conditions. These tasks have been performed by a consortium consisting of PIs and co-PIs from academic, national, and industrial laboratories. The beamlines and facilities are located in the National Synchrotron Light Source at Brookhaven National Laboratory. The PIs and co-PIs have extensive experience in the areas of catalysis, electrocatalysis and synchrotron techniques. The combined expertise of the team members will continue to create the synergy that is necessary to ensure the success of the dedicated beamline facilities for catalytic research.

FY 2014 HIGHLIGHTS

In 2014 we continued to develop integrated characterization tools that are appropriate for carrying out detailed in-situ studies on structure and dynamics of catalysts using synchrotron techniques. We further develop existing experimental methods that have not yet been extensively tested in the limit of real catalytic conditions, on small size particles and with fast acquisition times. We also participated in the transition of the catalysis program from NSLS to NSLS-II. This transition path also includes an intermediate stage by setting up catalysis operations at a dedicated XAS beamline at the SSRL. The SCC team are addressing the following key issues to assist the catalysis community during the transition: (1) coordinating with SSRL by providing personnel, in-situ reactors, and any necessary hardware/software

to accommodate SCC catalysis users during the transition period, (2) creating experimental database, sample preparation protocols, and data analysis methodologies for catalysis research in the new NSLS II beamlines, and (3) planning in-situ measurements of chemical, spatial and temporal properties of working catalysts using the state-of-the-art NSLS II characterization techniques.

Structure-Property Relationship in Metal Carbides and Bimetallic Alloys

Institution: Columbia University
Point of Contact: Jingguang Chen
Email: jgchen@columbia.edu
Principal Investigator: Jingguang Chen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

The electronic and catalytic properties of transition metals can be modified by incorporating carbon atoms to form carbides or by alloying with another metal to produce bimetallic alloys. The metal carbides and bimetallic alloys often demonstrate properties that are distinctively different from those of the pure parent metals. The primary goal of the current project is to use selected carbides and bimetallic alloys as model systems to unravel the relationship between the electronic/geometric structures and the chemical/catalytic properties to assist the rational design of catalytic materials. Furthermore, it is becoming apparent of the critical needs to identify alternative catalysts that can either replace Platinum (Pt) or substantially reduce the amount of Pt in many catalytic and electrocatalytic applications. The utilization of metal carbides and bimetallic alloys allows us to explore the possibilities of using these materials to replace or reduce the amount of Pt in catalysis and electrocatalysis.

FY 2014 HIGHLIGHTS

In 2014 we have focused on the utilization of carbide and bimetallic catalysts for the hydrogen evolution reaction (HER) from water electrolysis in two areas: (1) Utilization of monolayer precious metal over carbides in acid electrolyte. Using a combination of density functional theory calculations and experimental measurements we identified a correlation between hydrogen binding energy and HER activity for a wide range of metal-modified carbides with substantial reduction of precious metal loadings. (2) Discovery of non-precious bimetallic catalysts in alkaline environment. The alkaline environment enabled us to design non-precious bimetallic systems for water electrolysis. We have identified several bimetallic catalysts with HER activity similar to Pt, using a combined approach of theoretical and experimental studies on single crystal surfaces, electrochemical evaluation of polycrystalline thin films, and synthesis and test of porous catalysts relevant for device applications.

Chemical Imaging of Single-Particle Photo(electro)catalysis

Institution: Cornell University
Point of Contact: Peng Chen
Email: pc252@cornell.edu
Principal Investigator: Peng Chen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 6 Graduate(s), 1 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

The long-term goal of this program is to understand the fundamental principles governing the catalytic, photocatalytic, and photoelectrocatalytic properties of nanoscale catalysts, so as to acquire the knowledge and ability to engineer and control them to achieve desired catalytic properties. To attain this long-term goal, the program has included two major projects studying nanoscale metal and semiconductor catalysts. In one project, we aim to study the chemical catalysis on single metal nanoparticles of various morphologies and probe the catalytic activity and dynamics in a spatiotemporally resolved manner within a single particle. In the other second project, we aim to understand the correlation between surface reactivities of photogenerated holes and/or electrons in a spatially resolved manner on single semiconductor nanostructures under solar water oxidation conditions, as well as the correlation among each nanostructure's hole/electron surface reactivities, photocurrent responses, and structure/morphology. Both projects use super-resolution single-molecule reaction imaging of single particles, which our group has pioneered. The knowledge obtained will help understand the fundamental principles governing the catalytic properties of nanoscale catalysts, contributing to the efforts in meeting society's energy challenge.

FY 2014 HIGHLIGHTS

In FY 2014, we have successfully used super-resolution single-molecule reaction imaging to reveal hidden surface reaction intermediates in single-nanoparticle catalysis (Journal of Physical Chemistry C, 2014, 118, 26902–26911). Detecting and characterizing reaction intermediates is important for elucidating reaction mechanisms, yet challenging because of the low populations of intermediates, especially in heterogeneous catalysis. We studied two complementary types of Au nanocatalysts -- mesoporous-silica-coated Au nanorods and bare pseudospherical Au nanoparticles -- in catalyzing the oxidative deacetylation of amplex red, a synthetically relevant and increasingly important probe reaction. We have revealed a kinetic intermediate, down to the subparticle level. We formulated a quantitative reaction mechanism, which further allowed for the evaluation of the large reactivity inhomogeneity among the individual nanocatalysts. We have also used super-resolution single-molecule reaction imaging, combined with photoelectrochemical measurements of single semiconductor TiO₂ nanorods, to reveal the correlation among surface hole and electron reactivity and local photon-to-water oxidation conversion efficiency (manuscript in preparation). Semiconductor nanostructures are preferred photoelectrode materials for photoelectrochemical water splitting, a potentially economical and sustainable route toward solar energy conversion. At the photoanode, oxygen evolution catalysts (OECs) are generally needed to increase performance. Yet it is unclear what types of surface sites to deposit OEC to achieve optimal performance. We find that surprisingly on TiO₂ nanorods, the reactive sites for water oxidation are also the sites for recombination. This knowledge enables us to deposit site-selectively an OEC to reveal the optimal sites for enhancement in photocurrent and reduction in onset potential, leading to a strategy to rationally engineer photoelectrodes with a minimal amount of catalyst.

Understanding Nitrogen Fixation

Institution: Princeton University
Point of Contact: Paul Chirik
Email: pchirik@princeton.edu
Principal Investigator: Paul Chirik
Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

During the funding period, we have intensively investigated the feasibility of hydrogen atom transfer (HAT) as a means to make new N-H bonds in the coordination sphere of group 4 metallocene complexes. This thrust is motivated by our experience with this class of compounds as well as their rich N₂ functionalization and cleavage chemistry. Our overall goal is to establish design principles which allow for the fixation of N₂ to NH₃ using H₂ as the source of both protons and electrons. In order to develop a catalytically competent system, an understanding of the underlying thermodynamics of HAT to bound nitrogen-containing fragments is key. Towards this end, we synthesized a number of model nitrogen-containing titanium and zirconium metallocene compounds and studied the thermochemistry of HAT as a function of ligand, metal, and hydrogen-atom donor. Initially, we targeted substituted bis(cyclopentadienyl) -titanium and -zirconium amide (NH₂) complexes. In any hypothetical sequence linking N₂ and H₂ to NH₃ via hydrogen atom transfer, the final intermediate is expected to be a metal amide species. Though many metal amides have been reported in the literature, they are known to be unreactive towards H₂ and we were thus particularly interested in the thermodynamics governing the formation of this final N-H bond. By analyzing the pK_a and reduction potentials of a series of group 4 metal amides, we were able to determine the N-H bond dissociation free energies (BDFE) of a variety of complexes and correlate this data to the ligand environment and metal identity. Data for N-H BDFEs in the coordination sphere of a metal is sparse yet essential for designing catalytic systems based on the HAT design principle. With this data in hand, we turned to the investigation of metal co-catalysts capable of catalytically cleaving H₂ and supplying hydrogen-atom equivalents to the nitrogen fragment and demonstrated NH₃ synthesis.

FY 2014 HIGHLIGHTS

Several important milestones were reached during the past year of DOE support. Most notably we have demonstrated the potential of hydrogen atom transfer in the synthesis of ammonia from its elements. Such research is critical if this important molecule is to be synthesized from carbon-neutral and renewable hydrogen. This approach is a new strategy for breaking strong metal-ligand bonds and opens new opportunities for catalysis as a key challenge in product release has been overcome. Other highlights include synthesis of organic molecules using N₂ and CO as building blocks, the diatomic molecules with the two strongest bonds in chemistry.

Bimetallic Catalysts for Heterocycle Transformations: Energy Efficient Routes to Monomers and Chemical Feedstocks

Institution: Cornell University
Point of Contact: Geoffrey Coates
Email: GC39@CORNELL.EDU
Principal Investigator: Geoffrey Coates
Sr. Investigator(s): Anne LaPointe; Cornell University
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$380,000 (2014-2016)

PROGRAM SCOPE

The goal of this research proposal is the development of new catalysts for carbonylation and rearrangements of heterocycles. The project focuses on two specific aims: 1) the development of the next generation of catalysts for enantioselective heterocycle carbonylation, and 2) the application of bimetallic catalysis in non-carbonylative reactions. The proposed work will focus on the development of new bimetallic catalysts for a broader range of reactions, including non-carbonylative transformations. The first specific aim is the development of enantiopure catalysts that can carbonylate epoxides and related heterocycles with control of absolute configuration of stereochemistry. Building on important discoveries during the last funding period, we will continue the development of catalysts capable of kinetic resolution of both *cis*- and *trans*-disubstituted epoxides. The resulting stereodefined molecules will be particularly interesting monomers for the synthesis of semi-crystalline aliphatic polyesters. A variety of methods—including *in situ* kinetic measurements, steric and electronic ligand variation, and DFT calculations—will be used to gain mechanistic insight and guide catalyst development. The second specific aim is the exploitation of bimetallic catalysts in non-carbonylative reactions. One main goal in this endeavor is to develop selective internal epoxide rearrangement to carbonyl compounds. The energy-efficient synthesis of environmentally benign materials from renewable resources is becoming increasingly important as fossil fuels become more limited and increasingly expensive. Carbonylation chemistry is an attractive synthetic route to monomers for biodegradable and biocompatible polymers and fine chemicals using biorenewable sources. Finally, we believe that the mechanistic information regarding bimetallic substrate activation and functionalization will have important broader impacts in the field of catalysis.

FY 2014 HIGHLIGHTS

A new enantiopure Lewis acid/carbonyl cobaltate carbonylation catalyst was discovered and applied to the regiodivergent carbonylation of racemic *cis*-disubstituted epoxides. The products were enantioenriched *trans*- β -lactones showing 90% ee or better, which were further elaborated into anti-aldol products in a one-pot sequence. The effectiveness of this new catalyst in inducing enantioenrichment was attributed to the *cis*- α coordination geometry of the ligand around the Lewis acidic metal-ion. Moreover, the reaction of *cis*-2-heptene oxide with the enantiopure catalyst was studied in detail to confirm that the epoxide underwent a regiodivergent carbonylation reaction. Lastly, regiodivergent carbonylation was applied to the synthesis of an important fragment of Globomycin. Future work will focus on the further development of enantioselective carbonylation catalysts as well as new reactions involving catalysts bearing enantiopure ligands.

Hydrocarbon, Oxidation, Dehydrogenation and Coupling over Model Metal Oxide Surfaces

Institution: Virginia Polytechnic Inst. and State U.
Point of Contact: David Cox
Email: dfcox@vt.edu
Principal Investigator: David Cox
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

This project is directed at understanding structure/function relationships in transition metal oxide surface chemistry, with an emphasis on chemistry related to the dehydrogenation and oxidation of small alkanes. Our work has focused on the surface chemistry of oxides of chromium, manganese and iron, with a current focused on manganese oxides. These neighboring fourth row transition metals allow access to oxides with metal atoms in 2+ and 3+ oxidation states (among others) with d electronic configurations ranging from d³ for Cr³⁺ to d⁶ for Fe²⁺. Because Cr₂O₃ and Fe₂O₃ have the same crystalline structural, it is possible to examine surface chemistry between these compounds where any differences in selectivity are strictly related to differences in d electronic configuration and not geometric (atomic) structure. These oxides and their combinations are members of a class of reducible oxide materials important for a variety of applications in catalysis because of the ability of surface cation sites to cycle between different oxidation states (primarily 3+ and 2+). Chemistry on model (single crystal) oxide surfaces is being investigated using the tools of UHV surface science for insight into the surface properties that control selectivity in oxidation, dehydrogenation, and coupling (C-C bond formation) reaction pathways of small hydrocarbons over iron oxides. Temperature programmed desorption (TPD) is being used to investigate the reaction pathways of hydrocarbon oxygenates (alcohols, carboxylic acids, etc.) and hydrocarbon halides (iodides, chlorides, etc.) Dissociative adsorption of these molecules provides access to oxygenated surface intermediates and hydrocarbon fragments which can be used to examine the site requirements for selective and non-selective hydrocarbon oxidation, dehydrogenation, coupling, and oxygen insertion reactions. Synchrotron-based photoemission and NEXAFS measurements are planned to characterize the surface intermediates.

FY 2014 HIGHLIGHTS

The preparation and characterization of different manganese oxides on MnO(100) has been investigated spectroscopically and with TPD of a variety of probe molecules. Mixed valence Mn₃O₄ is readily prepared by oxidation, but accessing Mn₂O₃ is difficult in vacuum via high temperature oxidation. Na incorporation during high temperature oxidation has also been found to stabilize the Mn in a 3+ oxidation state through the formation of NaMnO₂ surface layers. Fundamentals of the interaction of Na with MnO(100) in the absence of an oxidizing environment have also been examined. For low Na exposures, an irreversibly adsorbed monolayer of oxide-like Na is formed. Heating at temperatures above 450 K drives the Na subsurface, and heating to 1000 K causes a loss of Na in the surface region due to diffusion into the bulk MnO.

Moving to Sustainable Metals: Multifunctional Ligands in Catalytic, Outer Sphere C-H, N-H and O-H Activation

Institution: Yale University
Point of Contact: Robert Crabtree
Email: robert.crabtree@yale.edu
Principal Investigator: Robert Crabtree
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Catalysts for conversion of glycerol to lactic acid were found, a topic which proved acceptable to Nature Comm. Catalyst deactivation was of great interest, providing a number of metal clusters stabilized by NHCs rather than the conventional carbonyls. This was published by Angew Chem. A number of our catalysts proved useful for the Yale Solar team, who found that electrochemical activation gave the best results in water oxidation. A series of hydroxamate ligands proved to give highly unusual distorted structures with our Cp*Ir system; we hope these will prove active in cheap metal catalysis. Loss of Cp* was an unexpected activation pathway in a series of transfer hydrogenation catalysts. Two reviews on different aspects of catalyst deactivation were published in Chem Rev and J Organometal Chem. A heterogeneous Co-phosphine catalyst proved useful in a number of catalytic conversions although we are very puzzled how it works. Finally, a borohydride catalyzed hydrosilylation was discovered in applying a control reaction to a supposedly Ni-catalyzed reaction - in fact the Ni is not needed.

FY 2014 HIGHLIGHTS

The glycerol to lactic acid conversion is our top result this year; the energy relevance is that glycerol is a biodiesel byproduct and lactic acid is useful in numerous commercial applications.

Testing the Predictive Power of Theory for Determining the Structure and Activity of Nanoparticle Electrocatalysts

Institution: Texas-Austin, University of
Point of Contact: Richard Crooks
Email: crooks@cm.utexas.edu
Principal Investigator: Richard Crooks
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

The objective of this research is to strengthen the correlation of experiment and theory as it relates to catalysis applications. Measurements of structure and catalytic activity of nanoparticles are related to theoretical calculations. This is done using dendrimer-encapsulated nanoparticles (DENS) as model electrocatalysts. Their small size of ~55-300 atoms, which corresponds to ~1-2 nm, allows for direct comparison to density functional theory (DFT) calculations performed on nanoparticles of the same number of atoms. This is an interesting size range because there are often large deviations from bulk behavior. With DENS, a small change in the number of atoms produces changes in the electrocatalysis results. By combining experiment and theory we not only validate theoretical models, we also gain a much deeper understanding of the structure/function relationship of DENS. To make theoretical activity predictions, a simple thermodynamic parameter is calculated and this is used as a representation of the overall reaction. This is often the binding energy of an adsorbate. Our research focus is on allowing theory to lead experiments, which will make it possible for calculations to predict the composition and structure of new and more active catalysts. For example, new catalyst candidates for the oxygen reduction reaction (ORR), hydrogen evolution reaction (HER), and CO oxidation were predicted during the past year. This was done by varying the composition of the DENS in an alloy-core@shell configuration. This catalyst architecture has many advantages. The noble shell enhances the durability of nanoparticles for catalysis and the alloy-core composition allows for fine tuning of the catalytic

properties. One such predicted case has been realized experimentally, and has therefore validated this approach for designing new catalytic materials.

FY 2014 HIGHLIGHTS

Catalytic materials containing an atomically thin Pt surface layer are a promising alternative to pure Pt nanoparticle catalysts for the oxygen reduction reaction (ORR). Pt-shelled catalysts can be stable, have significantly less Pt loading than commercial alternatives, and can exhibit higher activities. Recent progress has also been made using near-surface alloys to tune the activity of the catalytic surface. One such promising geometry is a monolayer shell covering a random alloy core of variable composition. These alloy-core@shell nanoparticles have both the robustness of core@shell structures and the tunability of random alloy particles. In a recent study, we predicted ORR activity trends of 2 nm alloy-core@Pt-shell nanoparticles using density functional theory (DFT) calculations with oxygen binding as the reactivity descriptor. The combination of Au and Pd in the nanoparticle core was found to be particularly interesting because variations of the core composition between pure Au and pure Pd are calculated to shift the oxygen binding on the Pt shell to values both weaker and stronger than bulk Pt. Our predicted trends in ORR activity, as well as the optimal core composition, provided a testable model for experiments. Accordingly, we synthesized and characterized dendrimer-encapsulated nanoparticles having the general structure AuPd@Pt, and then measured the electrochemical ORR reaction rates. The experimental findings were in nearly exact agreement with theoretical predictions over the entire range of core compositions. As predicted by theory, the composition Au_{0.28}Pd_{0.72}@Pt was found to have a higher activity for the ORR than even pure Pt. The ability to predict systematic tuning of catalyst performance and then test these predictions using fairly simple synthetic methods is a significant advance forward in the field of catalysis.

Modeling of Late Transition Metal Catalysts for Energy Applications

Institution: North Texas, University of
Point of Contact: Thomas Cundari
Email: tomc@unt.edu
Principal Investigator: Thomas Cundari
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The major goals of DOE-BES supported research in the Cundari Group are to study the structure and reactivity of novel and emerging ligand systems in catalysis; to model novel catalysts for olefin hydroarylation; to identify mechanisms of group transfer by late transition metal complexes as a route to more efficient use of hydrocarbon feedstocks; and, to integrate modern computational chemistry research with the work of leading experimental groups and fellow DOE-BES contractors to better understand mechanisms and intermediates of transition metal catalysis pertinent to the DOE research mission.

FY 2014 HIGHLIGHTS

The most exciting research highlight of the FY 2014 has been the elucidation of the mechanism of action of promising catalysts for the direct production of styrene from benzene and ethylene. Most

ethylbenzene – which is produced on an enormous per annum scale in the U.S. – is then oxidized to styrene. A process for the direct production of styrene that could circumvent the ethylbenzene intermediate would be a major practical and fundamental breakthrough in catalysis. Initial work on related hydroarylation catalysts were carried out by two former Cundari Group members - Mr. (now Dr.) Bruce Prince and Mr. (now Dr.) Manny Gonzalez - for first-generation Pt(II) catalysts. We have sought to leverage these advances in the study of improved Rh(I) catalysts. The computational studies in our lab are being carried out in conjunction with long-term collaborator and fellow DOE-BES grantee, Prof. T. Brent Gunnoe at U. Virginia.

Sub Nanometer Sized Clusters for Heterogeneous Catalysis

Institution: New Mexico, University of
Point of Contact: Abhaya Datye
Email: datye@unm.edu
Principal Investigator: Abhaya Datye
Sr. Investigator(s): Yong Wang; Washington State University
Students: 2 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$550,000 (2014-2016)

PROGRAM SCOPE

The focus of this project is the synthesis, characterization and reactivity of transition metal moieties ranging from single atoms to clusters of about 1 nm in diameter that are present on high surface area supports. A major barrier in the utilization of sub-nm clusters is that they are subject to Ostwald ripening, leading to growth in size to form nanoparticles. Previous work suggests that trapping single atoms on the support could help to slow the rates of ripening. Transition metals that are bound to the support through a covalent bond (for example M-O-S, where S is the support) would be expected to be more stable than zero-valent transition metal atoms. Hence, one of the goals of this project is the creation of suitable anchoring sites on high surface area catalyst supports. Conventional (non-reducible) oxide supports provide only limited number of sites to anchor ionic species. Reducible oxides provide many more sites for anchoring due to the presence of defects, such as vacancies. But reducible oxides are often not available in high surface area form, and they may not be as robust (can react to form carbonates, for example, or sinter easily) compared to the commonly-used high surface area supports such as silica, alumina, or carbon. Increasing atomic trapping sites on conventional catalyst supports is therefore important for improving the stability of sub-nm metal clusters on a supported catalyst. Another goal of this project is to expand the applicability of single atom catalysts to a broader class of catalyzed reactions. Transition metals in ionic form are perfectly situated for further manipulation of their catalytic activity by use of ligands, as in homogeneous catalysis. Understanding the principles that help in the design of robust single atom catalysts is one of the research challenges that is addressed in this project.

FY 2014 HIGHLIGHTS

Low temperature CO oxidation performance is important for meeting DOE goals for more efficient combustion engines. Metallic Pd is poisoned by CO at low temperatures. We have identified a novel pathway for CO oxidation on atomically dispersed ionic Pd sites which are present even on industrially-relevant gamma alumina. Aberration corrected STEM confirms the presence of isolated Pd species on alumina supports. The presence of La on the alumina, which is added to improve the hydrothermal stability of the alumina, results in enhanced stability of the ionic Pd species. Our proposed reaction

mechanism involves oxygen coming from the lattice, as shown by DFT calculations. The ionic Pd bound to alumina activates CO which then picks up a lattice oxygen. The vacancy site then adsorbs dioxygen, a second CO picks up the extra O, and the cycle repeats itself. Atomically dispersed Pd species show a positive order of reaction in CO, very different from that on metallic Pd. In a second project, we investigated the manipulation of Fe catalysts by the addition of Pd. A series of Pd/Fe₂O₃ catalysts were synthesized, characterized, and evaluated for the hydrodeoxygenation (HDO) of m-cresol. It was found that the addition of Pd promotes the catalytic activity of Fe while the product distributions resemble those of monometallic Fe catalysts, showing high selectivity towards the production of toluene (C-O cleavage without saturation of aromatic ring and C-C cleavage). A possible mechanism, including Pd assisted H₂ dissociation and Pd facilitated stabilization of metallic Fe surface as well as Pd enhanced product desorption, was proposed to be responsible for the high activity and HDO selectivity in Pd-Fe catalysts. The synergistic catalysis derived from the Pd-Fe interaction proved to be applicable to other precious metal promoted Fe catalysts, providing a promising strategy for future design of highly active and selective HDO catalysts using earth abundant Fe.

EARLY CAREER: Natural Catalysts for Molten Cellulose Pyrolysis to Targeted Bio-Oils

Institution: Minnesota, University of
Point of Contact: Paul Dauenhauer
Email: hauer@umn.edu
Principal Investigator: Paul Dauenhauer
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$320,000 (2014-2015)

PROGRAM SCOPE

Lignocellulosic biomass heated above 400 degrees Celsius thermally degrades to a short-lived liquid mixture which can be upgraded to liquid transportation fuels. In this work, we understand the fundamental reaction chemistry of degrading biopolymers and evaluate the role of inorganic catalysts on directing the pyrolysis chemistry to improved fuel precursors. The degradation of large biopolymers occurs via two sets of chemistries that we have previously described: (a) primary reactions break down biopolymers to volatile compounds, which can evaporate, while (b) secondary reactions are the conversion of volatile compounds within the biopolymer melt prior to evaporation. Inorganic catalytic materials are primarily capable of interacting with mobile chemical species within molten biopolymers, which means that they have the potential to catalyze desirable secondary pyrolysis reactions. Targeted secondary catalysis reactions include catalytic reduction and/or defunctionalization to produce chemical targets with unreactive functional groups.

FY 2014 HIGHLIGHTS

In 2014, we discovered the first catalytic method for tuning the pyrolysis of lignocellulosic biomass to desirable fuel precursors prior to vapor product formation. Inorganic catalytic materials are primarily capable of interacting with mobile chemical species within molten biopolymers, which means that they have the potential to catalyze desirable secondary pyrolysis reactions. With this insight, we selected furan decarbonylation as the target chemistry to evaluate the potential for selective secondary catalysis within biopolymer melts. Results indicated that supported metals including Pd and Pt on carbon, silica or alumina supports can dramatically alter the distribution of pyrolysis products. Evaluation of a range of experimental conditions discovered that up to 90% of furan carbonyl groups could be eliminated via

catalytic impregnation of Pd/C catalysts. This fundamental insight will be valuable for developing a catalytic technology to produce stable pyrolysis oils which can serve as a replacement for petroleum.

Structure and Function of Supported Base Catalysts

Institution: Virginia, University of
Point of Contact: Robert Davis
Email: rjd4f@virginia.edu
Principal Investigator: Robert Davis
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

Solid bases are heterogeneous catalysts that have not been broadly exploited compared to solid acids. Thus, much of our effort over recent years has been focused on understanding how a variety of solid bases, including metal oxides, mixed metal oxides and zeolites, function as catalysts in chemical transformations. Our recent work with transesterification and Guerbet reactions, however, suggests that materials with surfaces exposing appropriately co-located acid and base sites are superior catalysts compared to materials traditionally considered as solid bases. In this project, the concept of acid-base cooperativity is being evaluated on catalysts for C-C bond forming reactions such as alcohol coupling and aldol condensation. Given the increasing production of ethanol in the US and elsewhere using non-traditional sources of carbon, a better understanding of the catalytic transformations of ethanol is needed. The specific objectives of this project are to synthesize acid-base bifunctional solid catalysts, to characterize their surfaces by adsorption microcalorimetry and IR spectroscopy of adsorbed bases, acids and amphoteric molecules, and to evaluate the reactivity of the bifunctional catalysts in steady-state and transient ethanol coupling reactions as well as model aldol condensation and alcohol dehydrogenation reactions.

FY 2014 HIGHLIGHTS

We have made substantial progress with understanding the acid-base nature of hydroxyapatite relative to magnesia and zirconia, and how that nature influences activity in the Guerbet coupling reaction. In particular, DRIFTS and adsorption microcalorimetry of acid-base probe molecules provided an excellent ranking of surface affinity for various types of adsorbates. We have also utilized isotopic transient analysis to evaluate the surface coverage of intermediates leading to butanol during the steady state reaction over magnesia and hydroxyapatite, as well as estimate the intrinsic turnover frequency of the catalytic cycle.

Towards Rational Nanoscale Control of Catalysis: A Fundamental Study of Zeolite Structure and Nucleation

Institution: Rice University, William Marsh
Point of Contact: Michael Deem
Email: mwdeem@rice.edu
Principal Investigator: Michael Deem
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Our goal is to employ the database of zeolite-like materials, and to develop and employ OSDA prediction and design methodology. We work with our theoretical colleagues to screen the database for interesting and useful physiochemical functions. We have worked with several academic groups to help them use this database. At present, roughly a dozen academic groups are using this database. This database is now being screened by colleagues at Georgia Tech (David Scholl), Berkeley (Berend Smit), Northwestern (Randy Snurr), Princeton, BASF, Chevron, and others. We have developed a computational procedure to predict chemically synthesizable organic structure directing agents for zeolites [2]. A major tool to influence zeolite nucleation and growth is the use of organic structure directing agents (OSDAs). These OSDAs must be soluble in the synthesis medium. They must also be stable under synthesis conditions. The OSDAs are occluded during the zeolite growth process, so they must fit geometrically within the zeolite. The OSDA must additionally interact with the zeolite framework with favorable energetics. We have applied this methodology to develop an OSDA to make HPM, a very interesting chiral zeolite, in collaboration with Mark Davis at Caltech, and the first successful synthesis of a specified molecular sieve through the use of an OSDA that is predicted from a recently developed computational method that constructs chemically synthesizable OSDAs. The general methodology demonstrated here to create STW may lead to new, simpler OSDAs for existing frameworks as well as a method to predict OSDAs for desired, theoretical frameworks. Two additional zeolites have been made by this approach.

FY 2014 HIGHLIGHTS

- 1) Synthesis of HPM, a very interesting chiral zeolite, in collaboration with Mark Davis at Caltech [5], and the first successful synthesis of a specified molecular sieve through the use of an OSDA that is predicted from a recently developed computational method that constructs chemically synthesizable OSDAs.
- 2) Explanation of long-standing conundrum of why there are so few 7-membered rings in known zeolites: the constraint of proximity to the low-density edge of predicted structures is what leads to a low probability of 7-membered rings.
- 3) Analysis of the ADOR transformation, showing that the preferential location of Ge in the double four-membered rings (D4R) of zeolite can be explained with periodic density functional theory calculations.
- 4) We identify, through a large-scale, multi-step computational screening process, promising zeolite structures for two energy-related applications: (i) purification of ethanol beyond the azeotropic limit in a single separation step from fermentation broths and (ii) two orders of magnitude better adsorption characteristics than current technology for linear and slightly branched alkanes with 18-30 carbon atoms encountered in petroleum refining.

William Schneider; Notre Dame, University of
Jeffrey Greeley; Purdue University
Students: 2 Postdoctoral Fellow(s), 12 Graduate(s), 0 Undergraduate(s)
Funding: \$700,000 (2014)

PROGRAM SCOPE

Our overall goal is the development of a new paradigm for catalyst discovery and optimization through Discovery Informatics, a model-based approach to catalyst design. To reach this objective, we are developing experimental and computational tools to create an information-rich database from which chemical descriptors and appropriate models can be identified. Our vehicle for heterogeneous catalysis is the water-gas shift (WGS) reaction for which we have kinetic and chemical characterization data on over 800 supported metal catalysts. Analysis of this database identifies WGS as a dual functional reaction and has focused our attention on the metal-support interface, which we are now modeling with density functional theory to understand and predict the chemistry the active catalytic sites it generates. For homogeneous catalysis, our test bed is single site olefin polymerization. Here we have developed software to facilitate the building of population balance kinetic models that allow inclusion of a variety of elementary kinetic steps to predict molecular weight distribution (MWD) as well as monomer loss, end-group identity resulting from chain termination, and number of active sites. Analysis of kinetic parameters obtained from fitting a rich set of data for families of catalysts has allowed us to identify kinetic mechanisms and steric and electronic descriptors that predict catalytic activity within families.

FY 2014 HIGHLIGHTS

We have correlated the increase in WGS rate and strong effects of Fe on both the activation energy and the CO order of reaction for Au on Fe-doped TiO₂ to the influence of Fe on the CO bonding to metal sites. Removal of Co from PtCo/MWCNT shows, on the other hand, that oxidized Co is the source of promotion and does so by enhancing dissociation of water. The unusually high rate for Pt or Au supported on Mo₂C is accounted for by promotion CO activation by the metal to enhance reaction with OH provided by the carbide support. A DFT study of WGS on Pd and Pt (111) surfaces confirms the importance of the carboxyl pathway and shows that: i) the metal alone cannot account for experimental results on supported metals, and ii) that coverage effects of the CO binding energy are important and can be accounted for with a new cluster expansion approach. Calculations on metal nanowire models of Pt on Al₂O₃ and Au on MgO confirm the carboxyl kinetic model and show enhanced H₂O activation at the metal/oxide interface and CO bonded to interfacial metallic sites. Applications to homogeneous

catalysts have moved to non-Cp coordination catalysts for olefin polymerization and oligomerization. We have discovered the importance of a binuclear catalyst complex to account for changes in rate and MWD at sub-stoichiometric activator conditions and correlated effects of the pendant group on several rate constants with corresponding changes in HOMO energy. Observation of a unique structural window as a function of pendant chemistry for oligomer formation, extraction of activation energies from the temperature dependence of the reaction network rate constants, comparison of the kinetic consequences of Ti, Zr, and Hf in a family of catalyst complexes, and co-polymerization of 1-hexene with styrene are currently being vigorously pursued. Kinetic modeling capabilities have been expanded with a new algorithm based on Dynamic Monte Carlo methods.

Control of Reactivity in Nanoporous Metal/Ionic Liquid Composite Catalysts

Institution: Johns Hopkins University
Point of Contact: Jonah Erlebacher
Email: Jonah.Erlebacher@jhu.edu
Principal Investigator: Jonah Erlebacher
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

In this proposal, we have been examining a new concept in nanostructured heterogeneous catalysis design – the ionic liquid (IL)/nanoporous metal (NPM) composite. The idea behind this structure is to tailor the chemical environment within the pores of a metallic electrocatalyst in order to enhance the aggregate composite activity; the mechanisms of enhancement being (a) bias of mass transport of reactants to the surface and products away from it, and (b) corralling of reactants and products to spatially separate them and reduce side reactions. We have made a particular focus on aqueous electrocatalysis under kinetically limited conditions, and in which the catalyst is a nanoporous metal and the biasing environment is an ionic liquid impregnating the pores. Of particular interest will be the electroreduction of gaseous species, primarily oxygen, at nanoporous electrodes separated from an aqueous phase by a thin ionic liquid layer. In typically aqueous electrocatalysis, reactivity is often limited by solubility of the gas in the aqueous (acid or base) phase. By using a hydrophobic ionic liquid with higher gas solubility than the aqueous phase, a diffusive driving force is added to the reaction driving force, biasing the gas to remain near the catalyst surface and increasing activity; activity is further enhanced if the ionic liquid has little solubility for the products. For oxygen reduction in acids, this concept has led to significant improvements in aggregate mass activity. Conversely, creation of new aprotic ionic liquids will be examined with an eye toward creation of reactive intermediates (e.g., peroxide or superoxide) species that can be made under electrochemical conditions that normally lead to hydrogen evolution or water reduction. These are being used for secondary oxidation reactions as they diffuse back into the aqueous phase, but in an orderly manner, without hydrogen evolution or production of other unwanted reduced species.

FY 2014 HIGHLIGHTS

Over the last year a critical technical accomplishment has been the development of a flow cell that allows the study of nanoporous Pt/Ni impregnated with hydrophobic ionic liquid catalysts with controlled amounts of ionic liquid. As a result, we have been able to perform a survey of ionic liquids properties and how they impact composite catalyst behavior for the oxygen reduction reaction. These

properties include oxygen solubility, viscosity, (a)proticity, ionic conductivity, and water solubility. Oxygen solubility turns out to be quite important, helping draw reactants to the catalyst surface. Interestingly, we also find that water solubility very critical. Ionic liquids with low water solubility lead to proton-diffusion limited reaction kinetics, which have never been observed in oxygen reduction studies before. This observation has led to elucidation of a new kinetic regime for reduction reactions, in which there is faster transport of reactants to catalytic surfaces than protons, which kinetically suppresses hydrogen evolution. This general result will now be applied to the reduction of other gaseous species.

EARLY CAREER: Bond-Formation and Catalysis by Base-Metal Unsaturated Isocyanides

Institution: California-San Diego, University of
Point of Contact: Joshua Figueroa
Email: jsfig@ucsd.edu
Principal Investigator: Joshua Figueroa
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This DOE Early Career Research Program Award seeks to develop and understand small-molecule-activation catalysis by base-metal unsaturated isocyanide complexes. The project is focused in two specific areas: 1) the development and mechanistic delineation of carbon dioxide (CO₂) reduction by manganese (Mn) m-terphenyl isocyanide electrocatalysts and 2) discovery of new bond construction and cleavage reactions by low-valent, low-coordinate m-terphenyl isocyanide complexes of cobalt. For specific area #2, CO₂ activation by one- and/or two-electron processes is also a primary goal. The development of catalytic and/or stoichiometric CO₂ activation schemes based on base-metal systems is being pursued as an effort to mitigate costs associated with precious metal mediated catalysis. In order to provide an electronic environment for base metals mimicking that traditionally found in the precious metals, strong-field m-terphenyl isocyanide ligands are employed throughout this work. This ligand class has several other advantages, including: (a) facile steric and electronic modification through synthesis and (b) convenient spectroscopic markers for the characterization of catalysts and intermediates, as well as for measurement of reaction progress. For specific goal #1, the ultimate outcomes of this work are the discovery of inexpensive, well-defined CO₂-electrocatalysts that operate efficiently at low over-potentials and a detailed analysis of their mechanism of catalysis. For specific goal #2, the ultimate outcomes of this work entail the discovery of new transition metal-mediated bond-activation paradigms in homogeneous solution.

FY 2014 HIGHLIGHTS

The most significant accomplishment during fiscal year 2014 was the isolation, detailed characterization and exploration of the reaction chemistry accessible to of the manganese monoradical complex Mn(CO)₃(CNAr^{Dipp2})₂. This species is a key intermediate in Group 7 metal electrocatalytic CO₂ reduction sequences and is the first to be isolated and studied in detail by a complement of spectroscopic and synthetic techniques. This monoradical displays an intriguing reaction chemistry with a diverse host of substrates. For example, reactions between Mn(CO)₃(CNAr^{Dipp2})₂ and nitrosoarenes result in the formation of side-on bound nitoxide radical ligands, which is in direct contrast to the chemistry reported for other, unstable, zero-valent Mn monoradicals. It was also shown that Mn(CO)₃(CNAr^{Dipp2})₂ species is not competent for CO₂ activation, which is a main finding of the work. The interconversion between

$\text{Mn}(\text{CO})_3(\text{CNAr}^{\text{Dipp}2})_2$ and the mono-hydride complex $\text{HMn}(\text{CO})_3(\text{CNAr}^{\text{Dipp}2})_2$ was also explored in detail and it is shown that neither complex is a major contributor to a productive CO_2 reduction sequence. In addition to a delineation of the chemistry accessible to $\text{Mn}(\text{CO})_3(\text{CNAr}^{\text{Dipp}2})_2$, fiscal year 2014 included significant synthetic and spectroscopic efforts leading to an extensive library of electronically diverse *m*-terphenyl isocyanide ligands. As a result of this study, topological and electronic criteria have been established for the construction of isocyanide ligands that present a significant π -acidic ligand field akin to carbon monoxide (CO), but that also promote coordinative unsaturation.

Supported Nanocluster Catalyst Formation in Contact with Solution: Kinetic, Mechanistic and Synthetic Fundamental Studies

Institution: Colorado State University
Point of Contact: Richard Finke
Email: rfinke@lamar.colostate.edu
Principal Investigator: Richard Finke
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$163,000 (2014)

PROGRAM SCOPE

The primary scope of our DOE-funded program is to examine and establish the kinetics and mechanism(s) of the nucleation, growth and agglomerative formation of supported-nanoparticle heterogeneous catalysts. One specific goal is to learn how to transfer the synthetic and mechanistic insights—that have been gained from the modern revolution in nanoparticle synthesis, characterization, and catalysis in solution—to the preparation of the next generation of improved, more selective, more active and longer-lifetime, solid-state supported-nanoparticle heterogeneous catalysts that are the primary type of catalyst used in commercial manufacturing.

FY 2014 HIGHLIGHTS

Five papers and one Ph.D. thesis were published during the 2013-2014 period. Significant among those is a paper “A Four-Step Mechanism for the Formation of Supported-Nanoparticle Heterogeneous Catalysts in Contact with Solution: The Conversion of $\text{Ir}(1,5\text{-COD})\text{Cl}/\gamma\text{-Al}_2\text{O}_3$ to $\text{Ir}(0)_{-170}/\gamma\text{-Al}_2\text{O}_3$ ”. This paper reports a new, unique mechanism for the formation of heterogeneous catalysts and for two basic steps in nanoparticle catalyst sintering—sintering being crucial to catalyst lifetime and, therefore, overall catalyst productivity and commercial value. Also published were two papers supporting a DOE Graduate Fellow and his work in the forefront area of water-oxidation catalysis (WOC), a catalytic reaction central to our secure energy future. That work determines the true catalyst in water-oxidation catalysis beginning with discrete metal-oxide precatalysts called polyoxometates, currently some of the most promising precatalysts in the WOC area. A critical review of the literature of polyoxometalates as water oxidation precatalysts was also written. Finally, a very important paper was written detailing that nucleation of the formation of $\text{Ir}(0)_n$ nanoparticles is, contrary to literature expectations, a simple second-order kinetic process in the concentration of the precursor, $[(1,5\text{-COD})\text{Ir}^I \cdot \text{P}_2\text{W}_{15}\text{Nb}_3\text{O}_{62}]^{8-}$. This is arguably a ground-breaking result, since it teaches that the previously widely used Classical Nucleation Theory, which predicts a nucleus much larger than two (Ir_n , $n \gg 2$), is not correct in at least this case. Given that nucleation is the key initial process underlying phase changes throughout nature, this finding has potentially very broad implications, specifically that very small nuclei, of even 2-3 monomers of the precursor phase, may be sufficient to nucleate the formation of new phases.

Atomically Dispersed Metal Surface Species As Catalysts for Alcohol Conversion, Hydrogen and Chemicals Production

Institution: Tufts University
Point of Contact: Maria Flytzani-Stephanopoulos
Email: mflytzan@tufts.edu
Principal Investigator: Maria Flytzani-Stephanopoulos
Sr. Investigator(s): Charles Sykes; Tufts University
Manos Mavrikakis; Wisconsin-Madison, University of
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$580,000 (2014-2016)

PROGRAM SCOPE

Isolated metal ion-centric sites stabilized on supports by $-O$ ligands were identified first in this project as the active sites for the water-gas shift reaction. This is true for both gold and platinum. Alkali addition is used to stabilize the active $Pt-O(OH)_x$ - or $Au-O(OH)_x$ - species on any support, including zeolites and mesoporous silica. The intrinsic activity is specific to the metal and invariant to the support type or alkali addition. These atom-centric species may catalyze other reactions. We have already demonstrated the $Au-O_x$ centers as catalysts for the methanol steam reforming reactions, and presently investigate ethanol reactions. Metals of interest include Au, Pd, and Cu on supports of tunable basicity, such as $ZnO-ZrO_2$, on which the metals can be dispersed atomically and the yields of desired valuable chemicals and hydrogen be maximized. A second major goal of the project is to develop single atom alloy (SAA) combinations, the first of which (PdCu) we have recently reported to be highly active and selective for the hydrogenation of alkynes. We have shown this both with model catalysts, e.g. Pd atoms deposited in Cu(111) in UHV, and with their nanoparticle SAA analogs, i.e. Pd atoms deposited in Cu nanoparticles and tested at ambient pressure, thus “bridging” the pressure and materials gap between surface science and catalysis. The information obtained from atomic-resolution STM is crucial for understanding and designing new catalysts; while the catalytic information drives the examination of new model catalysts in the UHV systems. Reactions of interest include selective hydrogenation of dienes and selective oxidation of alcohols on PdCu, PtCu, and PdAu. Development of atomic-scale catalysts will fulfill a long-standing DOE goal in catalysis; i.e. the achievement of efficient resource utilization and energy-efficient processes. The systems we investigate greatly reduce the use of expensive platinum group metals and demonstrate maximum atom efficiency.

FY 2014 HIGHLIGHTS

In several papers and review articles published this year, we have generalized our findings of single-site isolated metal ions held by $-O$ ligands on supports as the active sites for the water-gas shift reaction. In addition to the usual “active” oxide supports, “inert” supports as diverse as carbon nanotubes, zeolites, and mesoporous silica were used in order to demonstrate that a similarly structured single-site $M-O(OH)_x$ species is the catalytic site on any support. Inert supports may be used only with alkali ion addition. The alkali ions form a shell around the Pt or Au atoms, binding them through $-O$ ligands, and supplying the regenerable $-OH$ needed for the reaction. The apparent activation energy of the reaction is characteristic of the $M-O(OH)_x$ site, not the type of support; it is also invariant to the presence of the alkali. Hence, we can design such catalysts on Earth-abundant supports, while using only trace amounts of the precious metals. In other work, we reported that atomically dispersed gold in $ZnO-ZrO_2$ surfaces catalyzes with 100% atom efficiency the methanol steam reforming reaction, and the production of

acetone from ethanol at low temperatures. Working with single atom alloys, we have demonstrated that very low concentrations of individual, isolated Pt atoms in a Cu surface catalyze the industrially important selective hydrogenation of butadiene to butenes. Our experiments show that Cu binds butadiene weaker than Pt, but in nanoparticle systems the dissociation of molecular H₂ is often the rate limiting step on Cu. We have used a surface science and microscopy approach to interrogate the atomic geometry of Pt-Cu alloys. We discovered the minimum ensemble of Pt, a single atom, embedded in Cu(111) single crystal surfaces will dissociate H₂. Furthermore, isolated Pt atom geometries, unlike continuous Pt ensembles, are resistant to poisoning and maintain activity after many hydrogenation cycles.

Molecular-Scale Understanding of Selective Oxidative Transformation of Alcohols Promoted by Au and Au-Based Alloys

Institution: Harvard University
Point of Contact: Cynthia Friend
Email: friend@fas.harvard.edu
Principal Investigator: Cynthia Friend
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$183,000 (2014)

PROGRAM SCOPE

The project focuses on detailed mechanistic understanding of reactive processes –both for discovering new processes and for controlling selectivity in known reactions—using gold-based alloys as prototypes. We will focus on several key chemical processes that collectively illustrate a rational basis for the design of new catalytic materials and processes involving functionalization of alcohols and polyols: selective oxidation, amide synthesis, carbonylation, and alkylation. These processes were selected because they all have high value in chemical production and provide a foundation of knowledge for efficiently synthesizing key platform chemicals. Our objectives are (1) to understand and manipulate the key elementary steps in these potentially sustainable catalytic processes via studies with model systems and (2) to visualize and image these materials and reactions in order to provide a molecular picture of key catalytic studies. The proposed research is centrally related to the DOE-BES mission as articulated in several BES reports, including “New Science for a Secure and Sustainable Energy Future” and “Catalysis for Energy”. These reports emphasize the need for fundamental research in energy research, including the need to fabricate, design, characterize, and assemble new structures, including nanoscale alloys for energy-related applications.

FY 2014 HIGHLIGHTS

Significant advances in understanding important organic coupling reactions on oxygen-activated Au have been made in the project over the past year toward the overall objective of increasing reaction selectivity. Key results that advanced understanding of catalytic processes are: (1) development of a paradigm for predicting a hierarchy of binding affinity of important key reactants that includes binding of the primary functional group but also demonstrates the importance of weak (van der Waal’s) interactions between organic groups and the surface; (2) demonstration of the dependence of adsorbate stability on the coverage of adsorbed oxygen on Au—high O coverages destabilize strongly-bound acetate, for example. These principles have been tested in a variety of different reaction systems, including production of alkoxides and ethers via addition of alkyl groups to O on gold, alcohol coupling

reactions to form methyl esters, displacement and removal of strongly-bound poisons, e.g. carboxylates, from the surface, and investigation of the effect of fluorination on binding to the surface and on selective oxidation processes. We have also investigated model Ag/Au alloys and demonstrated that mixed Ag-Au sites exhibit different kinetics for both O recombination and for methanol coupling to methyl formate. This work is a springboard for understanding alloy materials more generally. Most recently, we have been able to image oxygen bound to Au(110) on an atomic scale along with reactive intermediates formed from reaction with the adsorbed O. These studies will provide us with molecular scale insight into how reactive species distribute themselves on the surface in order to assess the potential role of intermolecular interactions on their stability and reactivity. Our work establishes key paradigms for controlling reaction selectivity for complex processes on gold.

Activation of Carbohydrates for Applications in Biofuels and Biofeedstocks

Institution: North Carolina, University of
Point of Contact: Michel Gagne
Email: mgagne@unc.edu
Principal Investigator: Michel Gagne
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal is to develop new methods for the activation of carbohydrate C-O bonds for the synthesis of value added compounds and biofuels. One focus is on the reduction of silane-protected C-O bonds through the catalytic activation of silanes to generate an available hydride equivalent and a Lewis acidic silyl cation, which together provide a means for carbohydrate C-O bond reduction. Expanding this system to include deoxygenation of alcohol containing polymers to generate new polymeric materials is also included. Carbohydrate protecting group compatibility (i.e. acyl protecting groups) for wider application is a second focus. Lastly, the utilization of stoichiometric Lewis acids along with a competent aromatic nucleophile for the generation of C-aryl glycosides is also under investigation.

FY 2014 HIGHLIGHTS

$B(C_6F_5)_3$ -catalyzed hydrosilylative reduction of carbohydrates. We previously reported the complete reduction of glucose and methyl glucoside to a mixture of hexane and hexene isomers. This conversion of biomass was catalyzed by a cationic iridium complex supported by a tridentate POCOP ligand, and diethylsilane (Et_2SiH_2) provided the requisite hydride. More recently, we observed that the hydrosilylative reduction of monosaccharides, oligosaccharides, and even polysaccharides can be catalyzed by a non-metallic commercially available Lewis acid, specifically tris(pentafluorophenyl)borane, $B(C_6F_5)_3$. This potent catalyst allows the reduction to proceed even faster than the iridium-based catalyst, providing shorter reaction times (ca. 1 hour vs. 1 day for the iridium catalyst) and reducing a wider range of biomass-derived substrates including methyl cellulose. This work has now been published in *Angewandte Chemie* (Adduci, L. L.; McLaughlin, M. P.; Bender, T. A.; Becker, J. J.; Gagné, M. R. *Angew. Chem. Int. Ed.* 2014, 53, 1646–1649). To expand the utility of this methodology, we next targeted selective catalysis. We envisioned that cleaving some but not all of the carbon-oxygen bonds of carbohydrates would allow us to generate valuable feedstocks from inexpensive biomass sources by preserving some of the inherent chirality of carbohydrates. Gratifyingly, selective deoxygenation was achieved using bulkier tertiary silanes, namely dimethylethylsilane (Me_2EtSiH) and

triethylsilane (Et_3SiH), in place of the less bulky secondary silane Et_2SiH_2 . This work is currently being prepared for submission to Nature: Chemistry. It will be a high impact publication.

Dispersed Metal Cluster Catalysts by Design: Synthesis, Characterization, Structure and Performance

Institution: California-Davis, University of
Point of Contact: Bruce Gates
Email: bcgates@ucdavis.edu
Principal Investigator: Bruce Gates
Sr. Investigator(s): Ilke Arslan; Pacific Northwest National Laboratory
David Dixon; Alabama-Tuscaloosa, University of
Alexander Katz; California-Berkeley, University of
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

To better understand the class of supported metal cluster catalysts and to lay a foundation for the prediction of properties leading to improved catalysts, we have synthesized metal catalysts with well-defined structures and varied the cluster structures and compositions systematically—including the ligands bonded to the metals. These ligands include supports and bulky organics that are tuned to control both the electron transfer to or from the metal and the accessibility of reactants to influence catalytic properties. We have developed novel syntheses to prepare these well-defined catalysts and applied spectroscopic, microscopic, and computational methods to determine their structures, reactivities, and catalytic properties. The supports as ligands range from nearly flat MgO surfaces to silica to enveloping zeolites, and we use bulky calixarenes to provide controlled coverages of the clusters. We are working to achieve a deep, fundamental understanding of how to synthesize robust supported and ligand-modified metal clusters with controlled catalytic properties, thereby bridging the gap between active site structure and function in unsupported and supported metal catalysts. We are also investigating zeolites as catalysts and supports and investigating their delamination by determining tomographic TEM images. We have also used spectroscopy, scanning transmission TEM, and rates of cyclohexene hydrogenation as a reporter reaction (with Prof. R. Finke) to track the genesis of supported iridium clusters.

FY 2014 HIGHLIGHTS

We synthesized coordinatively unsaturated tetrairidium clusters with CO and phosphine ligands, learning to stabilize them in a decarbonylated state by using bulky calixarene phosphine ligands. Tetrairidium clusters with these ligands bonded to 3 of the 4 Ir atoms were supported on silica, giving stable catalysts for H-D exchange and ethylene hydrogenation. Both vacancies at Ir atoms in the apical position and at Ir atoms in the basal plane of the tetrahedral clusters bond to CO and to hydrogen. However—because of strong electronic effects of the electron-donor phosphines, demonstrated by density functional theory—only the apical vacancy sites bond to ethylene, and they alone catalyze its hydrogenation. This is a new kind of single-site catalyst, and the fine control of catalytic properties makes one think of enzymes. We used computational chemistry to predict the reaction chemistry of these catalysts and a broad family of phosphine-substituted iridium clusters, showing that differences in relative energies are consequences of both electronic and steric effects of the ligands. Phosphines are σ -electron donors that lead to increased carbonyl ligand dissociation energies as more phosphines are substituted. The trend is clear in small clusters but not for tetrairidium. Kinetically, more phosphine

substitution leads to easier dissociation of carbonyls, which usually occurs at bridging positions. Among the best-defined supports for metal cluster catalysts are zeolites, and delaminated zeolites provide high surface areas. To understand the delamination process, we used 3-D imaging in scanning transmission electron microscopy to obtain tomograms on the nanoscale showing that the delamination proceeds through two distinct steps: chemical treatment that leads to a swelled material and a subsequent calcination that leads to curling and peeling off of delaminated zeolite sheets. The results are new in characterizing direct, local morphological changes accompanying delamination.

Single-Site Noble Metal Catalysts on Crystalline Supports: Synthesis, Structure, Characterization, and Performance

Institution: California-Davis, University of
Point of Contact: Bruce Gates
Email: bcgates@ucdavis.edu
Principal Investigator: Bruce Gates
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$185,000 (2014)

PROGRAM SCOPE

The simplest supported metal catalysts, like organometallics in solution, consist of single metal atoms stabilized by ligands, which include the supports. Researchers worldwide are paying increasing attention to these single-site catalysts, but there are a number of issues that are commonly glossed over, including the nature of the bonding of the metals to the supports, the oxidation states of the metals, and the ligands present on the metals. Our goals are to synthesize such catalysts precisely, with an emphasis on metals that are noble—because of their importance in technology—and supports that are crystalline—because their well-defined structures facilitate fundamental understanding of the catalytic species on them. Our characterization methods include IR, NMR, EPR, X-ray absorption spectroscopies, high-resolution STEM, and density functional theory. We developed novel syntheses to prepare these well-defined catalysts, applying spectroscopic, microscopic, and computational methods to determine their structures, reactivities, and catalytic properties. Our supports are zeolites and high-area crystalline MgO. By understanding the roles of the supports and other ligands, we have tuned the reactivities and catalytic properties of supported rhodium, iridium, osmium, and platinum complex catalysts. We believe that the emerging understanding of this class of catalyst is fundamental and deep, providing a firm basis for representation of the structures and reactivities by theory and a foundation for discovery of catalysts with new and useful properties. The data identify metal–support bonds and ligands on the metals; they demonstrate the uniformity of the supported species; they provide insight into the metal oxidation states; they determine reactions of the ligands and reaction intermediates, pointing the way to the design of active and selective catalysts.

FY 2014 HIGHLIGHTS

Our catalysts consist essentially of isolated metal centers on supports made by precise syntheses from metal complexes such as Rh(diethylene)(acac), Ir(diethylene)₂(acac), or Pt(diacac) reacting with the surface of a structurally well-defined high-area crystalline support, a zeolite or MgO. The supported catalysts are mononuclear, cationic metal complexes; the supports provide oxygen ligands to the metals, anchoring them to the surfaces. A reason for working with catalysts having such well-defined structures is that they are susceptible to exact structural characterization. The new structures offer new catalytic

properties—especially high selectivities, which (as in homogeneous catalysis) are associated with unique catalytic species and catalytic cycles that may be elucidated in depth. We used electron microscopy to resolve individual atoms of Ir, Os, Pt, Au, and even Rh on zeolites and MgO. We found zeolite-supported iridium complexes that form unique, new, rather stable dinitrogen complexes, which we have characterized. We synthesized isolated single rhodium complexes on supports and selectively converted them to rhodium pair sites, which have markedly different reactivities in reactions involving H₂. We found a stable site-isolated platinum complex catalyst for CO oxidation. We elucidated patterns of the reactivity of supported metal complexes that depend on the support and other ligands bonded to the metal, showing how these induce delinking from the support and lead to the first steps of cluster formation. A review summarizing our conception of the field and recent results appeared in *Accounts of Chemical Research*, 2014, 47, 2612.

Oxide-Metal Interactions Studied on Core-Shell Catalysts

Institution: Pennsylvania, University of
Point of Contact: Raymond Gorte
Email: gorte@seas.upenn.edu
Principal Investigator: Raymond Gorte
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

Precious metal catalysts are widely applied for pollution control in gasoline and diesel exhausts, as well as many other chemical processes. Catalyst stability and activity are serious issues that are not completely resolved, especially with new regulations planned for methane emissions. Developing catalysts with improved stability and activity remains an important goal that could have a very large commercial impact. We are synthesizing and characterizing core-shell catalysts in which the metal core is surrounded by a thin porous shell of a catalytically active oxide. We are interested in understanding how the oxide shell can modify the activity and stability of metal catalysts.

FY 2014 HIGHLIGHTS

Novel Pd-zirconia core-shell catalysts have been synthesized using self-assembly methods. These were then studied for methane oxidation and were found to be as active and more stable than the analogous Pd-ceria catalysts. Both catalysts showed nearly identical reaction rates and thermal stabilities under dry conditions but the Pd-zirconia catalysts were very stable in the presence of water vapor. Coulometric titration and pulse-reactor studies demonstrated that zirconia in contact with Pd can be reduced and that the Pd-PdO equilibrium at 873 K is shifted to much lower oxygen fugacities. Because PdO is more active for methane oxidation, this observation provides a possible explanation for the superior performance of the Pd-zirconia catalyst. Au-titania, Core-shell nanostructures were also synthesized and characterized for room temperature CO oxidation. The alumina-supported catalysts showed higher activity and thermal stability than conventional Au/TiO₂ samples and were able to maintain their activity and 3-nm Au particles size upon calcination up to 873 K. Furthermore, it was found that the crystallization of titania was suppressed in the core-shell structure, resulting in a thin layer of small titania particles, which is favorable for the dispersion and thermal stability of Au nanoparticles.

EARLY CAREER: Unifying Principles for Catalytic Hydrotreating Processes

Institution: Houston, University of
Point of Contact: Lars Grabow
Email: grabow@uh.edu
Principal Investigator: Lars Grabow
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

Fast pyrolysis of biomass, a renewable and sustainable resource, is a promising low-cost technology that produces bio-oil suitable for use as transportation fuel after an appropriate upgrade step. The upgrade can be achieved by reducing the high oxygen content of up to 35 – 40 wt.% through hydrotreatment over heterogeneous catalysts, but the complexity of bio-oils with ca. 400 different oxygenated compounds and the fact that this technology has only recently gained interest are both responsible for the lack of fundamental knowledge in this field. In contrast, the petroleum industry has been using hydrotreating reactors with cobalt and nickel promoted molybdenum sulfide based catalysts for the removal of sulfur impurities for decades, and the catalyst structure, nature of the active site, and elementary reaction steps are largely understood. This project builds on the hypothesis that the hydrotreating processes for the removal of oxygen and sulfur are fundamentally similar at the atomic-scale and existing knowledge from the treatment of petroleum derived feedstock can be leveraged for the design of novel catalysts for the upgrade of bio-oil. Electronic structure simulations on high performance computing infrastructure and kinetic modeling will be used to improve our mechanistic understanding of bio-oil hydrotreatment and to derive characteristic catalyst properties that are responsible for high activity and selectivity. From the resulting structure-function relationships we can extract common features of hydrotreating catalysts and develop unifying principles that lead to the accelerated design of novel materials for bio-oil upgrade.

FY 2014 HIGHLIGHTS

The highlights for this recently awarded grant cover the period from July 15 to September 30, 2014. We have started to compare the hydrodeoxygenation (HDO) pathway of furan with the well-studied hydrodesulfurization (HDS) pathway of thiophene on Ru and Mo oxides and sulfides. Our preliminary results indicate that the reaction pathways for HDO and HDS are similar, but not identical, which may be attributed to the different crystal structure of the corresponding oxides and sulfides. More detailed investigations are ongoing.

The fully DOE-funded graduate student Sashank Kasiraju presented the first set of results at the 2014 CAMD Summer School on Electronic Structure Theory and Materials Design, DTU, Kongens Lyngby, Denmark and won the 'Best Poster Award'. The poster was titled 'Hydrodeoxygenation of Furan versus Hydrodesulfurization of Thiophene: A First Principles Investigation' and was co-authored by the 2nd DOE-funded graduate student Byeongjin Baek. The poster award was also featured on the University of Houston - Chemical Engineering Department News website:

<http://www.egr.uh.edu/news/201410/chbe-student-wins-overseas-poster-contest>.

The results of this DOE project have also been included in 3 invited talks given by PI Grabow:

1. "Water mediated proton transfer at metal/metal-oxide interfaces" Symposium in honor of Prof. S. Linc receiving the ACS Catalysis Lectureship, ACS Fall Meeting, San Francisco, CA, August 11th, 2014.

2. "Mechanism and nature of the active site of Ru/TiO₂ for hydrodeoxygenation of acetaldehyde" Catalysis for Biomass Conversion Symposium, ACS Fall Meeting, San Francisco, CA, August 2014.
3. "Computational Design of Catalytic Materials for Fuels & Chemicals Production using Activity Descriptors" The DOW Chemical Company Seminar Series, Freeport, TX, July 31st 2014.

Development of Transition Metal Catalysts for the Functionalization of Carbon-Hydrogen Bonds: Fundamental Studies of Catalytic Hydroarylation of Olefins

Institution: Virginia, University of
 Point of Contact: Thomas Gunnoe
 Email: tbg7h@virginia.edu
 Principal Investigator: Thomas Gunnoe
 Sr. Investigator(s):
 Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
 Funding: \$150,000 (2014)

PROGRAM SCOPE

With increased global demand for fossil resources, new technologies that provide useful commodity chemicals at lower cost and with reduced environmental damage are a priority, especially efficient and clean utilization of hydrocarbons derived from petroleum and natural gas. At the center of almost any new technology for catalytic hydrocarbon manipulation is metal-mediated C–H activation, yet the catalytic functionalization of inert C–H bonds of hydrocarbons remains one of the foremost challenges facing synthetic chemists. The net addition of aromatic C–H bonds across olefin C=C bonds, olefin hydroarylation, provides an atom economical reaction with broad potential including applications in both commodity scale processes as well as fine chemical synthesis. We have been studying olefin hydroarylation catalyzed by well-defined transition metal complexes. In the past year, we have prepared and pursued catalysis with new complexes based on Ru(II), Pt(II), Fe(II), and Rh(I). These studies have led to the development of new molecular catalysts for the production of alkyl arenes and vinyl arenes, which are used in plastics, soaps and detergents and in fuels. A primary focus has been centered on developing mechanistic understanding of the catalysts, thus allowing rationale development of improved catalysts.

FY 2014 HIGHLIGHTS

Support from this DOE grant has resulted in the publication of six manuscripts during FY2014. We have developed a detailed understanding of the influence of ancillary ligand for Pt(II) catalyzed hydrophenylation of olefins using bis-nitrogen chelates. More strongly donating ligands increase catalyst longevity, which is proposed to result from an increased selectivity for the production of ethylbenzene over styrene. Using a favorable entropic effect, switching the supporting ligand from 4,4'-di-tert-butyl-2,2'-bipyridyl to 2,2'-dipyridylmethane (dpm) results in an increase in both catalyst longevity (by a factor of > 5) and activity (by a factor of ~2). In unpublished work, we have designed a new d8 catalyst that is highly selective for the synthesis of styrene from benzene and ethylene. This process is quantitatively selective for styrene and uses an oxidant that can be recycled using oxygen. For octahedral Ru(II) catalysts, building on previous structure/activity relationships, we successfully realized the prediction that cationic variants of TpRu(L)(NCMe)Ph (Tp = hydridotris(pyrazolyl)borate) catalysts should provide more effective catalysts for ethylene hydrophenylation. Reaction of the cationic Ru(II) complex [(HC(pz⁵)₃)Ru(P(OCH₂)₃CEt)(NCMe)Ph][BAR'₄] [HC(pz⁵)₃ = tris(5-methyl-pyrazolyl)methane; BAR'₄ = tetrakis[3,5-bis(trifluoromethyl)phenyl]borate] (0.025 mol% relative to benzene) in benzene with C₂H₄

(15 psi) at 90°C gives 565 turnover numbers of ethylbenzene. The production of 565 turnovers of ethylbenzene corresponds to an approximate one-pass 95% yield with ethylene as the limiting reagent and is a 28-fold improvement compared to the charge neutral catalyst $\text{TpRu}(\text{P}(\text{OCH}_2)_3\text{CEt})(\text{NCMe})\text{Ph}$. In combination, the new cationic Ru(II) catalyst, the dpm-Pt(II) catalyst, and the new catalyst for styrene production are among the most effective for this class of catalyst for the production of alkyl and vinyl arenes using hydrocarbons.

Structured Carbon and Carbon-Oxide Composites as Catalysts and Catalyst Supports

Institution: Yale University
Point of Contact: Gary Haller
Email: gary.haller@yale.edu
Principal Investigator: Gary Haller
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Multi-walled carbon nanotubes (MWCNT) is a form of carbon that has two properties not shared by other carbon materials—it can have high surface area but with mesoporosity, rather than the microporosity of activated carbon, and be synthesized with good purity. It also has a hydrophobic surface which may be a disadvantage in aqueous media (making it difficult to disperse) and unreactive toward anchoring the catalytic active component (metal or oxide) to the MWCNT support. To provide anchoring sites and adjust the hydrophobicity, the surface can be functionalized by oxygen, usually accomplished by oxidation with nitric acid. The overall goal is to develop the fundamental catalytic science of MWCNT as structured carbon supports for reactions in aqueous media, with particular emphasis on reactions relevant to biomass processing. Two kinds of catalytic functions are desired: acid and hydrogenation. Acid catalysis is useful for aqueous hydrolysis, dehydration and alkylation and hydrogenation is often required to lower the O/C ratio, e.g., convert acids to alcohols in aqueous media. The two functions may be used in tandem, e.g., hydrolysis/hydrogenation of cellulose. Zirconium oxide may be a particularly flexible oxide for aqueous phase reactions because it can be both a support for metals and/or a strong acid catalyst when sulfated or tungstated. Thus, the zirconia/MWCNT composite suggests itself as a versatile platform for both acid and metal catalyzed reactions in hot water, or as a support for bifunctional catalysis by a metal particle in intimate association with a solid acid. The initial focus was on the synthesis and characterization of sulfated zirconia/MWCNT, followed by a comparison study of the synthesis and characterization of tungstated zirconia/MWCNT with respect to their relative aqueous stabilities and solid acid activities. These solid acids are to be converted to bifunctional catalysts by addition of a group VIII metal.

FY 2014 HIGHLIGHTS

The goal for $\text{ZrO}_2/\text{MWCNT}$ was to develop a hydrothermally stable support platform for a solid acid catalyst and we chose as our first example sulfated zirconia ($\text{S-ZrO}_2/\text{MWCNT}$) that has been well studied on bulk ZrO_2 . We have performed a combined Zr and S XANES analysis of $\text{S-ZrO}_2/\text{MWCNT}$ at the Zr LIII-edges and the S K-edge. A careful analysis of the S K-edge peak shape in the first and third derivative shows that the peak shape does not vary substantially at different treatment times at 450°C or after annealing at 550°C, well above the synthesis temperature, even though the S/Zr ratio decreases with both time at 450°C and temperature above 450°C. This would appear to rule out two different S species

unless they also had identical thermal stability. We propose instead that this peak be interpreted as one species with a two components; it can be compared to the two components of KHSO_4 . The spectrum of solid KHSO_4 maps onto the spectrum we observe for S-ZrO₂/MWCNT, while the spectrum of K_2SO_4 is identical to $(\text{NH}_4)_2\text{SO}_4$. On this basis we propose that the Brønsted site on S-ZrO₂/MWCNT is comprised of HSO_4^- anion interacting with a surface Zr cation (C. Liu *et al.*, *Top Catal.* (2014) 57, 696-705). Interaction between S and Zr already exists after impregnation but this interaction increases with a 250°C annealing because partial decomposition of $(\text{NH}_4)_2\text{SO}_4$ occurs, as detected by in-situ wide angle X-ray scattering, resulting in di-sulfur intermediate species, that more effectively accommodates and distributes the transferred charge than does the sulfur monomer. The picture that develops for S-ZrO₂/MWCNT acid sites is one where the Zr^{4+} cation plays a more passive role than usually attributed to it, but explains the perturbation of HSO_4^- by Zr interaction that results in a stronger acid, in terms of charge transfer (C. Liu *et al.*, *Top. Catal.* (2014) 57, 774-784).

Investigation of the Origin of Catalytic Activity in Oxide-Supported Nanoparticle Gold

Institution: Virginia, University of
Point of Contact: Ian Harrison
Email: harrison@virginia.edu
Principal Investigator: Ian Harrison
Sr. Investigator(s): Matt Neurock; Minnesota, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

Gold (Au) nanoparticles supported on reducible oxides such as TiO₂ demonstrate exceptional catalytic activity for a wide range of gas phase oxidation reactions such as CO oxidation, olefin epoxidation, and water gas shift catalysis. Scientists have recently shifted their hypotheses on the origin of the reactivity of these materials from the unique electronic properties and under-coordinated Au sites on nanometer-sized particles towards bifunctional sites at the Au-support interface. In 2011, we discovered a dual catalytic site at the perimeter of ~3 nm diameter Au particles supported on TiO₂ is responsible for oxidative catalytic activity. O₂ molecules bind with Au atoms and Ti⁴⁺ ions in the TiO₂ support and the weakened O-O bond dissociates at low temperatures proceeding to produce O atoms which act as oxidizing agents for molecules such as CO. Our DOE research has built on this finding and has been concerned with two aspects of the behavior of Au/TiO₂ catalysts: (1) Mechanistic behavior of dual catalytic sites in the oxidation of organic molecules such as ethylene and acetic acid; (2) Studies of the electronic properties of the TiO₂ (110) single crystal in relation to its participation in charge transfer at the occupied dual catalytic site. The research combines IR spectroscopic investigations of Au/TiO₂ catalysts with surface science on the TiO₂(110) surface and with modern density functional modeling. The goals of the work underway are to investigate the behavior of the dual Au/Ti⁴⁺ site for the partial oxidation of alcohols to acids, the hydrogenation of aldehydes and ketones to alcohols, and the condensation of oxygenate intermediates - all processes related to the utilization of biomass in the production of useful chemical energy sources.

FY 2014 HIGHLIGHTS

Our recent experimental and theoretical results provide insights into the active sites and pathways that control oxidation over Au/TiO₂ catalysts. Transmission infrared (IR) spectroscopic data show the direct involvement of the Au-Ti⁴⁺ dual perimeter sites, and density functional theory results connect the

electronic properties at these sites to their reactivity and to plausible reaction mechanisms. We also show the importance of interfacial Au-Ti⁴⁺ sites in adsorbing and activating O₂ as a result of charge transfer from the Au into antibonding states on O₂ causing di-σ interactions with interfacial Au-Ti⁴⁺ sites. This results in apparent activation energies for O₂ activation of 0.16-0.60 eV thus allowing these materials to operate over a wide range of temperatures (110-420 K) and offering the ability also to control H-H, and C-O bond scission. At low temperatures (100-130 K), adsorbed O₂ directly reacts with co-adsorbed CO or H₂. At higher temperatures, O₂ directly dissociates to form active oxygen adatoms (O*) on Au and TiO₂. These readily react with bound hydrocarbon intermediates via base-catalyzed nucleophilic attack on unsaturated C=O and C=C bonds or via activation of weakly acidic C-H or O-H bonds. The oxidative-dehydrogenation of model C₂-C₄ (acetic, propionic and butyric) carboxylic acids on Au/TiO₂ catalysts comprised of Au particles ~3 nm in size was investigated using IR spectroscopy and density functional theory. All three acids readily deprotonate to form their carboxylate analogs on the TiO₂ support which subsequently react to form a gold ketenylidene, Au₂C=C=O, intermediate along the way to their full oxidation. The adsorbed Au₂C=C=O intermediate species can be hydrogenated to produce ketene H₂C=C=O_(g), with an activation energy of 0.21 ± 0.05 eV. These studies show that selective oxidative-dehydrogenation of the alkyl side chains of fatty acids can be catalyzed by nanoparticle Au/TiO₂ at temperatures near 400 K.

Theoretical Investigation of Heterogeneous Catalysis at the Solid-Liquid Interface for the Conversion of Lignocellulosic Biomass Model Molecules

Institution: South Carolina, University of
Point of Contact: Andreas Heyden
Email: heyden@cec.sc.edu
Principal Investigator: Andreas Heyden
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$380,000 (2014-2016)

PROGRAM SCOPE

The overall research goal of this project is the development and validation of a hierarchy of multi-scale methods for computing activation and reaction free energies of elementary processes occurring at metal-liquid interfaces that are only up to two orders of magnitude slower than current conventional catalysis tools for catalytic gas-solid studies. As a result, these novel tools will permit within a decade computational metal catalysis studies at solid-liquid interfaces with similar ease to current gas-metal catalysis studies (assuming a similar growth in computing infrastructure as seen in the past couple of decades). Our hierarchy of novel multi-scale methods starts with (i) the use of implicit solvation models to approximately describe solvation effects on elementary reactions at metal surfaces, (ii) the application of our hybrid quantum mechanics (QM) and molecular mechanics (MM) solvation scheme for computing free energies of reactions at metal-liquid interfaces, and (iii) the inclusion of solvent coordinates in the reaction coordinate when computing free energies with our QM/MM approach. As model systems for our computational study, we investigate selectivity issues in the reductive deoxygenation of ethylene glycol, glycerol, and guaiacol over metal catalysts under aqueous-phase processing (APP) conditions. Of key interest in these studies is understanding the specific effect of the liquid phase on the reaction mechanism and selectivity descriptors for future catalyst design studies.

FY 2014 HIGHLIGHTS

Within fiscal year 2014, we have applied our novel implicit solvation model for metal surfaces (iSMS) methodology to investigate the effects of various liquid solvents on the hydrodeoxygenation of propanoic acid over a Pd(111) model surface and on reforming reactions of ethylene glycol over a Pt(111) model surface. We observed that polar solvents such as water accelerate both the decarbonylation and decarboxylation rate of organic acid. Particularly, the decarboxylation that involves the formation of a charged carboxylate species is accelerated by two orders of magnitude. Next, an aqueous-phase microkinetic model predicts a 0.4 eV lower apparent activation energy in liquid water versus gas phase for reforming of ethylene glycol. Particularly at lower temperatures does liquid water accelerate reforming reactions. We also investigated the hydrodeoxygenation of guaiacol over Pt and Ru model surfaces. While over Ru catalysts decarbonylation reactions and C-OH bond cleavage can occur, leading to the formation of phenol, we find that over Pt catalysts catechol is the main reaction product and deoxygenation occurs only after hydrogenation of the phenyl group. As a result, it is challenging to produce oxygenated, aromatic products over Pt catalysts. Finally, we developed a hybrid quantum mechanics/molecular mechanics solvation scheme for computing free energies of reactions at metal-water interfaces. This explicit solvation model for metal surfaces (eSMS) is the first practical computational methodology for considering solvation effects in heterogeneous catalysis that uses explicit water molecules and permits extensive sampling of liquid water. Importantly, we find that both the iSMS and eSMS methodologies predict similar solvent effects for C-C bond cleavage of ethylene glycol over Pt(111).

Directed Surfaces Structures and Interfaces for Enhanced Electrocatalyst Activity, Selectivity, and Stability for Energy Conversion Reactions

Institution: Stanford University
Point of Contact: Thomas Jaramillo
Email: jaramillo@stanford.edu
Principal Investigator: Thomas Jaramillo
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The overarching goal of the project is to tune the activity, selectivity, and stability of catalysts for key electrochemical energy conversion reactions. We aim to accomplish this goal by designing and tailoring the surface structure and interfacial properties of catalyst materials at the nano- and atomic-scale. These goals project are directly in-line with the Grand Challenge in Catalysis Science as described in the DOE's 'Basic Needs Report for Catalysis in Energy': to design and synthesize catalyst materials with geometric and electronic structures tailored for high catalytic activity, stability, and selectivity. This project

FY 2014 HIGHLIGHTS

Two highlights to report involve catalyst development for the hydrogen evolution reaction (HER) and the oxygen reduction reaction (ORR). For the hydrogen-evolution reaction (HER), it is known with MoS₂ that only edge sites turnover the reaction because the basal planes are catalytically inert. In an effort to develop a scalable HER catalyst with an increased number of active sites, we synthesized thiomolybdate

$[\text{Mo}_3\text{S}_{13}]^{2-}$ nanoclusters in which most sulfur atoms in the structure exhibit a structural motif similar to that observed at MoS_2 edges. Indeed the supported $[\text{Mo}_3\text{S}_{13}]^{2-}$ nanoclusters exhibited excellent HER activity and stability in acid. Imaging at the atomic scale with scanning tunneling microscopy allowed for direct characterization and measurement of turnover frequencies (TOFs), shown to be higher than those observed for other non-precious metal catalysts synthesized by a scalable route. For details, see: J. Kibsgaard et. al., *Angewandte Chemie*, Vol. 6 (2014) 248-253. For the oxygen reduction reaction (ORR), we tuned binding energies of oxygen-containing intermediates on a catalyst surface by a strategy in which we can weaken the binding energies by means of thin-film overlayers, and strengthen them through nanoscale effects. By engineering a core-shell nanoparticle morphology with the appropriate dimensions, we showed that bonding properties can be modified to improve the catalytic activity of the core-shell system. We demonstrate the application of this strategy for oxygen reduction by identifying Ru@Pt as a candidate core-shell material using density functional theory calculations, and then use these calculations to guide the synthesis of active Ru@Pt core-shell catalysts. The Ru@Pt particles, synthesized using a wet chemical method, exhibit ~2 times higher specific activity (based on electrochemical active surface area) than state-of-the-art Pt/C from TKK. For details, see: A. Jackson et. al., *ChemElectroChem*, Vol. 1 (2014) 67-71

Atomically Precise Metal Nanoclusters for Catalytic Application

Institution: Carnegie Mellon University
Point of Contact: Rongchao Jin
Email: rongchao@andrew.cmu.edu
Principal Investigator: Rongchao Jin
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

We are motivated to create atomically precise metal nanoclusters (e.g. gold and bimetallic ones) for catalytic application. We have successfully attained thermodynamically stable gold nanoclusters protected by thiolates, such as $\text{Au}_{18}(\text{SR})_{14}$, $\text{Au}_{20}(\text{SR})_{16}$, $\text{Au}_{25}(\text{SR})_{18}$, $\text{Au}_{36}(\text{SR})_{24}$, $\text{Au}_{38}(\text{SR})_{24}$, $\text{Au}_{64}(\text{SR})_{32}$, $\text{Au}_{99}(\text{SR})_{42}$, and $\text{Au}_{144}(\text{SR})_{60}$. The atomic structures of nanoclusters are revealed by X-ray crystallographically. Our target is to achieve structure-catalytic reactivity correlation and fundamental understanding of some important issues of nanocatalysis, such as the precise size effect and the identification of catalytically active centers. Our research matches the research objective of the BES mission “to support fundamental research to understand, predict, and ultimately control matter and energy at the level of electrons, atoms, and molecules.

FY 2014 HIGHLIGHTS

The central goal of our project is to explore the catalytic application of atomically precise gold and gold-based bimetallic nanoclusters. We have successfully prepared different sized, robust gold nanoclusters protected by thiolates, such as $\text{Au}_{25}(\text{SR})_{18}$, $\text{Au}_{28}(\text{SR})_{20}$, $\text{Au}_{38}(\text{SR})_{24}$, $\text{Au}_{99}(\text{SR})_{42}$, $\text{Au}_{144}(\text{SR})_{60}$, etc. These ultrasmall nanoclusters (< 2 nm diameter) exhibit discrete electronic structures due to quantum size effects, as opposed to quasi-continuous band structure of conventional metal nanoparticles. We are particularly interested in investigating the unique catalytic properties of nanoclusters and aim to reveal the structure-selectivity relationships. Highlights of our year 2 work include: 1) C-H bond activation on nanoclusters (work reported in *J. Catal.*); 2) Chemoselective hydrogenation of nitrobenzaldehyde and

derivatives in water with H₂ (work published in J. Am. Chem. Soc.); 3) O₂ activation: singlet 1O₂ generation by visible light photoexcitation of Au₂₅(SR)₁₈ nanoclusters (work published in Chem. Mater. & J. Phys. Chem. Lett.); 4) Nanocluster structures (published in J. Am. Chem. Soc. and Nanoscale); 5) Size dependence in chemoselective hydrogenation and ligand effect in semihydrogenation (published in ACS Catal.). We have indeed identified some unique catalytic properties of nanoclusters not manifested in conventional nanogold catalysts; for examples, i) using Au₂₅ nanocluster catalysts we obtained ~100% yield in semihydrogenation of alkynes to alkenes, and ii) using thermally robust Au₉₉ nanocluster catalyst we obtained ~100% selectivity (or ~93% yield) in chemoselective hydrogenation of the aldehyde group in nitrobenzaldehyde to nitrobenzyl alcohol. These unique properties are not observed in conventional nanogold catalysts and are remarkable. The available atomic structures of nanoclusters (metal core plus surface ligands) serve as the basis for structure-property correlations and have revealed the molecular adsorption/activation sites.

Developing the Science of Immobilized Molecular Catalysts

Institution: Georgia Institute of Technology
Point of Contact: Christopher Jones
Email: christopher.jones@chbe.gatech.edu
Principal Investigator: Christopher Jones
Sr. Investigator(s): Marcus Weck; New York University
C. David Sherrill; Georgia Institute of Technology
Seung Soon Jang; Georgia Institute of Technology
Students: 5 Postdoctoral Fellow(s), 6 Graduate(s), 2 Undergraduate(s)
Funding: \$700,000 (2014)

PROGRAM SCOPE

A team of experimental and computational researchers from multiple universities are collaborating to investigate supported molecular catalysts. Cooperative catalysis, whereby two or more active sites work in concert in promoting a catalytic reaction, is ubiquitous in biological systems. Design and understanding of synthetic cooperative catalysts is the scientific target of this small team program. Past and current work has focused on the utilization of different cooperative M-Salen catalysts (where M has been Co or Al), whereby two M-Salen catalysts work together in the rate-limiting step to catalyze the reaction. An interdisciplinary research team that can probe all aspects of catalyst synthesis, structure and properties is exploring this topic from both experimental and theoretical points of view. In particular, researchers at GT and NYU are developing design principles for supported M-Salen catalysts that follow bimetallic (Co- and Al-Salen) reaction pathways, chiefly a family of Co-Salen catalyzed epoxide ring-opening reactions. Increasingly, other cooperative catalytic systems are being considered, including those that utilize organic active sites combining Brønsted acids and Lewis bases. Using these model systems, the fundamental principles that can be used to understand and design future classes of supported, cooperative catalysts are being elucidated.

FY 2014 HIGHLIGHTS

- 1) Heteroatom-substituted aminosilica catalysts were developed to investigate acid-base cooperative catalysis. Tuning of the metal-based active sites could yield improved activity associated with adjacent, tethered basic amine sites.
- 2) Trianionic ligands were designed to make Co(III) complexes for alcohol ring-opening of epoxides in an attempt to avoid counter-ion loss during reaction of the catalyst. These materials were found to

be catalytically inert under the conditions studied. Computational characterization of the electronic structure shows that Co(III) complexes with trianionic ligands do not have sufficient Lewis acidity to activate the epoxide.

- 3) Electronic structure computations were performed on the proposed rate-determining step of hydrolytic kinetic resolution of epoxides as catalyzed by Co(III)-Salen complexes. This work explains the inactivity of Co-Salen-OH when it is the sole catalytic species present (it arises from a higher barrier height, not an inability to activate epoxide).
- 4) Shell-crosslinked micelles and multicompartiment nanoreactors were developed as catalyst supports in cascade reactions. The catalytic transformations that have been investigated are hydrolytic kinetic resolution (HKR), epoxidation, and asymmetric transfer hydrogenation using Co, Mn, Ru and/or Rh-based transition metal catalysts.
- 5) Poly(2-oxazoline) block copolymer based micelle nanoreactors were investigated using density functional theory and molecular dynamics simulation. Flory-Huggins Chi-parameters were calculated to assess the miscibility of the POX homopolymers with various reactants and products. The correlation of this Chi-parameter to the experimental reaction data provided from other team members suggested that the higher the miscibility of reactant in the phase of the corona polymer, the faster the reaction completion, which indicates that the transport of reactant and are determined by the molecular interactions with the micelles.

Transition Metal Activation & Functionalization of Carbon-Hydrogen Carbon-Carbon Bonds

Institution: Rochester, University of
Point of Contact: William Jones
Email: william.jones@rochester.edu
Principal Investigator: William Jones
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This project is directed towards fundamental investigations of the reactions of homogeneous transition metal complexes with aliphatic and aromatic hydrocarbons, saturated and unsaturated, and their functionalized derivatives (e.g. carbonyl, nitrile, halides). The studies provide fundamental information about the mechanisms and energetics of reactions of metal complexes with C–H, C–C, and C–X bonds in a wide variety of hydrocarbons. The key to understanding reactivity of these molecules lies in determination of the kinetic and thermodynamic selectivity for cleavage of these bonds by coordinatively unsaturated metal species. Determination of metal-carbon bond strengths is critical to understanding the thermodynamic factors that control the reactions. New ways to determine these bond strengths with a variety of substrates and new metal complexes will be explored. The work will be extended to include determination of metal-alkoxide bond strengths. New substrates for the cleavage of C–C bonds will be sought extending the examples that include sp , sp^2 , and sp^3 hybridized carbon. New metal complexes for cleaving these bonds will be found. The interplay between η^2 -coordination, C–H oxidative addition, and C–C oxidative addition will be applied to the cleavage of C–C linkages. We will examine in detail how Lewis acids can affect the kinetics and thermodynamics of C–C activation. In all of these areas, we will apply DFT theory to examine stabilities of reactants, intermediates, and transition states, providing a comprehensive understanding of strong bond activation. The success of this work will lead to new approaches for the manipulation of petroleum-based hydrocarbons and functionalized

derivatives. New processes for making and breaking strong bonds in organic molecules will be based upon the lessons learned from the kinetic and thermodynamic studies of the type presented here.

FY 2014 HIGHLIGHTS

The most important discoveries in C–H activation that have been made in this project include: (1) We have made a breakthrough in understanding factors that influence metal-carbon bond strengths by examination of the activation of CH₃CN by [Tp'Rh(CNR)] and comparing this to methane activation. Tp'Rh(CNR)(CH₂CN)H loses CH₃CN with a half-life of 3 days at 100°C, whereas Tp'Rh(CNR)(CH₃)H loses CH₄ with a half-life of 5 hours at 25°C, suggesting that the effect of an alpha-cyano substituent strengthens the metal-carbon bond. However, our kinetic methodology shows that the Rh–CH₂CN bond is actually 3 kcal/mol weaker than the Rh–CH₃ bond! This result shouldn't be so surprising considering the organic radicals that are formed (unstable ·CH₃ vs. stable ·CH₂CN). The greater apparent stability of the oxidative addition product arises because reductive elimination produces a wimpy H–CH₂CN bond (95 kcal/mol) whereas methane elimination produces a hefty H–CH₃ bond (105 kcal/mol). Hence the apparent 'stability' is associated with a weaker M–C bond! (2) We have extended this analysis to include a wide range of substituted methyl derivatives of the type Tp'(CNR)(H)Rh–CH₂X where CH₂X = CH₂Cl, CH₂OMe, CH₂OtBu, CH₂C(=O)CH₃, CH₂C≡CCH₃, CH₂aryl, CH₂CMe=CH₂, CH₂F, CHF₂ and CH₂CF₃. These substrates all show a linear correlation of D(Rh–C) vs. D(C–H) that is parallel to the line for the parent hydrocarbons, but displaced by ~7 kcal/mol higher in energy. This shift is attributed to the greater ionic contribution to the Rh–C bond in these derivatives. (3) This same trend has been investigated in Tp'(PMe₃)(H)Rh–CH₂X derivatives, and the same trends are seen separating the parent hydrocarbons from the substituted methyl derivatives. The difference here is that the slope is greater for the PMe₃ complexes. (4) The trend was also observed in a series of Tp'(P(OMe)₃)(H)Rh–CH₂X derivatives, but the slope of the trend was in between that seen with CNR and PMe₃ spectator ligands.

Control of Supported Molecular Catalysts Using Metallocalixarene Active Sites

Institution: California-Berkeley, University of
Point of Contact: Alexander Katz
Email: askatz@berkeley.edu
Principal Investigator: Alexander Katz
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$400,000 (2014-2016)

PROGRAM SCOPE

Molecular engineering of catalysts on surfaces has resulted in unique compositions that control the local density of grafted cations on surfaces (demonstrated on silica) as well as control of Lewis-acid catalysis via coordination geometry surrounding grafted metal cation on surface (also demonstrated on silica). In the first area, more robust grafted Ti center catalysts have been synthesized, which withstand the harshness of protic solvents and do not leach. In the second area, unique demonstration of coordination geometry linking to catalytic activity is made using organic ligands grafted on surfaces.

FY 2014 HIGHLIGHTS

We have synthesized a unique example of patterned grafted cations on surfaces, by tethering Ti(IV)-metallocalixarene complexes to an aromatic core. We have also demonstrated the resulting materials to

be more robust against leaching compared with the randomly distributed isolated grafted metallocalixarenes, which is attributed to encapsulation within mesopores of silica. Catalysis was used to demonstrate the grafting of all four calixarenes within a molecule to the silica surface, since this grafting makes the metallocalixarene complex an active catalyst for olefin epoxidation, compared to the lack of activity prior to grafting. We have also synthesized unique catalysts for the transformation of aldehydes to esters via Tishchenko reaction, using grafted Al(III)-calixarenes. This emerging area nicely connects homogeneous and heterogeneous catalysis, since alkoxides of Al have been long used as soluble catalysts for this reaction. Our results show that Al within an O environment enforced by a grafted calixarene and the silica surface is an active solid catalyst for the Tishchenko reaction. Preliminary data points to a pronounced effect of calixarene coordination and geometry on the catalyst activity.

Direct Epoxidations Using Molecular Oxygen

Institution: New Mexico, University of
Point of Contact: Richard Kemp
Email: rakemp@unm.edu
Principal Investigator: Richard Kemp
Sr. Investigator(s): Karen Goldberg; Washington, University of
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 1 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

Our work continues in the area of using homogeneous and to a more limited extent Cu-based heterogeneous catalysts with molecular oxygen to broadly examine oxygen transfer reactions to both organic and inorganic substrates to yield valuable, partially oxidized products. The oxidation reactions of primary interest to us are those that have no counterparts (either heterogeneous or homogeneous) when using gaseous O₂. Our homogeneous catalytic approach is centered upon the use of pincer-ligated late transition metal hydrides as the starting complex, which then adds O₂ to form reactive metal hydroperoxides. We have shown that these M-OOH species are stable enough in general to be fully characterized; yet reactive enough to transfer oxygen in certain cases to give oxidized products and a metal hydroxide complex. Addition of hydrogen to the M-OH species regenerates the starting hydride, along with water. Much of our work is directed towards preparing new complexes for evaluation, along with understanding these fundamental steps in the proposed catalytic cycle. While developing useful and efficient routes to these oxygenated organic compounds is the primary goal for our work, we are also interested in understanding the fundamental mechanistic chemistry of oxygen insertion and transfer using transition metal complexes. The understanding generated in our work should be applicable to other systems of interest to DOE, thus increasing the reach and impact of our fundamental studies. As this is a highly-collaborative project among our teams and outside collaborators, a highly communicative and integrated research effort between UNM and UW is required to accomplish these goals.

FY 2014 HIGHLIGHTS

We have prepared and characterized multiple new late transition metal pincer systems and investigated their ability to perform specific chemical transformations proposed in an olefin epoxidation sequence using molecular oxygen. Phosphine based PNP pincer systems of palladium and platinum capable of metal-ligand cooperativity were extensively studied. This work provided key insight into the

requirements of the ligand and metal center for O₂ reactivity with M-H bonds. The results were published in *Organometallics*. This past year, we also began a collaboration with Dr. Giuliano Giambastiani at the Institute of Chemistry of OrganoMetallic Compounds ICCOM-CNR in Florence, Italy. Palladium complexes bearing novel asymmetric PCN pincer ligands were prepared by their group and subsequently investigated by us. A variety of palladium hydroxide mononuclear and dinuclear complexes were synthesized, characterized and their reactivity with H₂ was investigated. A manuscript is in preparation. Finally, after further analysis of the requirements for the complete epoxidation cycle, promising new ligands have been identified and targeted. Inspired by the mechanism of organic peracid epoxidation, the bifunctional ligands will assist in both the activation of oxygen as well as the substrate oxidation step. In addition to journal articles, the work described above will also be incorporated into a PhD thesis at UW. We are also working on demonstrating the transfer chemistry of oxygen into inorganic substrates, in particular into the Si-H bond to form valuable Si-OH species. While O transfer is clearly occurring, the selectivities to unique products appear to be highly substrate-dependent. We anticipate understanding the structural features affecting selectivity in early 2015. As well, the heterogeneous work that has led to production of propylene oxide using Cu-based catalysts has been completed, and will be a key part of a PhD thesis at UNM.

Catalysis, Dynamics and Stability of Enzymes under Extreme Conditions

Institution: Brandeis University
Point of Contact: Dorothee Kern
Email: dkern@brandeis.edu
Principal Investigator: Dorothee Kern
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Biocatalysis offers attractive new alternatives to chemical catalysis and transformations. The power of enzyme-catalyzed chemical transformations for the production of molecules that require complicated chemistry, stereochemistry, selectivity and at the same time satisfy environmental constraints has been widely recognized. However, while a large range of physical conditions can be used for chemical reactions, a major challenge of biocatalysis is that enzymes usually function in aqueous solutions at ambient temperature, pressure, low ionic strengths and pH values around neutral. While these properties have historically restricted the applications of biocatalysts, the discovery of organisms that live under extreme conditions (called extremophiles) opens a new era for biotransformations.

- Since extremozymes are stable and active under these extreme conditions, they are attractive as biocatalysts to industries such as chemical synthesis, agriculture, laundry detergents and the pharmaceutical industry. Enzymes from extremophiles can be exploited either by using them directly or by using the knowledge of how they adapt to extreme conditions to modify mesophilic proteins accordingly.
- We utilize the unique properties of extremophiles to study protein structure, dynamics and catalysis under a wide range of conditions. The long-term goal is to identify basic physical principles of protein stability and dynamics and their linkage to enzymatic activity for future use in rational design of biocatalysts. The lack of understanding of protein dynamics is most likely the reason for the limited success of designing biocatalysts. This research proposal is aiming to provide such information.

FY 2014 HIGHLIGHTS

We have characterized at atomic resolution all the microscopic steps in the catalytic cycle of adenylate kinase, through a combination of NMR measurements during catalysis, pre-steady-state kinetics, MD simulations, and crystallography of active complexes. Surprisingly we found that the Mg^{2+} cofactor activates two distinct molecular events, phosphoryl transfer (>105-fold) and lid-opening (103-fold). Our results highlight the importance of the entire energy landscape in enzyme catalysis and suggest that adenylate kinases have evolved to catalyze key processes simultaneously by precise placement of a single, charged and very abundant cofactor in the active site. •We have investigated the detailed mechanism by which Adk accelerates the P-transfer step by more than 8 orders of magnitude. From the QM calculations we got profound insights that may be a crucial reason for why enzymes are better catalysts than simple catalysts: The transition state is not a single state but rather a collection of structurally quite different states. The “broad” nature of the transition state for the enzyme-catalyzed reaction might be an important feature for efficient lowering of the barrier. •We started investigating the evolution of enzymes 4 billion years back from the last common ancestor between modern thermophilic, mesophilic and psychrophilic Adk. First we measured the thermostability of all enzymes. The oldest ancestor is very thermostable. Thermostability decreases along the evolutionary branches to the psychrophile and mesophile, and re-evolves thermostability in the lineage to the modern thermophile. Even more exciting are the results about the evolution of enzymatic activity. Wolfenden and coworkers hypothesized that in evolution, chemical reactions that were possible in hot environments got too slow when the earth cooled down. In order for these reactions to proceed at these lower temperatures, nature evolved enzymes with a large decrease of the free enthalpy of activation.

EARLY CAREER: Multifunctional Oxygen Evolution Electrocatalyst Design and Synthesis

Institution: Carnegie Mellon University
Point of Contact: John Kitchin
Email: jkitchin@andrew.cmu.edu
Principal Investigator: John Kitchin
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

In this project we aim to develop new multicomponent oxide-based electrocatalysts for the oxygen evolution reaction using combined theoretical and experimental approaches. We use density functional theory to compute the electronic structure and reactivity proxies of model oxide materials. From the understanding generated from these calculations, we synthesize materials and characterize their oxygen evolution activity. We use *in situ* spectroscopic methods to characterize oxide electrodes under reaction conditions. We also develop new data sharing strategies to facilitate the reuse of our data by others.

FY 2014 HIGHLIGHTS

- Development of the jmax scientific publishing software suite. All of our papers have been written with this open-source tool.

- Obtained unambiguous evidence of an electrolyte promotion effect for Ni oxide-based electrocatalysts
- Found new descriptors for oxide reactivity using density functional theory

Molecular Engineering for Selective Catalysis

Institution: Northwestern University
 Point of Contact: Harold Kung
 Email: hkung@northwestern.edu
 Principal Investigator: Harold Kung
 Sr. Investigator(s): Mayfair Kung; Northwestern University
 Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
 Funding: \$100,000 (2014)

PROGRAM SCOPE

The unique properties stem from the constrained environment and enforced proximity of functional groups in a molecular-size cavity have given rise to very interesting material properties, most remarkably catalysis by enzymes. The goal of this project is to investigate such nanoconfinement effects in abiotic systems and understand the relevant chemical interactions, so as to enable design of catalytic structures of targeted properties. The approach is to synthesize structures with defined environment around an active site and explore how the environment influences the properties of the functional groups and metal complexes within. The experimental plan was to design, synthesize, and characterize structures of siloxane and carbosilane-based material and graphene oxide to explore the nanoconfinement effects. The first system is a core-shell bifunctional nanocage, which has been synthesized successfully by us recently. Preliminary results suggested that it could stabilize a monocarbonyl Co(I) complex formed by reaction of cobalt carbonyl with interior carboxylic acid groups. This complex has an uncommon oxidation state and ligand combination. This project will explore the formation, structural, chemical and catalytic properties of metal complexes in the nanocage derived from reaction of carbonyls of Co, Fe, and Ni. The effect of stability of metal oxidation states will be examined, together with their catalytic hydrogenation and oxidation capability. Other complexes of Pt and Au will be generated inside the core-shell nanocage, and the effect of forced binding to “hard” ligands on their catalytic properties will be examined. These complexes will be compared with complexes of Pd that binds more strongly with the interior functional groups. The second system is to explore a new class of nanocavity made from modified “holey” graphene oxide sheets.

FY 2014 HIGHLIGHTS

Discrete nanocages of a core-shell structure, in which the core possesses periphery carboxylic acids and the shell interior silanols, reacted with cobalt carbonyl to form a monocarbonyl Co(I) complex. The formation and stabilization of this complex of an uncommon oxidation state of Co was because of steric crowding, such that the motion of the interior carboxylic acid groups was restricted, which led to a condition in which the cobalt carbonyl could only react with a limited number of carboxylic acid groups to form the Co(I) complex. Its formation inside the nanocage was concluded from various characterization measurements. Its stoichiometry of one CO ligand per Co(I) was determined by measuring the amount of CO released after decomposing the complex. The oxidation state was confirmed with EPR spectroscopy. The initially EPR inactive Co species was transformed to one that displayed an EPR signal at $g=4.0$ after exposure to molecular O₂. The IR stretching frequency of the single CO ligand at 1958 cm⁻¹ was also consistent with a Co(I) oxidation state. The location of the Co(I) inside

the nanocage was inferred from the lack of redox peaks in CV measurement, and from the fact that it could be oxidized readily by the smaller phenyl azide but not the larger adamantane azide due to steric hindrance by the porous shell. Another complex, POSS-Sn-POSS, was prepared in which the Sn cation possessed a tetrahedral symmetry with four siloxy ligand bonds. Its coordination symmetry was confirmed by the chemical shift in the ^{119}Sn NMR, EXAFS, and single crystal X-ray diffraction pattern. The Sn cation was a Lewis acid, and it coordinated diethylamine in an anti- configuration, whereas it bound ethylene diamine in a syn- configuration, both forming an octahedral complex. Interestingly, it only interacted with triethylamine weakly without noticeable change in the coordination symmetry at Sn.

Development of Physically Transparent, Predictive Structure-Performance Relationships for Rational Design of Multi-Component Catalytic Materials

Institution: Michigan, University of
Point of Contact: Suljo Linic
Email: linic@umich.edu
Principal Investigator: Suljo Linic
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 3 Undergraduate(s)
Funding: \$460,000 (2014-2016)

PROGRAM SCOPE

Metals are used as catalyst for many chemical transformations. These materials are usually heavily promoted with multiple additives which serve to further improve the rates and/or selectivity of the process. The central theme of the project is to study how perturbations of metal surfaces by chemical promotion (for example promotion by alkali adsorbates), poisoning, or alloying, affect their chemical and catalytic behavior. The ultimate objective is to develop simple, physically transparent, predictive models of chemisorption on these materials. To accomplish these objectives we utilize first-principles Density Functional Theory (DFT) calculations, ab-initio atomistic thermodynamics and kinetic simulations and a slate of experimental techniques to measure geometric and electronic structure of catalytic materials as well as their performance. We envision that these models can guide us in a rapid screening and discovery of efficient multi-component catalysts (e.g., alloys).

FY 2014 HIGHLIGHTS

- i. We have developed a very general and physically transparent framework, grounded in DFT calculations, to systematically study the effects of a perturbation of a metal surface on its chemical activity. This framework allows us to distinguish between various effects, including electrostatic, polarization, and electronic mechanisms. A fairly simple procedure was developed to evaluate independently the different contributions to the perturbation energy.
- ii. This model was utilized to probe the effects of alloying (or the formation of inter-metallic compounds) on the chemical activity of various sites in the alloy. Under these efforts we made the following observations: (a) Experimental measurements of the electronic structure of a number of Pt and Ni alloys along with DFT calculations were used to develop, verify, and validate simple predictive structure-property models relating the local geometric structure of alloy sites to their chemical activity (the strength of interaction with adsorbates). The fundamental advantage of the model is that the chemical activity is predicted based only on physical properties of elements that form the alloy in their unalloyed form, (b) The model was used to screen rapidly through a large alloy space seeking optimal alloy catalysts for a number of chemical reactions, including

electrochemical oxygen reduction reaction in acid and base leading us to the discovery of a few promising alloys for these important reactions.

- iii. We have synthesized and tested a number of Pt- and Ag-based alloys for ORR in acid and base respectively, demonstrated excellent performance of these electro-catalysts. Some of these alloys exhibited the performance that is potentially of commercial significance.

The Physical and Chemical Properties of Nanostructured Mixed-Metal Catalysts

Institution: Texas A&M University
Point of Contact: Li Liu
Email: li.liu@tamu.edu
Principal Investigator: Li Liu
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Overall Research Goals and Specific Objectives for the period 1/1/14-12/31/14 The main targets of this study has been to synthesize well-defined nanoparticles of Pt and Ni as well as mixed-metal nanoparticles on different substrates, including ultrathin oxide surfaces, graphene moiré structure, and hexagonal boron nitride pore-wire structures (h-BN) grown on refractory metals. Graphene moiré structure and h-BN substrates provide periodic and identical nucleation sites for metal particle formation. The focus of the research is an understanding of the effects of metal-substrate interactions on the structure/stability of nanoparticles and the effects of particle size and overall surface composition on their catalytic activity. The reactions we focused on were light alkane dehydrogenations. DOE Interest and Potential Impact: New strategies for the synthesis of well-defined nanostructured catalysts that are highly stable toward reaction conditions and thermal-induced sintering are necessary for the development of highly dispersed, size-limited catalysts for new catalytic applications. The development of *in situ* methods for characterizing the morphology of nanocatalysts and the surface species formed during reaction are keys to the ultimate synthesis of practical commercial nanocatalysts. These key issues are central to the proposed work.

FY 2014 HIGHLIGHTS

1. 'Graphene cover-promoted metal-catalyzed reactions' PNAS 111 (2014) 17023-17028 (collaborative project). Institutional Contributions: Texas A&M University:TPD, PMIRAS, and reaction kinetics Dalian Institute of Chemical Physics:LEEM Lawrence Berkeley National Laboratory: High pressure XPS Rensselaer Polytechnic Institute: DFT simulation
2. Dehydrogenation of n-hexane over sub-nanometer Ni particles (manuscript submitted) Conversion of n-hexane in the presence of hydrogen was studied on a series of model Ni/SiO₂ catalysts having an average Ni particle size from 1.1 nm to 5.5 nm. The model catalysts were prepared by vapor depositing Ni onto a planar SiO₂ film. It was found that over small (< 2 nm) Ni particles the principal reaction that occurs during n-hexane conversion at 673K was dehydrocyclization to benzene, whereas over larger Ni particles hydrogenolysis to methane and ethane is the predominant reaction. The effects of reactant partial pressures on product distributions and on the formation of carbonaceous deposits were also studied.

Supported Organometallic Complexes: Surface Chemistry, Spectroscopy, Catalysis, and Homogeneous Models

Institution: Northwestern University
Point of Contact: Tobin Marks
Email: t-marks@northwestern.edu
Principal Investigator: Tobin Marks
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$63,000 (2014)

PROGRAM SCOPE

Many important yet poorly understood catalytic reactions involve the creation and transformations of metal-hydrocarbyl, -hydride, -alkylidene/alkylidyne, and π -complexes on solid surfaces. An informative means to investigate these species and, by doing so, to create new or and/or improved homogeneous and heterogeneous catalysts, is via chemisorption and characterization, under controlled conditions, of structurally precise organometallic precursors on reactive surfaces having well-understood chemical and structural properties. For certain classes of metal hydrocarbyls, chemisorption on high surface area oxides is known to be accompanied by dramatic catalytic activity enhancements vs. their behavior in solution, and the origin of these effects is poorly understood. Under DOE support, we have explored catalytic processes at the homogeneous/heterogeneous interface, probing how (catalyst)-surface, (catalyst)-weakly interacting ligand group, and (catalyst)-catalyst interactions afford new, instructive, and useful reactivity. The focus on chemisorbed groups 4, 5, and f-element organometallics has moved from relatively simple oxides, to “super Brønsted acid” surfaces which create very electrophilic and reactive species in high densities (up to 100% active sites). Integrated product, *in situ/operando* spectroscopic, and mechanistic studies probe chemisorption pathways, adsorbate structures, catalytic reactions (scope, selectivity, kinetics, isotopic labeling, active site counting, etc.), and the energy storage properties of polyolefin/ferroelectric oxide composite materials prepared by this chemistry *in situ*. In parallel, homogeneous chemistry has focused on models for isolated and adjacent adsorbed species, moved to encompass group 10 metals, investigated the effects of weak interactions such as ion-pairing and proximate ligand substituents, (catalyst center)⁺(catalyst center) cooperative effects, and new catalytic transformations.

FY 2014 HIGHLIGHTS

The goal of this interdisciplinary homogeneous-heterogeneous catalytic research effort is to model, understand at a fundamental level, expand, and exploit the unique pathways by which organometallic molecules of varying nuclearity undergo chemisorptive activation and dramatic catalytic activity enhancement on solid surfaces. These processes connect to real-world, large-scale industrial hydrocarbon processes and to manufacturing cleaner, greener, more environmentally acceptable products, including those from sustainable resources. The research effort combines catalyst synthesis, surface chemistry and spectroscopy, homogeneous analogue catalysis, structural analysis, and computation, and involves collaboration with U.S. national laboratories and U.S. industry. Highlights over the past year included: 1) Investigated mononuclear and binuclear organometallic chemisorption on “super Brønsted acid” oxides, thereby elucidating their structures and the mechanisms by which these unusual, highly electrophilic species effect distinctive catalytic polymerization and hydrogenation processes, 2) Designed, synthesized, and characterized mononuclear and polynuclear catalyst precursors for the above chemisorption, and compared those catalytic properties to the same species in

homogeneous solution. Showed that adsorption on the super acid surfaces creates more electrophilic, less heavily ion-paired catalysts. 3) Computationally modeled both the chemisorbed catalysts and their reactivity/selectivity modalities, showing the importance of the surface in dispersing negative charge. Argued that the surfaces come very close to the “holy grail” of the ultimate non-coordinating anion. 4) Employed this information to design and catalytically produce new types of nanocomposite energy storage materials with very high charge storage capacity.

Atomic-Scale Design of Metal and Alloy Catalysts: A Combined Theoretical and Experimental Approach

Institution: Wisconsin-Madison, University of
Point of Contact: Manos Mavrikakis
Email: manos@engr.wisc.edu
Principal Investigator: Manos Mavrikakis
Sr. Investigator(s): Younan Xia; Georgia Institute of Technology
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$620,000 (2014-2016)

PROGRAM SCOPE

The first-principles design of heterogeneous catalysts can produce novel materials with significantly enhanced catalytic properties. Using state-of-the-art density functional theory (DFT) methods in conjunction with reactivity experiments and microkinetic modeling, we determine the detailed reaction mechanism of catalytic reactions of interest. By investigating these reactions over a series of monometallic surfaces, we elucidate reactivity trends which allow the identification of key reactivity descriptors. These descriptors are then utilized in the design of alloy catalysts that are predicted to have high activity and selectivity toward desired products. Because catalytic reactions are generally sensitive to the specific composition and geometric arrangement of atoms at and near the surface of the catalysts, these catalytic reactions can benefit tremendously by advanced inorganic synthesis methodologies delivering the theoretically predicted optimal nano-architecture of the catalytic nanoparticles. The novel catalysts synthesized with these methods are subsequently characterized and evaluated through a variety of state-of-the-art experimental methods.

FY 2014 HIGHLIGHTS

In a nutshell, our research combines quantum mechanical design at the atomic scale with advanced inorganic synthesis techniques to yield catalytic nanoparticles of controlled size and shape, characterized by improved activity and selectivity for targeted vapor phase and electrocatalytic reactions. We have made considerable progress toward our goals during this past year. In particular, we have made great strides in understanding fundamental aspects of: (1) complex metal/metal oxide interfaces, which are important for most heterogeneous catalysis in general, and in particular for the water gas shift reaction and the preferential oxidation of CO in hydrogen, (2) metal alloy catalysts, particularly for electrocatalytic reactions such as the oxygen reduction reaction (ORR) and methanol electro-oxidation, (3) new methods for the synthesis of size- and shape-selected monometallic and alloy nanocrystals as optimized catalysts.

Investigations of C-H Bond Activation and Doped Metal Oxide Catalysts

Institution: California-Santa Barbara, University of
Point of Contact: Eric McFarland
Email: ewmcfar@engineering.ucsb.edu

Principal Investigator: Eric McFarland
Sr. Investigator(s): Horia Metiu; California-Santa Barbara, University of
Michael Gordon; California-Santa Barbara, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$580,000 (2014-2016)

PROGRAM SCOPE

The goals of our research are: to improve the catalytic performance of complex metal oxides by chemical modifications such as doping with different anions or cations; to achieve a more thorough understanding of the basic mechanisms of catalytic processes on doped oxide surfaces; to discover new catalysts for alkane conversion to more valuable chemicals; to develop a broad theory-based framework in which hydrocarbon reactions with these catalysts may be more generally understood. The aim is to find catalysts that can operate under the conditions present in industrial reactors and that might be economically competitive with the commercial catalysts.

FY 2014 HIGHLIGHTS

During the last year of work we have completed a number of theoretical and experimental studies. In trying to understand why molten lithium chloride supported on MgO is one of the best performing ethane oxidative dehydrogenation catalysts, we are able to rule out LiOCl, LiO₂ and Cl₂(g) as oxidative intermediates using ab-initio molecular dynamics. In studies of the reactivity of vanadium pentoxide (V₂O₅) as an oxidation catalyst, possible surface reconstructions have been overlooked, which artificially increase the chemical reactivity of the (100) and (001) surfaces. Using DFT we found reconstructions for both surfaces. Based on oxygen vacancy formation energies, we now estimate the reactivity of the surfaces to be much closer to the stable exfoliation (010) surface. We previously reported ruthenium doped ceria to be active for CO₂ methanation. Further work has given insight into the mechanism of the reaction. We have shown that CO₂ methanation takes place through surface carbonate intermediates and depends on the degree of reduction of the ruthenium-doped ceria catalyst. Two component systems of catalysts and metal oxide reactants were explored for producing propylene from propane (and generally any alkane dehydrogenation) in yields above those possible by thermal dehydrogenation alone. Platinum- or chromium- based catalysts and copper or bismuth based selective hydrogen combustion solid oxides were explored. These material systems are potential drop-in replacements for existing propane dehydrogenation infrastructure. In new experiments, we built a molten lithium iodide salt reactor system for propane oxidative dehydrogenation and achieved the highest reported propylene yields from propane for any ODH catalyst. The addition of bromine to the melt has profound influence and, in the gas phase, iodine appears to facilitate the conversion of HBr and oxygen to bromine and water.

Selectivity Control through Modification of Metal Catalysts with Organic Monolayers

Institution: Colorado, University of
Point of Contact: J. William Medlin
Email: will.medlin@colorado.edu
Principal Investigator: J. William Medlin
Sr. Investigator(s): Daniel Schwartz; Colorado, University of
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 1 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

The overall goal of this work is to investigate the use of organic self-assembled monolayers as modifiers for supported metal and metal oxide catalysts. By tailoring the properties of the monolayer-forming species, one can control both the surface and near-surface environment to improve chemoselectivity in key reaction chemistries. A combination of catalyst screening experiments and surface vibrational spectroscopy is being used to understand mechanisms by which monolayers can influence catalyst activity and selectivity in several probe reactions.

FY 2014 HIGHLIGHTS

In recent work, we have shown that self-assembled monolayers can have at least three effects that profoundly influence catalytic activity and selectivity on late transition metal surfaces: (1) steric interactions, where the crowding by the monolayer allows only certain reactants or reactant conformations to reach the surface; (2) active site selection, where the monolayer blocks particular types of surface sites that are associated with undesired reactions; and (3) molecular recognition, in which interactions between the reactant and monolayer in the near-surface environment favor binding of the reactant in specific configurations. These mechanisms have been demonstrated for a number of key reaction chemistries, including hydrodeoxygenation of biomass-derived compounds, hydrogenation/isomerization of olefins, and hydrogenation of unsaturated aldehydes. Most recently, we have investigated factors that control monolayer stability, and have demonstrated strategies (such as cross-linking between monolayer ligands) that enhance the stability of organic films under reaction conditions.

Synthesis and Exploratory Catalysis of 3D Metals: Group-Transfer Reactions, and the Activation and Functionalization of Small Molecules Including Greenhouse Gases

Institution: Pennsylvania, University of
Point of Contact: Daniel Mindiola

Principal Investigator: Daniel Mindiola
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$380,000 (2014-2016)

PROGRAM SCOPE

Our research program has developed synthetic entries to molecular examples of well-defined vanadium and titanium nitrides given their implications in important transformations such as the dehydrogenation of alkanes. We have found that deprotonation of the parent titanium imido (^{tBu}nacnac)Ti≡NH(NtolyI₂) (^{tBu}nacnac⁻ = [ArNC^tBu]₂CH; Ar = 2,6-iPr₂C₆H₃) with KCH₂Ph forms the molecular titanium nitride anion as a dimer, {[K][(^{tBu}nacnac)Ti≡N(NtolyI₂)]}₂. From the parent imido or nitride salt, the corresponding aluminylimido–etherate adduct, (^{tBu}nacnac)Ti≡N[AlMe₂(OEt₂)](NtolyI₂), can be isolated and structurally characterized. The parent imido is also a source for the related borylimido, (^{tBu}nacnac)Ti=NBt₂(NtolyI₂). Other reactivity of the nitride or parent titanium imide will be presented as well as new ligand scaffolds (such as a phosphine-anilide) that can potentially support the terminal nitride or nitridyl ligand on titanium.

FY 2014 HIGHLIGHTS

During this period our group discovered synthetic entries to molecular complexes of vanadium and titanium nitrides. We performed mechanistic studies to try and understand the process to formation of terminally bound vanadium nitrides. In addition the reactivity of the vanadium nitride ligand has been explored via one- and two-electron reductants whereby the nitrido ligand acts as a conduit for electron transfer. We have also discovered routes to the first examples of well-defined titanium nitrides (in the form of nitride anions), via deprotonation of a parent imido ligand bound to titanium. Salt elimination reactions have allowed us to prepared new ligand scaffolds on titanium, and we have presently found a direct route to titanium nitrides complexes supported by a robust phosphino-anilide ligand.

Surface Chemical Studies of Gold Model Catalysts

Institution: Texas-Austin, University of
Point of Contact: Charles Mullins
Email: mullins@che.utexas.edu
Principal Investigator: Charles Mullins
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Gold nanoparticles have shown remarkable properties in catalyzing environmentally-important and industrially-relevant chemical reactions under relatively mild conditions. We are studying surface chemical reactions on model gold catalysts using ultrahigh vacuum surface science techniques as well as batch reactivity measurements at pressures between 1 and 100 Torr. We employ two major surface catalytic themes regarding the chemistry of these model gold surfaces that build on our experience from the recent past: (i) reactions of adsorbed hydrogen atoms with other relevant molecules on single crystalline gold samples in an ultrahigh vacuum environment and (ii) oxidation reactions on gold surfaces populated by nanoparticles of metal oxides (i.e., inverse model catalyst) at pressures between ~1-100 Torr in a batch reactor as well under ultrahigh vacuum conditions. We will physically characterize these model catalyst surfaces employing several surface sensitive tools. For chemical characterization, we will employ molecular beam surface scattering techniques, temperature programmed reaction spectroscopy, infra-red vibrational spectroscopy, density functional theory calculations (via a collaboration with Professor Graeme Henkelman), and higher pressure (1-100 Torr) batch catalytic measurements on our gold model catalyst surfaces. We will synthesize our inverse model gold catalyst surfaces employing a simple reactive physical vapor deposition technique on the Au(111) substrate. We expect that the proposed research will impact, more generally, the fundamental understanding of gold catalytic chemistry.

FY 2014 HIGHLIGHTS

We published six archival journal articles describing our experimental findings during this one year period. We also have created a new laboratory for conducting catalytic measurements on high surface area catalysts at atmospheric pressure via a flow reactor along with the necessary physical characterization measurements. This area of catalysis science is new to my group and the studies will complement the measurements that we make in ultrahigh vacuum employing single crystalline samples.

We are currently making measurements of vanadia supported gold catalyst for the water-gas shift reaction.

EARLY CAREER: Room Temperature Electrochemical Upgrading of Methane to Oxygenate Fuels

Institution: Connecticut, University of
Point of Contact: William Mustain
Email: mustain@engr.uconn.edu
Principal Investigator: William Mustain
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

With recent discoveries of vast amounts of shale methane deposits in Pennsylvania and the Dakotas, and the introduction of renewable biogas to the market, the availability of methane in the United States is at an all-time high. High petroleum prices and an increased emphasis on domestic energy security will make methane-to-fuels (MTF) processes even more important in the near-future than they are today. Current MTF processes are initiated through the steam reforming of methane to syngas ($\text{CO} + \text{H}_2$), followed by catalytic re-reduction of CO by H_2 to hydrocarbon and oxygenate fuels. Unfortunately, steam reforming requires a combination of high temperature (900-1100°C) and large heat requirement, making the process expensive, placing severe stress on materials, necessitating complex heat integration schemes, leading to poor reaction selectivity, requiring expensive gas separation processes and emitting a significant amount of CO_2 . The objectives of this research are to understand the underlying mechanisms for the direct electrochemical conversion of methane to syngas at room temperature, and develop new electrocatalysts that convert methane to methanol at room temperature (T 90%) to overcome the limitations of existing MTF processes. Methanol was selected as the target molecule because it can be used directly as an energy source and it is the primary precursor for the manufacture of many commodity chemicals, making it one of the most produced and important industrial chemicals in the world. However, this project will have far reaching applications, providing a new pathway for the electrochemical synthesis of complex oxygenates and long-chain hydrocarbons through the formation of new C-O and C-C bonds.

FY 2014 HIGHLIGHTS

In the past fiscal year, our team has taken several important steps forward. In this past fiscal year, the team has shown that our system is able to synthesize all of the targeted oxygenates: methanol, formaldehyde, and CO. The team has also demonstrated that the oxygenate selectivity can be controlled with the operating voltage (anode potential) as well as temperature. It was found that temperature is a more important parameter than initially thought, and methanol production increases considerably when the temperature is elevated above its boiling point, most likely related to its adsorption strength, and controlling the water balance in the cell is also very important. The team has made several key cell innovations that have improved performance, which in this case is the rate of oxygenate formation – including obtaining new commercial and custom membranes and optimizing catalyst composition. This project has also had a broader impact on our group and effort. In the past year, we expanded our effort and have started collaborating with Chinbay Fan's group at GTI for cell and process scale up. The team has also found that given alternative anode catalysts, our system is an efficient electrochemical concentrator and CO_2 compressor; some work has been put into proof of concept of this device. There

has also been an unexpected synergy with the NiO/ZrO₂ composite materials that are core to this project and some energy storage work going on in our group; in short, we have used the new structures formed in this Early Career project to improve the performance of metal oxide Li-ion batteries.

Water Splitting by Thin Film Metal-Oxo Catalysts

Institution: Harvard University
Point of Contact: Daniel Nocera
Email: dnocera@fas.harvard.edu
Principal Investigator: Daniel Nocera
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$209,000 (2014)

PROGRAM SCOPE

The scope of this project is to elucidate the mechanism of the oxygen evolution reaction (OER) by catalysts comprising self-assembled, the metal oxidic films (M-OEC catalysts). We have examined catalysts comprising the metals Mn, Ni and Co and have sought to uncover the chemical principles that underlie the electrodeposition of M-OECs and their mechanism of action in neutral or near neutral conditions. The project scope entails experiments aimed at addressing eight questions: (1) what are the mechanistic pathways for oxygen evolution mediated by M-OEC thin films; (2) what are the mechanistic pathways that govern the facile electrosynthesis of M-OECs; (3) how does charge and mass transport occur through electrodeposited films of these catalysts; (4) what are the periodic trends that underpin efficient OER catalysis; (5) can the metal ion composition of the OEC be used to systematically control activity, selectivity, and mechanism for the OER; (6) what is the role of proton-coupled electron transfer (PCET) in enabling efficient OER catalysis at intermediate pH; (7) how does the pH and electrolyte composition impact catalyst stability; and (8) can favorable equilibria be established such that OEC materials heal themselves. All of these questions bear particular relevance to the preparation, efficient operation, and longer-term stability of new water splitting catalysts.

FY 2014 HIGHLIGHTS

We continue to meet the goals of the program with the accomplishments described below for catalysts comprising the metals Mn, Ni and Co. Cobalt catalysts: Differential Electrochemical Mass Spectrometry (DEMS) and in-situ isotopic labeling studies have been performed to shed light on the microscopic oxygen formation step in OER by Co-OEC. The major OER pathway involves coupling of terminal oxygens, which are supplied from water solvent and the minor pathway involves coupling of ¹⁸O atoms present within the Co-OEC catalyst to terminal ¹⁶O from water. Synchrotron-based grazing incidence X-ray diffraction (GID) reveal that the Co-OEC films are composed of uniformly stacked nanoparticles of the catalyst. Motivated by the recent reports of Co cubanes behaving as WOCs we undertook OER studies and showed that the OER activity is not due to the cubane but rather to Co(II) impurities, which form the Co-OEC. A second important conclusion of this study is that when glassy carbon electrodes are used as anodes in OER studies, degradation of the electrode surface to form CO₂ can occur. Manganese catalysts: An active Mn-OEC has been developed for strong acid solutions by defining the nucleation and growth kinetics rate law as compared to the OER rate law. At pH = 0, the OER potential is sufficient to ensure that the catalyst will nucleate and grow (i.e., self-heal) thus delivering the first acid stable OER catalyst using non-critical materials. The mechanism of Mn-OEC electroactivation has been defined. It involves a comproportionation of MnO₂ and Mn(OH)₂ to produce Mn₂O₃ or Mn₃O₄. Nickel catalysts: We

have elaborated the OER mechanism of Ni-OECs by using high-energy X-ray scattering and pair distribution function analysis to identify the structure of the activated catalyst definitively and used this data together with DEMS data to provide insight into the mechanism of the O₂ formation process itself.

Catalytic Applications of H Atom Transfer from Transition-Metal Hydride Complexes

Institution: Columbia University
Point of Contact: Jack Norton
Email: jrn11@columbia.edu
Principal Investigator: Jack Norton
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

The goal of the project is to understand how transition-metal hydrides are regenerated from transition-metal compounds and hydrogen. We have shown that, in the presence of trityl radicals (Ar₃C•), a cobaloxime (CoII) reacts with H₂ to generate a species capable of transferring H• to those radicals. We are studying at high H₂ pressures the equilibrium for H₂ addition to cobaloximes, trying to characterize the species responsible for H• transfer. We will look for H/D exchange between hydrogen gas and the O-H-O hydrogen bonds in Co(dmgh)₂. Investigating whether chromium radicals CpCr(CO)₃• can catalyze H₂/D₂ exchange will help us test the mechanism we have proposed for the activation of dihydrogen by chromium radicals. We will also test a related hypothesis, that the sterically encumbered (C₅Ph₅)Cr(CO)₃• cannot cleave H₂. We have shown that the V-H bond is weak enough to be a good H• donor. However, the weakness of that V-H bond makes it difficult for •V(CO)₄(P-P) to cleave H₂. We will attempt to reduce •V(CO)₄(P-P) in the presence of weak acid and thus to regenerate V-H.

FY 2014 HIGHLIGHTS

Axial ligands have effects on the ability of cobaloximes to generate transferable H atoms from H₂. An active cobaloxime catalyst contains one and only one axial ligand. Co(dmgbF₂)₂ will coordinate only one Ph₃P; the addition of additional Ph₃P (beyond 1 equiv) to a solution of Co(dmgbF₂)₂ does not affect its turnover in catalyzing H• transfer from H₂. We have examined the UV-vis spectra of Co(dmgbF₂)₂ in CH₃CN under hydrogen pressures up to 70 atm; a Co(I) compound with an exchangeable proton is eventually formed. We have determined the bond dissociation free energy and pK_a of the cobaloxime-H bond in that new Co(I) compound to be 50.5 kcal/mol and 13.4, respectively, in CH₃CN, in agreement with previous reports.

Templating Routes to Supported Oxide Catalysts by Design

Institution: Northwestern University
Point of Contact: Justin Notestein
Email: j-notestein@northwestern.edu
Principal Investigator: Justin Notestein
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$100,000 (2014)

PROGRAM SCOPE

Supported oxide catalysts constitute a large and important family of catalytic materials, and they are applied to a number of fuel- and energy-relevant areas, such as the production of energy-intensive basic chemicals and feedstocks from biomass or petroleum crudes, emissions controls needed in automotive and power generating stations, and in upgrading fuels or synthesizing fuel additives. This program on 'Templating Routes to Supported Oxide Catalysts by Design' seeks to understand and control the design rules for oxide-oxide interfaces so that more active and selective catalysts may be synthesized and used to solve pressing energy needs. The program encompasses three areas: 1) developing new methods to quantify and then to increase the number of active species in a mixed oxide catalyst sample, 2) developing new methods into hard-to-synthesize catalyst morphologies from pre-built cluster precursors, and 3) developing new classes of catalyst materials via nanocavity oxide supports. These three areas target gaps in our knowledge of atomically-precise syntheses and the resulting synthesis-structure-function relationships, specifically where the catalytic oxides cannot be adequately described as either isolated cations transition or extended crystallites. It is in this range of compositions that catalytic activity is strongly dependent on the catalyst atomic structure, and also where there are the greatest opportunities for developing new or better controlled reactivity. This program seeks to give researchers new methods of atomically-precise synthesis and tools to make quantitative comparisons of catalyst syntheses and thus to rationally develop new materials. These techniques promise better control of these catalysts at the atomic scale, which in turn offers to improve the efficiency of these processes and to lead to new catalysts required for the evolving energy and fuels landscape.

FY 2014 HIGHLIGHTS

Four areas of supported oxide catalysts were advanced in FY 2014. First, building off prior BES-supported work, we demonstrated novel FeO_x-ceria catalysts with improved performance in the reduction of NO, as relevant for emissions treatment, and developed corresponding quantitative structure-reactivity correlations. (Applied Catalysis B). In a related approach, we showed that that highly dispersed TiO_x, TaO_x, or MoO_x on alumina improve Pd-catalyzed denitrogenation (Catalysis Letters), as relevant for the processing of hydrocarbon fuels. In parallel, we then developed two related techniques where phenylphosphonic acid chemisorption quantifies a) the number of solvent-accessible TiO_x in mixed oxides (J. Catalysis) and b) the subset of these that are undercoordinated and therefore participate in oxidation reactions (ChemCatChem). These are the first studies to directly give the active fraction of sites in a mixed oxide Lewis acid catalyst, and we showed that the fraction of TiO_x participating in the reaction could be as low as 20% of those that were physically accessible to reactants. We have begun exploration of a novel cluster precursor to supported CuO_x catalysts, and in preliminary work, it has demonstrated unusual activity in NO reduction and cyclohexane oxidation. Finally, we have leveraged our prior demonstration that 1-2 nm nanocavities in an alumina film on titania impart reactant selectivity to photocatalytic oxidations and reductions. Here we selectively photodeposit Ag nanoparticles on the titania domains in a silica-on-titania material, resulting in smaller, more monodisperse nanoparticles than for controls. The nanostructure of these materials also eliminated significant sintering of the Ag, a key parameter for practical catalyst implementation. (Chemistry of Materials)

Catalytic Growth of Molecular-Scale Wiring

Institution: Columbia University
Point of Contact: Colin Nuckolls
Email: cn37@columbia.edu

Principal Investigator: Colin Nuckolls
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The goal of this proposal is to develop catalytic methods for the synthesis of carbon-based nanoelectronic materials. This is a field that is currently limited by the dearth of methods available to cleanly produce atomically defined materials such as carbon nanotubes and graphene ribbons. This proposal tests the hypothesis that ring-opening alkyne metathesis polymerization (ROAMP) can serve as the basis for creating an entire class of new electronic materials. The importance to the Department of Energy and its mission is three-fold. First, the science in this proposal will develop new methodology that will expand the tool kit of catalytic processes and will apply what is learned to problems in Materials Science. Second, this approach will afford tailorable materials useful in nanoscale charge-transport applications such as highly efficient solar cells, single molecule devices, and light emitting diodes. Third, because many of these types of molecules proposed here are unknown (as are the methods to form them), there is potential to discover previously unknown physical phenomena that could have broad impact.

FY 2014 HIGHLIGHTS

This work has been focusing on application in biological labeling.

- i. We have had several important “firsts”. We have developed the first example of a living ROAMP reaction.
 - ii. Further shown that multidentate ligands in the form of salicylimine ligands create more well-behaved living polymerizations.
 - iii. Building from these studies, we recently developed the first new bench stable catalytic system that is able to effect the ROAMP reactions in protic solvents such as methanol and water.
 - iv. We have also begun a detailed mechanistic study of the ROAMP reaction of a dibenzocyclooctadiyne derivative reaction, and have identified a metallotetrahedrane intermediate in the reaction.

Reactivity & Structural Dynamics of Supported Metal Nanoclusters using Electron Microscopy, In-Situ X-Ray Spectroscopy, Electronic Structure Theories, & Molecular Dynamics Simulations

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Ralph Nuzzo
Email: r-nuzzo@illinois.edu
Principal Investigator: Ralph Nuzzo
Sr. Investigator(s): Anatoly Frenkel; Yeshiva University
Judith Yang; Pittsburgh, University of
John Rehr; Washington, University of
Students: 5 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$640,000 (2014)

PROGRAM SCOPE

In a program of collaborative research, we will develop quantitative understanding of the complex dynamical attributes of the atomic and electronic structures of supported metal-cluster catalysts as they exist under operando conditions. We will focus on supported mono- and bimetallic clusters in sub- to 5nm size range. Our goals are: 1) Unveiling the correlations between dynamic structure, electronic properties, and reactivities in nm-scale catalysts; and 2) Development of new analytical methodologies that will test and validate advanced techniques enabled by the NSLS-II synchrotron at Brookhaven National Laboratory and theory-directed means of computational modeling. We will advance the capabilities of spectroscopic, diffractive, and imaging methods based on electron and X-ray probes as well as the time, length, and energy scales required by theory in order to provide predictive simulations, work enabling a new set of unified capabilities for operando characterization. Our work will provide new methodologies for investigating catalysts at work, overcoming limitations in analytical methods that have historically made the characterization of complex materials structures and chemistries over the entangled lengths scales that are important in mechanisms of catalysis extremely challenging. The key focus of our work will be to develop an integrated multiplatform combination of spectroscopy, imaging and scattering methods for use in studies of catalytic reactions carried out under operando conditions. To support the development of a directly-coupled theoretical framework, we will investigate factors affecting the flow of charge between the metal atoms and adsorbates, and the correlations that exist between these factors. Finally, we will examine mechanisms of selected prototypical catalytic reactions. The main result of the entire project will be the benchmarking of a new, state of the art capability for use in mechanistic studies of complex catalytic systems.

FY 2014 HIGHLIGHTS

We have made significant progress in the multidisciplinary efforts to understand the nature of the atomic scale structure and dynamics of nanoscale catalysts. Foremost in this regard is the progress made in our collaborative efforts to establish a validated toolset for the characterization of the nanoscale materials that are found ubiquitously in heterogeneous catalytic processes.

- 1) A. Frenkel and R. Nuzzo have demonstrated the utility of advanced XAS and XES spectroscopies (HERFD and RIXS) as a means through which the complex microscopic attributes of electronic charge distributions in a catalyst, and the mechanisms through which environmental conditions (e.g. temperature and pressure) modify them, can be understood—and further developing new theoretical frameworks for their analysis (together with J. Rehr).
- 2) J. Rehr, A. Frenkel and R. Nuzzo have highlighted the role of first principle simulations (DFT/MD-based) theory in obtaining the links that exist between multiple components of a catalytic system

(e.g. the precise atomic structure of a catalytic cluster, of a supporting oxide, and the bonding patterns of adsorbates) and the properties that are exhibited under reaction conditions.

- 3) J. Yang and R. Nuzzo developed quantitative methods of electron microscopy (e.g. QSTEM, for shape determination in supported metal catalysts and EELS, for studies of catalyst-support interface) that are complementary in nature to XAS-based measurements and provide important single-cluster-specific constraints to theory.
- 4) A. Frenkel and R. Nuzzo have applied XAS *in operando*, to investigate features relevant to catalytic properties, work that includes investigation of temperature and pressure dependent bonding dynamics of supported metal-cluster catalysts to adsorbates and an investigation of structural complexities and reconstructions of the catalysts evidenced in the hydrogenation of ethylene.

Atomic Level Studies of Advanced Catalysts for Hydrodeoxygenation

Institution: Virginia Polytechnic Inst. and State U.
Point of Contact: Shigeo Oyama
Email: oyama@vt.edu
Principal Investigator: Shigeo Oyama
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

The utilization of biomass for the production of fuels and chemicals is currently an area of great activity because of the recognition that fossil fuels are a finite resource and because of the imminent threat of global warming from the release of carbon dioxide. Biomass pyrolysis has great potential for the production of drop-in replacements for petroleum products, but the pyrolysis oil product has low heating value and stability and high corrosivity, and improvements are needed. This project involves the development of advanced hydrodeoxygenation (HDO) catalysts to reduce the oxygen content of the oil. The catalysts that will be developed are a class of highly active and stable materials, the transition metal phosphides. Initial tests in our laboratory and elsewhere have demonstrated that the catalysts are highly effective in oxygen removal from model bio-oil compounds. The specific compounds to be studied are a series of phosphide catalysts (MoP, WP, Fe₂P, CoP, and Ni₂P), as well as advanced bimetallic compositions. The study of bimetallic compositions is motivated by our recent finding that NiFeP has outstanding catalytic properties. The catalysts will be highly dispersed and will be studied by x-ray absorption spectroscopy (XAS). The novel catalysts will be tested with model compounds and the best compositions will be tried in a pilot scale unit with real feeds at realistic pyrolysis conditions. The substrates to be used will be 2-methyltetrahydropyran (2-MTHP) and guaiacol (GCOL), which are respectively models for cellulose and lignin. The work will include detailed studies of kinetics and spectroscopy to understand the mechanism of the HDO reaction and to relate it to the structure of the catalysts in their working state. The overall objective is to obtain information that can be used to improve the catalyst action by understanding the key factors that govern reactivity.

FY 2014 HIGHLIGHTS

Initial studies indicate that the best catalyst is Ni₂P. The temperature dependency of the catalyst activity for 2-MTHF HDO was determined and it was found that at 350°C Ni₂P/SiO₂ showed 100% conversion and 85% selectivity to n-pentane, with higher oxygen removal activity and less C-C bond cracking activity than commercial noble metal Ru/C and Pd/Al₂O₃ catalysts based on the same amount of active sites.

Contact time measurements were used to provide the reaction networks for both 2-MTHF and guaiacol. For 2-MTHF initial ring opening was found to be the rate-determining step and 2-pentanone and n-pentanal were intermediates. For guaiacol phenol HDO was the rate-determining step. Kinetics indicate 2-MTHF and H₂ are competitively adsorbed on surface. Analysis by a rake mechanism showed that 1-pentoxide derived surface species were the most prevalent, and in situ infrared spectroscopy confirmed the predictions.

New Horizons in C-F Activation by Main Group Electrophiles

Institution: Texas A&M University
Point of Contact: Oleg Ozerov
Email: ozerov@chem.tamu.edu
Principal Investigator: Oleg Ozerov
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This project expands a novel approach to activation and functionalization of C-F bonds. The key innovative aspect is the departure from the transition metal paradigm in C-F activation. While the thrust of much of the research in the area of well-defined C-F functionalization is in the direction of using electron-rich transition metal complexes, this project relies on an electron deficient main group catalyst and the process does not involve redox changes. Carbon-fluorine bonds are among the most robust functionalities in chemistry owing to their thermodynamic stability and kinetic inertness. Activation of C-F bonds is thus a fundamental challenge of note. It is also often viewed through the prism of remediation of polyfluoroorganic atmospheric pollutants such as chlorofluorocarbons (CFC), hydrofluorocarbons (HFC), and perfluorocarbons (PFC), all of which are very potent greenhouse gases. They are entirely anthropogenic and their sources (as waste) include some key industries, such aluminum, magnesium, and semiconductor production. Our chemistry utilizes highly reactive main group cations (silylium R₃Si⁺ or alumenium R₂Al⁺), or their closest approximation in solution, that engages the fluorine atom in the critical C-F cleavage step. The overall process is a conversion of a C-F bond into a C-H bond (hydrodefluorination or HDF) or into a C-Alkyl bond (alkylative defluorination, or AlkDF).

FY 2014 HIGHLIGHTS

In FY 2014, we focused on three directions. In one, preparative methods for the syntheses of substituted carborane anions continued to be improved. We prepared new derivatives of the RCB11Cl11 anion with different R groups for improved solubilities. In the second, the synthesis of fluorinated triphenylmethyl cations was pursued. We identified these cations as promising activators of X₃SiH silanes where X is a more electron-withdrawing group than a simple alkyl. Practical isolation of these highly reactive species as pure salts has proven challenging, but preliminary indications point to the viability of at least partially fluorinated triphenylmethyl cations. In the third direction, synthesis of triarylaminium salts with carborane anion partners was pursued. Halogenated triarylaminium cations were identified as promising strong one-electron oxidants that may be of wide general use, and of interest within the specific aims of our project as activators of disilanes by oxidation to silylium cations. We have been able to prepare well-defined triarylaminium-carborane salts with aminiums possessing redox potentials of +1.1V and higher vs ferrocene/ferrocenium. Some of this work was carried out by graduate students supported by either

private industrial funds or by a grant from the (private) Welch Foundation, which shares some of the goals with respect to highly reactive cations with the DOE project.

Heteroatom-Doped Carbon Materials as Oxygen Reduction Electro-Catalysts in Acidic and Alkaline Media

Institution: Ohio State University
Point of Contact: Umit Ozkan
Email: ozkan.1@osu.edu
Principal Investigator: Umit Ozkan
Sr. Investigator(s): Aravind Asthagiri; Ohio State University
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

The project is a systematic investigation of the heteroatom-doped carbon structures as electro-catalysts for oxygen reduction reaction (ORR) in acidic and alkaline media, using fundamental approaches based on catalysis, electro-chemistry and computational modeling. Oxygen reduction reaction remains as the major cause of efficiency loss in low-temperature energy conversion devices such as proton exchange membrane (PEM), anion exchange membrane (AEM) and direct methanol fuel cells (DMFC), and metal-air batteries, even when precious-metal catalysts are used as the cathodic electrodes. Our work focuses on two classes of heteroatom-doped carbon materials: those that are doped with one or more heteroatoms (e.g., N, P) without having a metal center as part of an active site and denoted as CN_x (CP_x) and those where a metal is part of the doped carbon matrix, denoted as (Me-N-C) where Me is a transition metal such as Fe or Co. The main objective of the project is arriving at a molecular level understanding of the nature of active sites, the material synthesis steps that create these active sites, and the structural/surface characteristics that impart electro-catalytic activity to these materials. The ultimate goal would be to elucidate the mechanistic steps involved in the oxygen reduction reaction and link them to molecular features over these catalysts.

FY 2014 HIGHLIGHTS

Two different classes of non-precious metal oxygen reduction reaction (ORR) catalysts for Proton Exchange Membrane (PEM) fuel cells, namely nitrogen-containing carbon nanostructures (CN_x) and iron-nitrogen co-ordinated catalysts supported on carbon (FeNC) were studied and compared for their activity and stability using both half and fuel cell tests. FeNC catalysts were found to be more active than CN_x catalysts, but the latter were more stable. The effect of acid-washing on the two was also markedly different: FeNC catalysts showed a significant decrease in ORR activity after washing due to leaching away of Fe from Fe-based sites. On the other hand, a marked increase in activity was noted for CN_x catalysts due to removal of inactive metallic particles blocking the active sites along with the non-conductive oxide support. In addition, various surface and bulk characterization techniques such as X-ray Photoelectron Spectroscopy (XPS), Temperature Programmed Oxidation (TPO), X-ray Absorption Near Edge Spectroscopy (XANES), Extended X-ray Absorption Fine Structure spectroscopy (EXAFS), Mössbauer spectroscopy, Transmission Electron Microscopy (TEM) and Superconducting Quantum Interference Device (SQUID) magnetometry were employed to gain key insights into the two classes of materials. We also used H_2S poisoning as a probe to investigate the nature of active sites in FeNC catalysts and compare and contrast the results with those for CN_x catalysts published previously by our group. FeNC catalysts showed a remarkable decrease in their activity when treated with H_2S attributed to poisoning

of Fe-based active sites in these catalysts due to iron-sulfur binding as also confirmed with XPS and EXAFS. These results were in sharp contrast with those for CN_x catalysts where an increase in activity was noted after H_2S treatment probably attributed to an increase in pyridinic-N species which were previously shown to correlate with activity in these materials.

Fundamental Studies of Metal Centered Transformations Relevant to Catalysis

Institution: Columbia University
Point of Contact: Gerard Parkin
Email: parkin@columbia.edu
Principal Investigator: Gerard Parkin
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

The specific objectives and research goals of the project are to obtain information that is relevant to metal mediated transformations that produce useful chemicals from natural resources. For example, considerable effort is currently being directed by researchers towards (1) the implementation of a "hydrogen economy", in which hydrogen serves as a fuel, and (2) the use of ubiquitous carbon dioxide as a renewable carbon source for the synthesis of useful chemicals. However, the practical realization of both of these objectives presents daunting challenges. For example, a principal problem with respect to the utilization of carbon dioxide as a chemical feedstock is concerned with the fact that it is not only thermodynamically a very stable molecule, but it is also kinetically resistant to many chemical transformations. Likewise, the energy efficient storage of hydrogen with a high volumetric energy density is a critical prerequisite to the implementation of a hydrogen economy. The discovery of new catalytic methods for (1) the rapid generation of hydrogen and (2) the functionalization of carbon dioxide are, therefore, crucial for advancing the use of hydrogen as a fuel and for utilizing carbon dioxide as an effective carbon source for commodity chemicals. In addition to improving catalytic efficiency for the above reactions, it is imperative to develop catalysts that do not utilize precious elements that are in short supply, which thereby provides an additional objective of the project.

FY 2014 HIGHLIGHTS

Specific emphasis has been directed towards the discovery of new transformations employing nonprecious metals that are concerned with the reduction of carbon dioxide via bicarbonate, the generation of hydrogen, the disproportionation of formic acid to methanol, and the use of formic acid in transfer hydrogenation reactions. (1) Dehydrogenation, Disproportionation and Transfer Hydrogenation Reactions of Formic Acid Catalyzed by Molybdenum Hydride Compounds: Much recent interest has focused on the use of formic acid as a hydrogen storage medium because it is a liquid at room temperature and, as such, is easy to handle and transport. It is, therefore, of considerable interest to develop more efficient catalysts for the release of dihydrogen from formic acid, which also incorporate earth abundant metals. Indeed, we have demonstrated that a series of cyclopentadienyl molybdenum hydride compounds are catalysts for this transformation. Interestingly, while dihydrogen and carbon dioxide are the primary products of decomposition of formic acid, methanol and methyl formate are also formed. The selectivity for forming methanol/methyl formate relative to dehydrogenation is dependent on the coligands, with the tricarbonyl compound exhibiting the greatest selectivity. The disproportionation of formic acid is a manifestation of a transfer hydrogenation reaction, which has also

been applied to the reduction of aldehydes and ketones. (2) Reduction of Bicarbonate to Formate in Molecular Zinc Complexes: The conversion of carbon dioxide to formic acid and formates has recently received much attention. In addition to the direct reduction of carbon dioxide, the reduction of bicarbonate to formate has also garnered interest due to the fact that bicarbonates are easier to handle than gaseous carbon dioxide. It is, therefore, significant that we have discovered that a zinc bicarbonate complex can be converted to a formate derivative by reaction with phenylsilane.

Controlling Structural Electronic and Energy Flow Dynamics of Catalytic Processes through Tailored Nanostructures

Institution: Central Florida, University of
Point of Contact: Talat Rahman
Email: Talat.Rahman@ucf.edu
Principal Investigator: Talat Rahman
Sr. Investigator(s):
Students: 5 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014)

PROGRAM SCOPE

The research project “Controlling Structural, Electronic, and Energy Flow Dynamics of Catalytic Processes through Tailored Nanostructures” started in a DOE initiative calling for research projects that provide an unconventional approach to the investigation of catalytic processes. Throughout this project we focus on the notion that controlling the dynamics of a catalytic system in a pre-determined fashion may hold the key to fundamental improvements in the efficiency of catalytic reactions. In this context, we consider both the dynamics of reactants, as they undergo chemical transformation at the active sites of a heterogeneous catalyst and our project also strives to highlight the importance of the dynamics of the catalyst, i.e. its constant structural (e.g., morphology, density and nature of surface defect sites) and chemical (e.g., oxidation state of surface atoms, variation in the composition of the surface layer) reorganization during the course of catalyzing a chemical process in a reactive environment. In addition, we believe that control of the flow of energy, typically in the form of electronic excitations, will emerge as an important concept, in particular with regards to photo-activation of catalytic reactions, as set forth in the DOE Catalysis for Energy report. In this context we develop methods for the catalytic growth of MoS₂ monolayers as photon-harvesting components.

FY 2014 HIGHLIGHTS

The main thrust of our joint experimental and theoretical research effort has focused on the chemical/catalytic activity of MoS₂ and its modifications through defects, reconstruction/sulfur loss and adsorbates. We have identified a Mo₂S₃ surface structure that, though meta-stable, can persist in the presence of adsorbates - such as formic acid, anthraquinone, etc. - even at temperatures at which they constantly bind and desorb. This molybdenum-sulfur compound (MoSC) exhibits far higher affinity to adsorbates even than the step edges of MoS₂, suggesting that if MoSC of this or similar composition can form under catalytic conditions, they may actually carry the bulk of the material’s activity. Following this finding, and other work on MoSCs, the question of the origin of the activity of MoSC has gained renewed momentum and scrutiny. We have highlighted the effect of vacancy clusters and alkali dopants (experimentally and theoretically) in controlling the electronic structure of MoS₂. Our theoretical work predicts defect-laden MoS₂ to be chemically reactive. Furthermore, the joint-edges formed between two sheets of MoS₂, also show interesting metallic and magnetic properties. We have also completed a

project on understanding the nature of the reactive sites for methanol decomposition on titania supported Au nanoparticles. In the same vein, to understand further the factors that control chemical reactivity and selectivity for ammonia decomposition on RuO₂(110) under ambient conditions, we have applied our *ab initio* approach for modeling of reaction rates. In the past year, our experimental investigations have applied three sets of strategies: atomic scale imaging, temperature dependent photoluminescence and x-ray absorption spectroscopy, and photoluminescence imaging. These have been complemented by theoretical modeling and simulation of the same systems using *ab initio* electronic structure calculations based on density functional theory (DFT).

EARLY CAREER: Computational Design of Graphene-Nanoparticle Catalysts

Institution: Massachusetts, University of
Point of Contact: Ashwin Ramasubramaniam
Email: ashwin@engin.umass.edu
Principal Investigator: Ashwin Ramasubramaniam
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The overall goal of this project is to develop a systematic computational approach for the rational design of nanoscale transition-metal catalysts supported on graphene, a two-dimensional sheet of carbon atoms arranged in a honeycomb lattice. The use of graphene, as compared to traditional carbon supports, has been experimentally shown to enhance significantly the catalytic activity of metal nanoclusters in fuel cell electrodes. However, there is no clear mechanistic understanding of the role played by graphene supports in improving catalyst performance. This project will develop and implement computational models to understand and predict electronic interactions between transition-metal nanoclusters and graphene supports, taking into account practical complexities that arise from statistical variations in cluster size and morphology, quantum size effects at the nanoscale, and the presence of physical and chemical defects in graphene. Model transition metal/graphene catalysts will be employed for statistical sampling of selected reactions pathways to probe the influence of substrate-cluster interactions on reaction thermodynamics and kinetics. The fundamental understanding gained from these studies could guide the rational design of superior, graphene-supported, transition-metal nanocatalysts with potential applications in energy conversion pathways for alternative fuels.

FY 2014 HIGHLIGHTS

We have made substantial progress in three areas: 1) understanding CO oxidation graphene-supported Pt clusters, 2) establishing thermodynamic pathways for methanol decomposition on Pt clusters, and 3) development of genetic algorithms for global structural optimization of graphene-supported Pt clusters. We performed DFT studies of CO binding on unsupported and graphene-supported Pt clusters using extensive statistical sampling to account for variability in coordination of surface Pt atoms. Defective graphene supports were shown to substantially reduce CO binding energies due to a downshift of the cluster d-band center, which is a direct consequence of strong Pt-C bonds at the defect. We studied CO oxidation on supported and unsupported Pt clusters and found a preferred mechanism without the involvement of adsorbed oxygen precursors. The barriers for this mechanism were found to be lower on defective graphene-supported Pt clusters in agreement with thermodynamic calculations. The results were reported in one journal publication, a PhD thesis, and three conference presentations, with a

second publication in review. DFT studies are now underway to establish the thermodynamic pathways and reaction mechanisms of the full gas-phase methanol decomposition reaction on graphene-supported Pt clusters and establish a direct link with experiments. Separately, we implemented a Genetic Algorithm (GA) to calculate low-energy isomers of supported clusters. As ultra-small Pt clusters do not adopt high-symmetry structures as commonly assumed, a more robust approach for calculating ground-state structures is desirable. Our GA combines inexpensive empirical potentials for initial screening followed by more careful DFT optimization. A noteworthy feature of our GA is that it interfaces directly with the widely used, open-source LAMMPS software. As LAMMPS supports a wide range of interatomic potentials, our approach greatly simplifies portability of the GA to different materials.

Exploiting the Flexibility and the Polarization of Ferroelectric Perovskite Surfaces to Achieve Efficient Photochemistry & Enantiospecificity

Institution: Pennsylvania, University of
Point of Contact: Andrew Rappe
Email: rappe@sas.upenn.edu
Principal Investigator: Andrew Rappe
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

This project applies state of the art quantum mechanical modeling to the study of heterogeneous chemical transformation processes on complex surfaces. Three attributes make this a unique and transformative approach to small molecule heterogeneous photocatalysis for energy and new surfaces for enantiomer separation: 1. The proposed catalysts are new complex oxide alloys whose optical properties have been optimized to enable visible light absorption and excited electron or hole transport to the surface for redox photochemistry. 2. These materials have bulk electric polarization, and the resulting surface charge triggers surface reconstructions that are highly favorable to redox catalysis. 3. The polarization can be reoriented relative to the surface, enabling reversible rumplings, stoichiometry changes, and handedness at the surface. Integrating these positive features, two main projects are proposed: exploring the surfaces of multi-component complex oxides $(A,A')(B,B')O_3$ for photocatalytic splitting of CO_2 and H_2O , and pioneering new surfaces for the separation of racemic mixtures into enantiomers. These projects have the potential to provide efficient chemical fuels from solar energy, and to reduce the costs of medicines and other chiral chemicals.

FY 2014 HIGHLIGHTS

The development of increasingly sophisticated techniques to synthesize and analyze oxide surfaces gives us the ability to engineer surfaces for heterogeneous catalysis. Another critical requirement in this endeavor is a deep thermodynamic and kinetic understanding of surface reconstruction behavior. We explore the reconstruction behaviors of Ti-based perovskite type oxides: $BaTiO_3$, and $PbTiO_3$, which exhibit ferroelectricity. We investigate the effect of their switchable polarization, in addition to the effects of temperature and the chemical potentials of their constituent elements. We find that these oxides undergo surface reconstruction transformations that generally result in enrichment of their catalytically active component (Ti). An applied electric field changes the material's polarization, which then alters the surface electronic properties, and thereby affects their sensitivity towards stoichiometric

changes. We also demonstrate kinetic tunability from a particular surface phase coexistence observed in BaTiO₃, namely the *c*(2×2) and *c*(4×4), where the diffusion behavior of the TiO units that compose both surfaces strongly dictate their degree of agglomeration. Ultimately, we wish to use these well-defined surface reconstructions in heterogeneous catalysis, for example in electrolytic water splitting, or generation of H₂ and O₂ from water using electrical work, which requires two different catalysts. One catalyst enhances oxidation (O₂ evolution reaction), the other enhances reduction (H₂ evolution reaction), and both are expected to perform optimally and stably in the same chemical condition. We studied the interaction of water with a reduced, TiO₂-terminated surface reconstruction of BaTiO₃ containing Ti adatoms using density functional theory. In this study, we found that water could oxidize the undercoordinated surface Ti adatoms through four possible channels: molecular adsorption, dissociative adsorption, acid-base reaction, and oxidative adsorption.

Supramolecular Ensembles in Catalysis

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Thomas Rauchfuss
Email: rauchfuz@illinois.edu
Principal Investigator: Thomas Rauchfuss
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

The project “Organometallic and Catalytic Chemistry of Functionalized Complexes” consists on three subprojects focused on applications of specialty ligands. The program advances the theme that transformations of small molecules are most efficiently catalyzed by complexes of ligands that control redox, proton-transfer, and π -donation. The first project addresses fundamental questions associated with how electron-transfer influences reactions of homogeneous catalysts. We introduce a new redox-active ligands of the type FcCH₂PR₂ where Fc is a modified ferrocene. These ligands are less non-innocent and more easily installed than traditional non-innocent ligands. The second project, which grew from work in the previous contract period, explores the formation and reactivity of a diphosphine-dialkoxide platform derived from coupling of phosphine aldehydes. This study promises to deliver a sterically and electronically novel platform. The third project focuses on an acyl-pyridinol ligand for controlling reactivity of iron hydride. The effort exploits a new route to a close mimic of a cofactor in a biological hydride transfer catalyst and examines associated tautomeric equilibria.

FY 2014 HIGHLIGHTS

We synthesized a new family of RuNi dithiolates featuring geometrically flexible Ni centers that enable both acid-base and redox chemistry, behavior which is characteristic of the hydrogenases. Crystallographic characterization of these compounds revealed short Ru–Ni distance and tetrahedral Ni sites. Variable temperature NMR studies show that the Ni center is rigid. The reduced complexes are highly basic. The mixed valence Ru(II)Ni(I) complex, a structural model for the Ni-L state of the [NiFe]-hydrogenases, was characterized crystallographically, spectroscopically, and in terms of its reactivity. Measurements indicate that these cations are described as Ru(II)–Ni(I). Correspondingly, the neutral precursor is best described as Ru(II)Ni(0). The fast electron self-exchange rate of 107 M⁻¹s⁻¹ between [1]⁰ and [1]⁺ confirms the minor reorganization associated with this redox, consistent with a Ni(0)/Ni(I) oxidation.

PROGRAM SCOPE

The discovery by Haruta more than a decade ago that by co-feeding H₂ with propylene and O₂ and using Au/TiO₂ as the catalyst, one can produce PO with high selectivity provides the potential for a single-step, direct and green solution to this long standing catalytic partial oxidation challenge. Moreover, the catalytic chemistry of this system offers unique opportunities to study the role of *in situ* generated hydrogen peroxide as a selective olefin oxidant and to probe the catalytic properties of nanometer and subnanometer metal particles. We focus here on Au/TS-1 catalysts, which display the improved stability and activity associated with isolated Ti centers, and probed the nature and location of the active Au. Since proximity of Au and Ti is required for the catalysis, the activity of Au on a support made by coating TS-1 with an S-1 shell showed that Au clusters small enough to enter the MFI pore structure are active for PO production. Addition of Au to uncalcined TS-1, the pores of which were still blocked by the template, led to an unprecedented 20 hour activation period. Correlated changes in apparent surface area and other supported data showed that peroxide generated from H₂ and O₂ over the Au particles burned some of the template out of the pores, allowing Au migration to the Ti anchor points that create the active sites in the pores. Analysis of the most active catalysts yet reported, with a rate of reaction of 300 g_{PO} h⁻¹ kg_{cat}⁻¹, showed that the Cs salt used in deposition precipitation of the Au in these catalysts helps to stabilize the small Au particles in the TS-1 pores, thus maximizing the number of stable Au sites. These studies all confirm the importance of Au clusters small enough to enter the TS-1 pore structure as active sites for propylene epoxidation.

FY 2014 HIGHLIGHTS

Recent work has focused on three areas. The first is closure of the work on Au supported on uncalcined TS-1 supports, Au/U-TS-1. The motivation for that work was to force the gold to be deposited on the outer surface of the TS-1 crystallites by blocking the interior pore structure by not removing the template around which the TS-1 structure grows during its synthesis. Second is elaboration of the discovery that the reaction rate of Au/TS-1 can be dramatically enhanced by using Cs₂CO₃ instead of our standard Na₂CO₃ as the pH control agent during the deposition precipitation (DP) of the Au. The third is examination of the effects of the residual Na left from the standard DP process, the Cl left from the chloroauric acid gold precursor, and the method of activation.

Influence of Multi-Valency, Electrostatics and Molecular Recognition on the Adsorption of Transition Metal Complexes on Metal Oxides: A Molecular Approach

Institution: Pennsylvania State University
Point of Contact: Robert Rioux
Email: rioux@engr.psu.edu
Principal Investigator: Robert Rioux

Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)

Funding: \$150,000 (2014)

PROGRAM SCOPE

The synthesis of heterogeneous catalysts is comprised of numerous unit operations, all of which impact the properties (morphology, metal particle size, distribution) of the final catalyst and ultimately its catalytic performance. The absence of knowledge of the molecular details that transforms a transition metal complex (TMC) and support material (metal oxide or carbon) into a functioning catalyst hinders our ability to synthesize catalysts with desired properties (i.e., average particle size and monodispersity). The initial association (or adsorption) of transition metal precursors onto the support surface during catalyst synthesis has received very little attention. We have examined the molecular level details of catalyst synthesis with a significant emphasis on the chemistry that occurs at the solid-liquid interface during the initial adsorption of transition metal complexes. The mechanism (outer-sphere, electrostatic, inner-sphere) by which TMCs adsorb to neutral and charged solid-liquid interfaces will be examined. The objectives of the proposal are (1) to quantify TMC adsorption on charged metal oxide interfaces under electrostatic conditions utilizing isothermal titration calorimetry (ITC); (2) measure and quantify TMC speciation in solution via capillary electrophoresis; (3) assess the kinetics of TMC adsorption at charged interfaces via in-situ streaming potential measurements; (4) quantify molecular recognition and multivalency during inner-sphere adsorption of siloxide-based and organometallic TMCs with ITC; (5) quantify the influence of adsorption mechanism on particle growth and final particle size during pretreatment (drying, calcination, reduction) by synchrotron-based x-ray absorption and scattering. The in-situ approach will provide a direct correlation between the mechanism of TMC adsorption and the pretreatment regime with the overall properties of the final catalyst.

FY 2014 HIGHLIGHTS

We have continued to develop the isothermal titration calorimetry technique to measure the adsorption of solvated transition metal precursors to amphoteric oxides. In collaboration with Tom Mallouk (PSU chemistry), we demonstrated that the final particle size and the dynamics of particle sintering of Rh was correlated to the measured heat of adsorption on Dion-Jacobsen perovskites. Interestingly, the difference in the heat of adsorption is quite small but lead to drastically different final particle sizes after reduction. We have continued this work on perovskites by sampling across the periodic table examining both early and late transition metal precursors. The interactions between Rh and the other transition metals is covalent in nature as previously suggested by XPS and confirmed by x-ray absorption spectroscopy. In a parallel study, we have used ITC and adsorption isotherms of cationic and anionic Pt precursors on silica and alumina as a function of pH; adsorption under this situation is dominated by electrostatic forces. Once again, we have confirmed that the solution conditions during adsorption influences the overall thermal behavior of the catalyst. With the appropriate choice of transition metal precursor, the greater the difference between the solution pH and PZC of the support, the greater quantity of adsorption and the higher the precursor heat of adsorption (normalized per mole). At a maximum pH/PZC difference, there are minimal changes in the quantity of precursor adsorbed, but significant differences in the measured heat of adsorption. This is manifested in significant differences in particle size at comparable surface coverage. The thermodynamics of the precursor adsorption under electrostatic conditions appear to be independent of metal identity, but highly dependent on the inner-sphere ligands. We continue to pursue a quantitative understanding of electrostatic adsorption in order to refine proposed mechanisms.

Lewis Acid Pairs for the Activation of Biomass-derived Oxygenates in Aqueous Media

Institution: Massachusetts Institute of Technology
Point of Contact: Yuriy Roman
Email: yroman@mit.edu
Principal Investigator: Yuriy Roman
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of this project is to understand the mechanistic aspects behind the cooperative activation of oxygenates by catalytic pairs in aqueous media. Specifically, we investigate how the reactivity of a solid Lewis acid can be modulated by pairing the active site with other catalytic sites at the molecular level, with the ultimate goal of enhancing activation of targeted functional groups. A main goal of this work is to devise rational pathways for the synthesis of porous heterogeneous catalysts featuring isolated Lewis pairs that are active in the transformation of biomass-derived oxygenates in the presence of bulk water. Achieving this technical goal requires closely linking advanced synthesis techniques; detailed kinetic and mechanistic investigations with comprehensive characterization studies of both materials and reaction intermediates. Two technical aims are pursued: 1) Coupling Lewis and Brønsted acid sites for enhanced transfer hydrogenation chemistry. Tin- or zirconium-containing zeolites (e.g., Sn- and Zr-Beta) are active transfer hydrogenation catalysts. We demonstrate an integrated catalytic process for the efficient production of gamma-valerolactone (GVL) from Furfural (Fur) via sequential transfer hydrogenation (TH) and hydrolysis reactions triggered by zeolites with Brønsted and Lewis acid sites. 2) Pairing Tin/Borate Lewis acid pairs for the selective epimerization of carbohydrates. When paired with homogeneous Lewis acidic borates, Sn-Beta promotes 1,2 intramolecular carbon shifts in carbohydrates wherein a bond between C-1 and C-3 is formed, with C-1 moving to the C-2 position with an inverted configuration. We perform mechanistic studies interrogating the structure of Sn-O-B-O-Si active site and its interaction with hexoses and pentoses. In addition, the use of dynamic nuclear polarization nuclear magnetic resonance is introduced for the analysis of Sn-containing zeolites prepared with natural abundance ^{119}Sn precursors.

FY 2014 HIGHLIGHTS

- Demonstrated the first example of dynamic nuclear polarization NMR for the characterization of zeolites. Published in JACS 2014
- Performed a detailed kinetic evaluation of the transfer hydrogenation chemistry with solid Lewis acids to produce gamma-valerolactone

Towards Realistic Models of Heterogeneous Catalysis: Simulations of Oxidation Catalysis from First Principles

Institution: Notre Dame, University of
Point of Contact: William Schneider
Email: wschneider@nd.edu
Principal Investigator: William Schneider
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$160,000 (2014)

PROGRAM SCOPE

The primary goal of this program is to develop more robust, validated models of energy-related catalytic reactions at metal surfaces. We focus on the catalytic chemistry of molecular oxygen (O_2), because catalytic oxidations are a central element of environmental catalysis (e.g. of functionalizing feedstocks, of operating fuel cells, or of cleaning the exhaust from an internal combustion engine), and because reliable, quantitative models have been elusive. Noble metals (Pt, Pd, Ag, ...) are the most common metals used for catalytic oxidations, but the detailed mechanisms by which these function, how reaction mechanisms depend on the structure and composition of the catalyst, and how temperature, pressure, or other reaction conditions effect these mechanisms, are not well understood either qualitatively or quantitatively. The objective of this work is to produce a conceptual framework and mathematical models that reliably describe and predict the environment-dependent mechanisms and rates of catalytic reactions of oxygen over a range of catalytic materials. Achieving this objective will facilitate the design and discovery of superior performing, more robust, and less expensive catalysts, as well as provide the insights necessary to more efficiently design and interpret experiments. We use the catalytic oxidation of NO to NO_2 as a relatively simple yet practically important model, but the implications extend outside this particular context. While the focus here is on oxidation catalysis, the methodologies are applicable to any heterogeneous catalysis.

FY 2014 HIGHLIGHTS

Progress in FY 2014 occurred along three primary fronts.

- 1) We reported new applications of our 'coverage-aware' kinetic models. We used our previously published results for oxygen adsorption on Pt to demonstrate a method to reliably predict temperature-programmed desorption spectra. We further extended the oxygen adsorption DFT models to all the late transition metals and used the results to predict the relative rates of NO oxidation over those metals.
- 2) Energies extracted from DFT do not account for the finite temperature effects that contribute to adsorption free energies, and several recent publications suggest that conventional free energy approximations are substantially in error at temperatures relevant to catalysis. To address these problems, we used DFT and statistical mechanics to compute these free energies exactly. Further, we developed an approximate approach that is no more expensive than the methods used today and that provides much more reliable results.
- 3) The models described above are limited to the description of adsorbate chemisorption. Yet it is known that under some circumstances adsorbates can reconstruct surfaces. Predicting the conditions under which such rearrangements happen, and their quantitative impacts on observed catalytic reactivity, remains a significant challenge. We used a cluster expansion approach to discover the evolution of surface structure with O coverage on Pt(111), encompassing both chemisorbed and Pt "reconstructed" adsorbates. The model correctly recovers the chemisorbed structures found before, recovers the O-induced reconstructions previously identified, and discovers new, stable reconstructed forms. This model can now be used as a basis for understanding the kinetics of the surface reconstruction and its decomposition.

The Polymerization of Olefins and Alkynes with New Alkylidene Catalysts

Institution: Massachusetts Institute of Technology
Point of Contact: Richard Schrock
Email: rrs@mit.edu
Principal Investigator: Richard Schrock
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

A major application of well-defined (isolable with designed activities) metathesis catalysts is ring-opening metathesis polymerization (ROMP). We have developed a large number of metathesis catalysts with the object of controlling the stereoregularity of polymers prepared through ROMP. The object has been to prepare homopolymers that have essentially a single structure. Currently all cis polymers can be prepared with two possible tacticities. We plan to expand the design of catalysts in order to allow us to prepare all four major polymeric ROMP structures derived from a wide variety of norbornadienes or norbornenes. The next level of control is to prepare polymers from two different monomers to give AB copolymers, again with a single structure. Since polymer properties are dictated by polymer structure, we predict that precise control of polymer structure will have major implications in the design of specialty polymers for a wide variety of applications that have emerged in the last decade in which atactic ROMP polymers have been employed.

FY 2014 HIGHLIGHTS

Among the major accomplishments in the last year is the ability to synthesize polymers through ROMP with pure cis, syndiotactic or cis, isotactic structures. Most recently we have been able to prepare polymers with these structures from dicyclopentadiene, norbornene, and tetracyclododecene; all are monomers that yield tactic polymers, the hydrogenated form of which can be crystalline and high melting. A third structure that has now been achieved is an AB polymer with a cis, syndiotactic structure in which A and B are enantiomers. This has become possible with catalysts that are chiral at the metal and whose chirality inverts with each insertion step. The chirality at the metal controls, through a diastereomeric relationship, which enantiomer is inserted in the each step. Finally, for the first time we have been able to prepare perfectly alternating stereoregular AB copolymers in which A and B are two different monomers. This is possible because of the fact that Mo and W catalysts exist in two isomeric forms that are in equilibrium with one another through rotation about the M=C bond. Monomer A reacts with one form (anti) selectively to give a trans C=C bond and the other form (syn), which then reacts selectively with monomer B to give the second trans C=C bond and the other form (anti) back again. We hope to be able to extend this approach to the synthesis of perfectly alternating conjugated copolymers in which (for example) A is an electron donor and B is an electron acceptor.

High Temperature Chemistry of Aromatic Hydrocarbons

Institution: Boston College, Trustees of
Point of Contact: Lawrence Scott
Email: lawrence.scott@bc.edu
Principal Investigator: Lawrence Scott
Sr. Investigator(s):
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)

Funding: \$50,000 (2014)

PROGRAM SCOPE

The primary goal of this research is to uncover all the principal reaction channels available to polycyclic aromatic hydrocarbons (PAHs) at high temperatures in the gas phase and to establish the factors that determine which channels will be followed in varying circumstances. The efficient production of clean energy from fossil fuels will remain a major component of the DOE mission until alternative sources of energy eventually displace coal and petroleum. Hydrocarbons constitute the most basic class of compounds in all of organic chemistry, and as the dominant species in fossil fuels, they figure prominently into the programs of the DOE. Much is already known about the normal chemistry of hydrocarbons under ambient conditions, but far less is known about their intrinsic chemistry at temperatures close to those reached during combustion. An understanding of the fundamental molecular transformations, rearrangements, and interconversions of PAHs at high temperatures in the gas phase, as revealed by careful studies on small, well-designed, molecular systems, provides insights into the underlying chemistry of many important processes that are more complex, such as the generation of energy by the combustion of fossil fuels, the uncatalyzed gasification and liquefaction of coal, the production of fullerenes in fuel-rich flames, and the formation of soot and carcinogenic pollutants in smoke (e.g., benzo[a]pyrene). The rational control of any of these processes, whether it be the optimization of a desirable process, such as the recent commercialized combustion synthesis of C₆₀ and other fullerenes, or the minimization of an undesirable one, requires a clear knowledge of the basic chemistry that governs the fate of the species involved. Advances in chemistry at the most fundamental level come about primarily from the discovery of new reactions and from new insights into how reactions occur. Harnessing that knowledge is the key to new technologies and carbon-rich materials.

FY 2014 HIGHLIGHTS

Our latest research has focused on elucidation of the mechanism of acene-to-phenacene rearrangements of aryl radicals, a fundamental class of skeletal reorganization of polycyclic aromatic hydrocarbons (PAHs) that was recently discovered in our laboratory. To test our hypothesis for the mechanism of this new class of rearrangements, we synthesized 9-bromo-9-[¹³C]anthracene, 1-bromo-1-[¹³C]naphthalene, and 7-bromo-7-[¹³C]benz[a]anthracene and studied their chemical behavior at high temperatures in the gas phase under conditions of flash vacuum pyrolysis (FVP). All three syntheses involved the capture of ¹³CO₂ by a Grignard reagent as the key step for incorporation of the ¹³C isotopic label. Several steps were required to synthesize each Grignard reagent, and several additional steps were then required to convert the intermediate ¹³C-labeled carboxylic acids to the FVP precursors. FVP of 9-bromo-9-[¹³C]anthracene produces two and only two isotopomers of ¹³C-labeled phenanthrene: 4a-[¹³C]phenanthrene and 9-[¹³C]phenanthrene, and that is precisely the result predicted by our mechanistic hypothesis. The major product is 4a-[¹³C]phenanthrene, and the only other significant product is 9-[¹³C]phenanthrene. These two isotopomers are formed in a 60:40 ratio. The lesser amount of 9-[¹³C]phenanthrene reflects the slow but competitive intervention of a 1,3(peri)-hydrogen shift at the stage of the 9-anthracenyl radical. Earlier studies in our laboratory predicted and demonstrated experimentally the 1,3(peri)-hydrogen shift rearrangement in other aromatic hydrocarbons, so we were expecting it to show up here, too. The results of our FVP experiments with 1-bromo-1-[¹³C]naphthalene, and 7-bromo-7-[¹³C]benz[a]anthracene were likewise entirely consistent with predictions based on our proposed mechanism. We conclude from these experiments that acene-to-phenacene rearrangements of aryl radicals do involve the rupture of ring-fusion bonds in cata-condensed PAHs at high temperatures.

Hierarchical Design of Supported Organometallic Catalysis for Hydrocarbon Transformations

Institution: California-Santa Barbara, University of
Point of Contact: Susannah Scott
Email: sscott@engineering.ucsb.edu
Principal Investigator: Susannah Scott
Sr. Investigator(s): Baron Peters; California-Santa Barbara, University of
Albert Stiegman; Florida State University
Students: 3 Postdoctoral Fellow(s), 6 Graduate(s), 3 Undergraduate(s)
Funding: \$550,000 (2014)

PROGRAM SCOPE

This project aims to decipher the structure and behavior of active sites in supported metal oxide catalysts by synthesizing and studying well-defined and uniform sites. This effort, in turn, will create the insight necessary to prepare heterogeneous catalysts that are more uniform and therefore more active and selective, while remaining both self-activating and regenerable. Our goal requires a close integration of organometallic synthesis and surface chemistry, the best available structural characterization techniques and detailed reactivity studies (kinetics, mechanisms). An essential element of this work is the exploration, using computational approaches, of the plausibility of our structural and mechanistic proposals, both for the correct interpretation of experimental results and to suggest new research directions. The latter is particularly important in terms of understanding the origin of self-activation in the active sites.

Specific objectives include (1) understanding the origin of self-activation in heterogeneous single-atom catalysts for olefin metathesis and polymerization, such as $\text{Re}/\text{Al}_2\text{O}_3$ and Cr/SiO_2 , and (2) designing computational models for these amorphous materials that inform and predict catalyst response to changes in preparation protocols and/or reaction conditions. We also aim to (3) develop new spectroscopic and kinetic methods to challenge these materials mechanistically, again with the goal of developing detailed molecular-level understanding of their activation and deactivation processes. Finally, we aim to (4) transfer this understanding to the synthesis of new catalytic materials based on knowledge of the active site requirements for a given process.

FY 2014 HIGHLIGHTS

We discovered a new, highly active system for olefin metathesis, using chlorinated alumina to support and activate the single-component catalyst CH_3ReO_3 (MTO). We observed a dramatic increase in reactivity for propylene homo-metathesis in a batch reactor, for MTO is grafted on $\text{Cl}/\text{Al}_2\text{O}_3$ compared to $\gamma\text{-Al}_2\text{O}_3$. Furthermore, the increased stability of the metathesis catalyst was easily demonstrated under flow conditions. The cumulative TON for the chlorinated catalyst reached 20,000 after 2,000 min on stream, while it leveled off under 5,000 for the unchlorinated catalyst. Cl seems to prevent deactivation of the Re active sites as well as promote their activity. We also explored the activation of the Phillips ethylene polymerization catalyst Cr/SiO_2 , in which Cr(VI) is reduced to Cr(II) by CO. Using in-situ UV-vis spectroscopy, we showed that reduction proceeds first through a Cr(IV) species at 250°C, then to a Cr(II) species at 320°C. We observed the Cr(II) sites directly for the first time using High Field High Frequency EPR spectroscopy. Upon addition of ethylene, the Cr(II) sites are oxidized quantitatively to Cr(III). The initiating site is a vinylCr(III) species, formed concomitantly with ethyl radicals which, in turn, couple to form n-butane as a byproduct. We also investigated a surface organometallic model for the active sites by grafting $\text{Cr}[(\text{CH}(\text{SiMe}_3)_2)_3]$ onto silica. The supported organochromium catalyst spontaneously initiates polymerization of gas phase ethylene at low pressure (ca. 125 Torr) with a rate law that is first-order in

both $P(C_2H_4)$ and moles of Cr. The specific activity and apparent activation energy of the model catalyst closely resemble that of the conventional Phillips catalyst, suggesting that they share a common polymerization mechanism. Analysis of the products of low-pressure ethylene oligomerization Field Desorption-MS revealed not only integer but also half-integer numbers of ethylene subunits.

Understanding Surfaces and Interfaces of Photocatalytic Oxide Materials with First Principles Theory and Simulations

Institution: Princeton University
Point of Contact: Annabella Selloni
Email: aselloni@princeton.edu
Principal Investigator: Annabella Selloni
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

The overall goal of this project is to obtain a complete picture of the atomic structure, electronic properties and (photo-)reactivity of transition metal oxide surfaces and oxide-water interfaces. Major specific objectives are: (i) to determine the structure and reactivity of defect-free and defected TiO_2 surfaces and interfaces; (ii) to understand the behavior of photoexcited electrons and holes at TiO_2 surfaces and TiO_2 -water interfaces; (iii) to extend the knowledge gained for TiO_2 to other promising (photo-)catalytic metal oxides.

FY 2014 HIGHLIGHTS

Chemical Dynamics of the First Proton Coupled Electron Transfer (PCET) of Water Oxidation on TiO_2 Anatase - Despite its widespread use in photo-electrochemical water splitting, TiO_2 is not very efficient due to its large overpotential for the oxygen evolution reaction (OER). To understand the origin of this limitation, we analyzed the kinetics of the first PCET, which is the rate-determining step of the OER on TiO_2 . We used a periodic model of the TiO_2 /water interface that includes a slab of anatase TiO_2 and explicit water molecules, sampled the solvent configurations by First Principles Molecular Dynamics, and determined the ET energy profiles by hybrid functional calculations. Our results indicate that the proton and electron transfer are not concerted but sequential. The PT has a significant activation energy, whereas the following ET is essentially barrierless and occurs via an inner sphere process involving a shared hole state. These results also explain the higher OER activity that is observed at high pH.

TiO_2 /Ferroelectric Heterostructures as Catalysts for Water Oxidation – We studied the OER activity of epitaxial heterostructures of TiO_2 anatase on strained polar $SrTiO_3$. Results show that the TiO_2 reactivity is tuned by electric dipoles dynamically induced by the adsorbates during the reaction. The combined effects of these dipoles and epitaxial strain significantly reduce the thermodynamic barriers and improve the OER efficiency.

Mechanism and Activity of Water Oxidation on Pure and Fe-doped NiO_x - Mixed Ni-Fe oxides are promising electrocatalysts for water oxidation due to their low cost and high activity. We studied the OER energetics on selected surfaces of pure and mixed Ni-Fe oxides that are possible candidates for the catalyst's active phase. Based on the computed overpotential, Fe-doped β - $NiOOH$ is even more active than RuO_2 , a well-established OER catalyst, and could thus contribute to the active phase of Fe-doped NiO_x .

Transition Metal Mediated Transformations of Small Molecules

Institution: Pennsylvania State University
Point of Contact: Ayusman Sen
Email: axs20@psu.edu
Principal Investigator: Ayusman Sen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Catalysis at metal centers is of great scientific, as well as practical, importance because of the high efficiency, high specificity, and low energy demands often associated with such systems. The two major themes of our research are (a) the design of metal-based systems for the synthesis of novel classes of polymers and (b) the identification of new metal-catalyzed systems for the conversion of biomass to fuels and chemicals, and related “green” chemical processes. Recent work encompasses several aspects of organotransition metal chemistry and catalysis. These include (a) the study of steric and electronic effects in ethene/norbornene copolymerization by neutral salicylaldiminato-ligated palladium(II) catalysts and (b) rhodium-catalyzed reduction of sulfoxides to sulfides with HI and CO/H₂. In addition, we have designed new materials to reversibly sense and capture carbon dioxide. We are also addressing key questions concerning the mechanistic steps involved in these transformations.

FY 2014 HIGHLIGHTS

We have discovered a novel one-step process for the reductive deoxygenation of a wide range of organic compounds, including biomass-derived molecules, by a combination of metal catalyst and hydrogen iodide (HI). The mechanism involves close synergy between HI and metal catalyst. HI serves a two-fold purpose: HI acts as a dehydration agent in the initial step of the reaction, and as a reducing agent for the conjugated carbinol group in a subsequent step. Iodine is formed in the reduction step and metal-catalyzed hydrogenation reforms HI. The metal catalyst, in addition to catalyzing the reaction of iodine with hydrogen, also functions as a hydrogenation catalyst for C=O and C=C bonds. We have also discovered a new class of absorbents for carbon dioxide, amino alcohols. They reversibly absorb carbon dioxide at ambient temperature. Carbon dioxide is released back by simply purging the material with air or nitrogen. By coupling the process with a standard pH indicator, the system acts as a sensitive and reversible carbon dioxide sensor with a visual color output. Solid state sensors can be readily fabricated by supporting the amino alcohol and the pH indicator on alumina. This colorimetric response is completely reversible and is not interfered by moisture, oxygen or trace CO₂, present in ambient air.

Late Transition Metal M-Or Chemistry and D6 Metal Complex Photoeliminations

Institution: Missouri, University of
Point of Contact: Paul Sharp
Email: sharpp@missouri.edu
Principal Investigator: Paul Sharp
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This program is focused on the photochemistry of transition metal halo, hydroxo, and hydroperoxo complexes related to solar energy conversion and storage. In particular, reductive elimination reactions of halogens, HOX (X = a halogen), hydrogen peroxide, and water are sought as components of photo-driven, catalytic, endergonic splitting of small molecules.

FY 2014 HIGHLIGHTS

Highlights include:

1. Discovery of a series of platinum(IV) complexes that undergo net photolytic reductive elimination of halogens with record quantum yields.
2. Completion of a mechanistic investigation into the net photo reductive elimination of chlorine that indicated chlorine transfer to alkene traps from a platinum complex excited state.
3. Discovery of the first photo reductive elimination of H₂O₂ (dihydrogen trioxide) from a metal hydroxo-hydroperoxo complex. In addition to being only the second synthetic method for H₂O₂, the O-O bond formation is important component of water to hydrogen and oxygen schemes.
4. Discovered controlled C-H activation by photo-generated hydroxy radical from platinum(IV) hydroxo complexes. Hydroxo radicals are generally considered promiscuous reactants and our discovery suggests the possibility of controlled reactivity.

EARLY CAREER: Decoupling the Electronic and Geometric Parameters of Metal Nanocatalysts

Institution: Indiana University
Point of Contact: Sara Skrabalak
Email: sskrabal@indiana.edu
Principal Investigator: Sara Skrabalak
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

It is a grand challenge to predictably control the geometric and electronic factors governing the performance of metal catalysts. Shape-controlled core@shell metal nanocrystals can address this challenge by providing independent control of these parameters through the binary composition and architecture. Shape-controlled nanocrystals express crystal facets with defined atomic arrangements, which are being exploited to achieve geometric control by selecting for specific interactions between adsorbates and a surface. These shape-controlled nanocrystals are then coupled with a core@shell architecture, where the core metal is anticipated to perturb the electronic structure of the shell metal as a function of shell thickness, providing a means of controlling the interaction strength between a molecular substrate and surface. Model systems have been identified and are being evaluated to establish that the geometric and electronic factors governing the performance of a metal catalyst can be independently controlled through the use of shape-controlled core@shell nanocrystals to achieve superior activity and/or selectivity. Concurrent with this study, new synthetic strategies to novel nanocatalysts including sub-10 nm shape-controlled core@shell nanocrystals, concave core@shell nanocrystals, and shape-controlled core@shell nanocrystals consisting of electropositive non-noble metal cores will be validated. Collectively, these experiments will establish shape-controlled core@shell nanocatalysts as transformative platforms toward efficient catalysis.

FY 2014 HIGHLIGHTS

To meet the research objectives of this grant, we undertook the first study in which the two main geometric parameters governing the performance of metal nanocatalysts – nanocrystal size and shape – were systematically decoupled. A series of size-controlled {100}-terminated Pd nanocubes and {111}-terminated Pd octahedra were studied as selective hydrogenation catalysts. The intrinsic catalytic activity of both Pd nanocubes and octahedra toward selective hydrogenation of 2-hexyne increased with increasing nanocrystal size and was attributed to an ensemble effect. We also found that the Pd octahedra were more active than Pd nanocubes, and this finding is consistent with previous reports that found alkynes bind more strongly to Pd(100) surfaces than Pd(111) surfaces, which can retard hydrogen binding and/or product desorption. These results are significant because they indicate that the geometric size effect can be decoupled from the geometric shape effect by keeping the nanocrystal shape constant and vice versa. These results were published in ACS Catalysis in 2014.

Nitrogen Atom Transfer From High Valent Iron Nitrides

Institution: New Mexico State University
Point of Contact: Jeremy Smith
Email: jesmith@nmsu.edu
Principal Investigator: Jeremy Smith
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Complexes containing the terminal iron nitrido unit can be stabilized with tripodal supporting ligands that enforce three-fold symmetry. However, the nitrogen atom transfer reactivity of these complexes tends to be modest and therefore new strategies are required to increase their reactivity. A key aspect of the electronic structure of three-fold symmetric tris(carbene)borate iron(IV) nitrido complexes is a low energy LUMO that is stabilized by Fe spd mixing. It is hypothesized that the energy of this orbital, and hence electrophilicity of the nitrido ligand, can be predictably tuned by changes to the supporting tripodal ligand. Specifically, changes to: (1) the donor strength, and (2) the bite angle of the supporting ligand, as well as (3) the oxidation state of iron, are expected to modify the electrophilicity of the nitrido ligand. These hypotheses will be tested by preparing iron nitrido complexes (in multiple oxidation states) supported by new tris(carbene)borate ligands that differ in their donor strength and bite angle, and investigating their reactivity in two-electron nitrogen atom transfer reactions. Reaction of the nitrido ligands with a series of substrates will be used to evaluate the impact of the supporting ligand on the thermodynamic propensity towards nitrogen atom transfer, as well as develop structure/activity relationships. Particular emphasis will be placed on nitrogen atom transfer to unsaturated hydrocarbons (e.g. alkenes, dienes), which combined with the development of methods for regeneration of the iron nitrido complexes, will lead to new cycles for the synthesis of nitrogen-containing heterocycles.

FY 2014 HIGHLIGHTS

A detailed investigation into the scope and mechanism of the reaction between the iron(IV) nitride and styrene, which yields an iron(II) aziridino complex, has been undertaken. These investigations reveal that the reaction occurs in a stepwise manner, likely by two one-electron steps that result in loss of stereochemistry. The reaction is faster with electron-poor styrenes and is also subject to steric

constraints. Intriguingly, the aziridination reaction is reversible, allowing for the first example of aziridine cross-metathesis. A functionalized aziridine can be liberated from the iron center, allowing for a synthetic cycle for aziridine cross-metathesis to be established. New, strongly donating bidentate ligands have been developed to isolate three-coordinate iron and cobalt complexes. While attempts to use bis(carbene)borate and tris(carbene)borate ligands to prepare iron alkylidenes and alkylidynes have been so far unsuccessful, one such ligand stabilizes an unusual paramagnetic isocarbonyl complex that has a formal iron(0) oxidation state. This reduced complex is reactive towards dihydrogen, and thus may provide a homogeneous model complex for the Fischer-Tropsch reaction. Efforts have also been made to prepare iron phosphido and sulfido complexes with tris(carbene)borate ligands. These investigations have led to the isolation of an η^3 -cycloP₃ complex which is unusual due to its triplet spin configuration. Attempts to prepare a sulfido complex have resulted in conversion of the carbene ligands being converted to thioimidazole donors.

Copper-Catalyzed Aerobic Oxidation of Arenes and Alcohols

Institution: Wisconsin-Madison, University of
Point of Contact: Shannon Stahl
Email: stahl@chem.wisc.edu
Principal Investigator: Shannon Stahl
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

Our DOE-sponsored research addresses two critical challenges in modern catalysis research: (1) replacing precious metals with earth-abundant elements as catalysts for chemical synthesis and energy-related applications and (2) controlling the reactivity of molecular oxygen in selective aerobic oxidation reactions. Numerous metalloenzymes feature first-row transition metals in their active sites, and an array of Cu- and Fe-containing enzymes mediate aerobic oxidation of organic molecules. In contrast, many of the recent synthetic advances in aerobic oxidation catalysis utilize noble metals, such as Pd, Rh. The development of new industrially useful catalyst systems derived from first-row transition metals remains a key challenge for the field. Our DOE-sponsored research efforts focus on the development and investigation of copper-catalyzed aerobic oxidation reactions. Although the systems of interest bear some resemblance to copper oxidase enzymes, the catalytic mechanisms that have emerged from these studies are more closely related to organometallic oxidation reactions catalyzed by noble-metal (e.g., Pd, Pt) catalyst systems. Our research has focused on the discovery and/or mechanistic characterization of two important classes of aerobic oxidation reactions catalyzed by homogeneous copper catalysts: (1) oxidative functionalization of arene C–H bonds and (2) chemoselective oxidation of primary alcohols.

FY 2014 HIGHLIGHTS

Research progress from our FY2014 DOE project included results from both of our two project areas: (1) investigation of Cu-catalyzed methods for aerobic oxidation of aromatic C–H bonds (one publication) and (2) development and mechanistic characterization of (bpy)Cu/TEMPO-catalyzed aerobic alcohol oxidation (six publications). Specific highlights included the following:

- A. Observed Divergence between Organometallic and Single-Electron-Transfer Mechanisms in Cu(I)-Mediated C–H Oxidation of a Single Substrate.

Key publication:

- Suess *et al.* 'Divergence between Organometallic and Single-Electron Transfer Mechanisms in Copper(II)-Mediated Aerobic C–H Oxidation.' *J. Am. Chem. Soc.* 2013, 135, 9797–9804.
- B. Development of Highly Efficient Methods for Aerobic Alcohol Oxidation and Characterization of their Reaction Mechanism.

Key publications:

- Steves & Stahl. 'Copper(I)/ABNO-Catalyzed Aerobic Alcohol Oxidation: Alleviating Steric and Electronic Constraints of Cu/TEMPO Catalyst Systems' *J. Am. Chem. Soc.* 2013, 135, 15742-15745.
- Greene *et al.* 'Continuous-Flow Aerobic Oxidation of Primary Alcohols with a Copper(I)/TEMPO Catalyst.' *Org. Process Res. Dev.* 2013, 17, 1247-1251.
- Ryland & Stahl. 'Practical Aerobic Oxidations of Alcohols and Amines with Homogeneous Cu/TEMPO and Related Catalyst Systems.' *Angew. Chem. Int. Ed.* 2014, 53, 8824-8838.
- Ryland *et al.* 'Mechanism of Alcohol Oxidation Mediated by Copper(II) and Nitroxyl Radicals.' *J. Am. Chem. Soc.* 2014, 136, 12166–12173.

Our work in the latter area was particularly noteworthy because some of the work was carried out in collaboration with three pharmaceutical companies in an effort to facilitate large-scale application of our methods. This work was recognized in October 2014 with the Presidential Green Chemistry Challenge Award (Academic category).

 Funding: \$850,000 (2014)

PROGRAM SCOPE

The Institute for Catalysis in Energy Processes (ICEP) is a multi-investigator project in the Northwestern University Center for Catalysis and Surface Science (NU). It has strong connections to the catalysis research group at Argonne National Laboratory (ANL) through joint appointments of several PIs. The overarching theme of ICEP research is Chemical Catalysis: Manipulation and Understanding of Oxidation Catalysts. The objectives of the project are 1) Elucidate the structure-function relationships in oxidation catalysts of several forms, supported molecular oxides, supported metal nanoparticles, and supported metal atoms and 2) Understand the roles of different oxidizing species in catalytic oxidation.

Specific objectives for the project year have been 1) Develop the oxidation of cyclohexene as a versatile and informative probe reaction for oxidation pathways, 2) Develop the capability to carry out catalytic reaction experiments with a variety of oxidants: O₂, H₂O₂, NO, N₂O, organic hydroperoxides and begin reaction studies, 3) Synthesize and characterize new catalytic materials with novel structures designed to probe specific questions about structure-function relationships, and 4) Advance our characterization methodologies, both experimental and computational, to obtain an atomic scale picture of our catalytic materials and their function.

FY 2014 HIGHLIGHTS

Detailed studies using X-ray absorption near edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) combined with HRTEM examined the influence of SrTiO₃ termination on the structure and composition of supported, catalytic Pd nanoparticles prepared by ALD. On the SrO termination the average Pd particle size is 2-3 nm independent of the loading. On the TiO₂ termination the size increases with loading. The Pd particle composition shifts with increasing numbers of ALD cycles from oxide to metallic state. We successfully imaged the Ce and O atom positions on the different surfaces of CeO₂ nanoparticle supports by using the aberration-corrected high resolution electron microscopy (HREM). To study the direct participation of support atoms in the catalytic site responsible for selective propane oxidation by supported Au, well-defined Ti-containing ligands for the Au particles have been created that can serve as a surrogate of the metal-support interface. This approach was used to study how the presence of Ti species influences catalytic oxidation of propane. Using mononuclear Ti ligands only, acetone is formed. With dinuclear Ti ligands both acetone and propene are formed. Vanadium oxide monomer species were introduced into well-defined sites in a metal organic framework (MOF) structure. The resulting, molecularly well-defined species were active for the oxidative dehydrogenation of cyclohexene to benzene with a performance similar to conventional alumina-supported vanadia catalysts. Using SrTiO₃ as the support for vanadium oxide small amounts of cyclohexadiene were also observed for the first time. The interaction of supported vanadia species with a second surface cation, either W or Mo, was examined by x-ray standing wave measurements to better understand the behavior of complex, multicomponent catalysts. The presence of vanadia makes normally non-reducible W reducible by hydrogen under mild conditions.

Porous Transition Metal Oxides: Synthesis, Characterization, and Catalytic Activity

Institution: Connecticut, University of
Point of Contact: Steven Suib
Email: steven.suib@uconn.edu
Principal Investigator: Steven Suib
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 8 Graduate(s), 0 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

The goals of this project are to synthesize well-ordered crystalline mesoporous transition metal oxide (MTMO) materials with monomodal uniform pore sizes; to prepare and characterize ordered mesoporous thin films; to optimize catalytic activity, selectivity, and stability in oxidation catalysis using amorphous porous oxides and crystalline microporous and mesoporous materials; to investigate the role of mesoporous materials in battery systems; and to develop novel *in situ* characterization methods for syntheses, selective oxidations, and battery studies. The assembly of these materials involves

inverted micelles. Characterization of the nucleation process has been done with Fourier transform infrared spectroscopy. Morphological studies have been done with a combination of scanning and transmission electron microscopy methods. A unique feature of these MTMO materials is that various compositions can be prepared such as CoO, Co₃O₄ and other known structures of metal oxides. This in turn allows enhanced thermal stability of such materials that are most often made by preparations similar to MCM-41 or by replica methods, both of which are rather limiting. Various metal oxides of titanium, manganese, iron, cobalt, nickel, copper, zinc, zirconium, aluminum, silicon, tin, cerium, and many others have been made. Taking advantage of the control of pore size has led to enhanced activity in coupling reactions as well as oxidation reactions. The adsorptive properties of these materials are enhanced since the synthesis process allows numerous ordered pores greater in void volume than typical mesoporous materials. The primary focus of our work has been in understanding catalytic selective oxidation reactions of hydrocarbons with both microporous and mesoporous metal oxides. Details of reaction mechanisms are under investigation.

FY 2014 HIGHLIGHTS

This year we have successfully made uniform monomodal pore sized crystalline walled mesoporous metal oxides of various compositions and structures. In addition, metal sulfide, phosphated materials, sulfated materials, and mixed metal oxide systems have been made. These materials have been screened for adsorption of various sulfur and nitrogen poisons and catalytic activity. These materials have been expanded to systems throughout the periodic table that have outstanding thermal stabilities, physical, and chemical properties. In this last year we are focusing on the characterization of the mechanisms of formation of these materials, which are made of nano-size crystallites that align during synthesis and do not sinter. In addition, we are studying specific catalytic activity of these different systems and applications regarding adsorption, sensors, and battery materials. Optimization of properties and correlation of such properties to desired functions are being pursued. Highlights include a major publication in Nature and numerous invitations for presentations of the above materials. Unique magnetic, optical, structural, porous, electronic, and other properties have been realized.

Polynuclear Aromatic Hydrocarbons with Curved Surfaces: Buckybowls

Institution: Mississippi State University
Point of Contact: Andrzej Sygula
Email: asygula@chemistry.msstate.edu
Principal Investigator: Andrzej Sygula
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

This program deals with the synthesis, structural studies, and chemistry of curved-surface, polynuclear aromatic hydrocarbons (PAHs) with carbon frameworks structurally related to fullerenes. They are referred to as “buckybowls” or “fullerene fragments”. Previous work under this DOE sponsored program produced several new buckybowls and, more importantly, resulted in a development of efficient, gram-scale solution synthetic methodologies for preparation of small buckybowls, most notably corannulene (C₂₀H₁₀) and its derivatives. During this funding cycle we plan to employ the corannulene-based synthons previously developed in our laboratory to prepare a number of highly nonplanar molecular architectures with two or more corannulene subunits. This “bottom-up” approach will produce well

defined carbon-rich systems of nanometric scale which, besides their “pure chemistry” value will have a potential for applications as novel materials in separation sciences, nanoelectronics, photovoltaics and catalysis. We have two broader objectives for the cycle: Synthesis of Bowl Shaped Systems of Nanometric Dimensions: Utilizing the palladium-catalyzed cyclotrimerization reaction of 1,2-didehydrocorannulene and Diels-Alder cycloaddition methodology we will prepare a number of large, highly nonplanar systems with multiple corannulene subunits. Molecular Receptors with Corannulene Pincers: As we showed recently “molecular clips” with corannulene pincers can act as molecular receptors for fullerenes, binding through $\pi-\pi$ convex-concave stacking of the curved conjugated carbon networks. We propose a preparation and testing of a number of new molecular receptors with two or more corannulene clips with improved affinity and specificity toward guest molecules, including fullerenes. An integrated approach to the design of efficient clips will lead to molecular receptors for fullerenes which are even more efficient than “buckycatcher”, prepared recently in our laboratory.

FY 2014 HIGHLIGHTS

We have initiated rigorous studies of thermodynamics of host-guest association of molecular clips and tweezers in organic solvents. In addition to ^1H NMR titration experiment we probed the thermodynamics of association employing Isothermal Calorimetry (ITC). [J. Phys. Chem. B, 2014, 118, 11956]. The results show that thermodynamics of the host-guest complex formation in solutions is more complicated than expected and proposed by the existing computational models. ITC experiment proves that $-\Delta S$ values for the association are generally either negligibly small or even negative, in contrast with the strongly positive values predicted by the available computational models. In addition, our study demonstrates the significant reductions of the association constants resulting from switching solvents, the changes which are not predicted the solvation model. A series of inclusion complexes and/or solvates of buckycatcher were characterized by the X-ray diffraction study, demonstrating a remarkable versatility of the clip to accommodate guest molecules of various sizes and shapes. [Cryst. Growth Des. 2014, 14, 2633]. Dramatic variations of the intercentroid distances between the central five-membered rings of the corannulene pincers (from 7.87 to 11.51 Å) in the inclusion complexes expose an impressive flexibility of the buckycatcher tether. The unprecedented concave-convex conformations of buckycatcher were found in two of the studied solvates. An x-ray structure of the crystal of buckycatcher grown by high-vacuum sublimation (i.e. in the absence of solvents) in Marina Petrukhina laboratory showed that the clip “grabs itself” if it does not have any proper guest molecules around. [Chem. Commun. 2014, 50, 2657]. The generation and X-ray structure of the dianionic form of buckycatcher (with two Ru counteractions) was also achieved by collaboration with Petrukhina. The first report characterizing the buckycatcher dianionic state was highlighted in the RSC blog Chemistry World.

Metal/Organic Surface Catalyst for Low-Temperature Methane Oxidation: Bi-Functional Union of Metal-Organic Complex and Chemically Complementary Surfaces

Institution:	Indiana University
Point of Contact:	Steven Tait
Email:	tait@indiana.edu
Principal Investigator:	Steven Tait
Sr. Investigator(s):	
Students:	0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding:	\$150,000 (2014)

PROGRAM SCOPE

Pressing energy challenges require new innovations in the development of catalyst systems that bridge the capabilities of two traditionally distinct fields of catalysis: homogeneous and heterogeneous catalysis. Homogeneous catalysis has key advantages in the design of well-defined single-site metal centers to achieve high selectivity in reactions. Heterogeneous catalysts generally have high activities and are developed with greater thermal stability. Bridging these fields will open new opportunities in energy science and technology. Catalysis research is a critical component of the solution portfolio to our energy challenges, but requires new advances in developing high activity and high selectivity in key energy processes. This project explores new possibilities in catalysis by combining features of homogeneous catalysts with those of heterogeneous catalysts to develop new, bi-functional systems. We are studying the interactions of metal–organic catalysts with surface supports and their interactions with reactants to enable the catalysis of critical hydrocarbon reactions at lower temperatures. These systems consist of metal–organic complexes that form by redox assembly at solid surfaces to produce well-defined single-site metal centers in a uniform oxidation state. The tunability of these systems will allow a high degree of control over the surface chemistry. This work addresses fundamental chemistry problems in these systems. What are the essential ingredients for highly-ordered and well-defined single-site metal centers? How do the metal–organic complexes interact with the surface? Can those metal center sites be tuned for selectivity and activity as they are in the homogeneous system by ligand design? Study of these systems brings together the advantages of heterogeneous catalysis with those of homogeneous catalysis, and takes this a step further by pursuing the objective of a bi-functional system.

FY 2014 HIGHLIGHTS

The central hypothesis of the FY 2014 period was that single-site transition metal complexes could be formed by on-surface redox chemistry with appropriate ligands at a metal surface. We have experimented with different methods to achieve single-site metal center stabilization at the surface, specifically, multiple organic ligand coordination environments for Pt metal centers on a surface support. Design of ligands for effective Pt complexation at surfaces was pursued with two key design principles in mind: effect metal coordination by electron accepting ligand and bidentate coordination site with a diverging geometry to allow attachment of ligand on both sides of the molecule. These design principles led to a highly successful ligand, dipyridyl tetrazine, a redox-active sub-unit to enable charge transfer within the adsorbate layer, i.e., redox-assembly at the surface. We have discovered the formation of single-site Pt(II) centers within coordination chains on a reconstructed Au(100) surface. We demonstrated that these redox-assembled chains are stable to 150°C, bringing them into a temperature range of high interest for moderate temperature reactions. They also serve as easily tuned model systems for exploring the chemistry of single-site transition metals that hold potential for future applications in tandem catalysts and development into a zeolite or other highly-stable support structure. This system is one of several that have been developed in the exploration of metal coordination at surfaces that allow us to better understand the synthesis and the chemical activity of these systems with the goal to develop a highly-selective and tunable surface catalyst by metal–organic complexation at the gas/solid interface. We have also identified key questions for ongoing research, including exploration of mixed valence systems, ligand designs for efficient assembly, chemical activity and selectivity, and extension of these results to other catalysis systems.

Understanding the Catalysis on Early Transition Metal Oxides-Based Catalysts Through Exploration of Surface Structure & Chemistry During Catalysis Using in-situ Approaches

Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The current DOE project explores phase transformation, the accompanying changes of surface chemistry, and their impacts on catalytic activity and selectivity for reduction of nitric oxide and water gas shift (WGS). Our work to date has shown the complexity of surface chemistry of early transition metal oxide-based catalysts, the flexibility of oxide surfaces in restructuring a surface phase to tune catalytic performance, and the possibility of development of new catalytic phases through phase transformation under reaction conditions. We developed nonstoichiometric CoO_{1-x} nanorod catalyst which exhibits 100% selectivity for production of N_2 from NO with high activity at 250°C . Through a surface restructuring during catalysis, $\text{Pt}_1\text{Co}_n/\text{Co}_3\text{O}_4$ and $\text{Pd}_1\text{Co}_n/\text{Co}_3\text{O}_4$ catalysts were formed. They exhibit high activity in the reduction of nitric oxide with H_2 . In addition, new phase $\text{Pt}_m\text{Co}_n/\text{CoO}_{1-x}$ with high activity in WGS was developed by restructuring $\text{Pt}_1/\text{Co}_3\text{O}_4$ catalytic surface under a WGS condition. We have also developed oxide-based catalysts for other conversion of methane and other reactions.

FY 2014 HIGHLIGHTS

We have performed the following work: (1) in-situ studies of surface chemistry of Co_3O_4 and Co_3O_4^- based catalyst during water gas-shift and design of a new bi-functional catalyst, Pt-Co alloy nanoclusters supported on nonstoichiometric CoO_{1-x} bimetallic catalysts; (2) preparation and in-situ studies of Co-Ru bimetallic layers on Co_3O_4 nanorods for reduction of CO_2 ; (3) catalysis and in-situ studies of CeO_2 with doped metal cations for generation of syngas through partial oxidation of CH_4 ; (4) catalysis and in-situ studies of reduction of NO with CO on nonstoichiometric CoO_{1-x} ; (4) catalysis and in-situ studies of water-gas shift on mesoporous CeO_2 loaded with metal nanoclusters consisting curvy metal-oxide interface; (6) chemical transformation of methane to methanol⁹ and acetic acid¹⁰ through oxidation in solutions, (7) in-situ studies of surface oxide, $\text{Rh}(110)\text{-}1\times 2\text{-O}$ at atomic scale during CO oxidation.

Catalysis of Small Molecule Activation By Proton Coupled Electron Transfer

Institution: Delaware, University of
Point of Contact: Klaus Theopold
Email: theopold@udel.edu
Principal Investigator: Klaus Theopold
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

The objective of this project is the catalysis of 'proton coupled electron transfer' (PCET) to metal bound fragments derived from the most abundant small molecules (i. e. O₂ and N₂). There are many important chemical challenges that are tied to this fundamental reaction. Among these are: i) metal catalyzed oxidations of organic molecules utilizing O₂ as the oxidant ii) reduction of O₂ to water close to the thermodynamic potential – in other words, the cathode of any fuel cell based on reactions with O₂ iii) transfer of reduced nitrogen species to organic substrates iv) fixation of nitrogen at modest temperatures and pressures The realization that 'hydrogen atom abstraction', i. e. an elementary step occurring e. g. during the course of metal-catalyzed hydroxylations or aminations, must be considered a PCET process brings into focus the broader issue of the synchronous delivery of protons and electrons to metal bound atoms and molecules. The conceptual separation of H⁺ and e⁻ and their respective sources and destinations leads directly to a consideration of redox-active ligands, and the role they might play in facilitating PCET processes. One of the facets of the proposed research is to create metal complexes with redox-active functional groups, and thereby functionally mimicking metalloenzymes with electron transfer sites. The methods employed involve the synthesis and characterization of coordination compounds of various transition metal (Cr, Mn, Fe, Co) as well as the study of their reaction mechanisms. Diversity in coordination geometries will create opportunities for new chemistry. Redox-active versions of these ligands will facilitate PCET processes. Benefits of this research include the potential discovery of new catalytic processes and the advancement of fundamental knowledge about chemistry and catalysis.

FY 2014 HIGHLIGHTS

1) We have prepared a series of ferrocenyl substituted tris(pyrazolyl)borate ligands, including the Tp(Fc,Me) ligand (Inorg. Chem. 2014, 53, 9424). Various transition metal complexes of the latter ligand have been prepared. The reactivity of such complexes, particularly vis-a-vis the resistance of the ligand to H-atom abstraction and its redox activity are currently being explored. 2) We have continued the investigation of the chemistry of TpCo(I) and TpFe(I) dinitrogen complexes, with particular regard to the activation of dioxygen and other small molecules. Imido complexes of this metal fragment continue to play an important role in our work. 3) We have investigated - experimentally as well as computationally - the apparent 4-electron oxidative addition of O₂ to a low-valent NacnacCr(I) fragment, which results in the formation of a Cr(V) dioxo complex. This reaction is spin-forbidden, and we have found that the minimum energy crossing point (MECP) between the two potential energy surfaces (PES) is of relatively high energy. Accordingly, a more complicated mechanism, involving the formation of a dinuclear chromium intermediate, appears to be operative (JACS 2013, 135, 16774).

EARLY CAREER: Early-Late Heterobimetallic Complexes Linked by Phosphinoamide Ligands: Tuning Redox Potentials and Small Molecule Activation

Institution: Brandeis University
Point of Contact: Christine Thomas
Email: thomasc@brandeis.edu
Principal Investigator: Christine Thomas
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal of this project is to investigate bimetallic combinations of early and late transition metals linked by phosphinoamide ligands. We have previously found that the interaction of an electron-withdrawing Zr center can decrease the electron density at a Co center to such an extent that the complex's reduction potential is increased by as much as 1 V compared to monometallic Co analogues. We aim to investigate whether this phenomenon is true for an array of early/late heterobimetallic combinations, and whether the ability to tune redox potentials via metal-metal donor-acceptor interactions may provide a method to perform small molecule activation and catalysis with decreased overpotentials. While early/late heterobimetallic complexes may find a variety of applications in catalysis, we are particularly focused on their application towards the activation of strong sigma-bonds in small molecule substrates such as carbon dioxide.

FY 2014 HIGHLIGHTS

A number of independent areas were explored to address the overall goals of the project. To explore the mechanism of carbon dioxide activation by Zr/Co complexes, we used a series of control experiments as well as some fundamental studies of C=O bond activation using ketone substrates to better understand the unique mechanism of carbon dioxide activation. In particular, we explored the unique role that Zr and Co play in these reactions and the cooperativity between the two metals that inevitably leads to reactivity that would not be possible with a single metal center. We have found that a single-electron pathway involving initial coordination to the Zr center may be operative, but that the key step in the cleavage of a C=O bond involves coordination of the substrate (CO₂) to both Zr and Co. We have also investigated the reactivity of other small molecule substrates with reduced Zr/Co heterobimetallic complexes and, among other discoveries, uncovered a four-electron redox process by which N=N double bonds are cleaved. The role of the phosphinoamide ligands that link Zr and Co has been assessed by several studies involving variation of the ligand substituents, using the IR stretches of metal-bound carbonyls and differences in reactivity and redox properties as probes. While the Zr/Co heterobimetallic system we have studied has led to some unprecedented reactivity and some important fundamental insight into the cooperative roles of two metals in a bimetallic system, we have concluded that this system is hindered by the strength of the metal-heteroatom bonds that are formed with the Zr center as a result of sigma and pi bond cleavage reactions. Thus, we have investigated new metal-metal combinations, including homobimetallic complexes in which the two metals are distinguished only by the different donors in the two coordination sites available, including Cr/M (M = Fe, Co, Cu, Ir, Rh), Ti/M (M = Fe, Co, Ni), and Co₂ complexes.

In-Situ NMR/IR/RAMAN and *Ab Initio* DFT Investigations of Pt-Based Mono- & Bi-Metallic Nanoscale Electro-Catalysts: From Sulfur-Poisoning to Polymer Promoters to Surface Activity Indexes

Institution: Georgetown University
Point of Contact: YuYe Tong
Email: yyt@georgetown.edu
Principal Investigator: YuYe Tong
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 3 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

While continue to focus on the surface chemistry of sulfur (S) and other conventional poisonous species on Pt-based electrocatalysts, we are exploring a novel perspective of it, which was inspired by some very

interesting previous observations. Specifically, it was observed that the traditionally undesirable species can actually promote, rather than poison, catalytic activity of Pt-based electrocatalysts. This includes that (1) at <20% low coverage, adsorbed S species can promote considerably CO oxidation reaction (COR), methanol oxidation reaction (MOR), and oxygen reduction reaction (ORR); (2) adsorbed PVP can enhance substantially MOR and formic acid oxidation reaction (FAOR); and (3) adsorbed iodine can improve significantly the stability of PtCu alloy electrocatalyst for ORR. These observations are along the line of a new emerging area of research in which many traditional poisoning species have been observed to promote catalytic reactions. However, much of the surface chemistry that governs such behaviors remains to be uncovered and their potential practical applications are largely unexplored. Therefore, we are pursuing two primary objectives: 1. Advance significantly our fundamental understanding of the surface chemistry that governs the observed promotion in catalytic activity by some traditionally poisonous species (sulfur, PVP, and iodine) on Pt-based electrocatalysts through meticulous *in situ* spectroelectrochemical (NMR/IR/Raman) interrogations of the relevant systems. 2. Identify, Investigate, and establish correlations between the chemical descriptors of activity, such as the surface d band center or/and reactivity indexes and the associated electrochemical reactivity. An important aspect is that the activity indexes defined within the DFT framework are directly related to the surface local density of states at the Fermi level which are measurable by *in situ* electrochemical (EC)-NMR and calculable by the state-of-the-art *ab initio* DFT calculations

FY 2014 HIGHLIGHTS

1. Study of the PVP effect.

- a. By using a liquid phase UV photo-oxidation technique, we were able to eliminate the tenacious PVP off the octahedral/tetrahedral (O/T) and cubic Pt NPs. This enabled us to separate the NP surface orientation from the PVP effect. We observed that the MOR activity was enhanced by the O/T Pt NPs compared to Pt black and the cubic Pt NPs. The *in situ* ATR-SEIRAS data strongly suggests that the enhancement in MOR was probably related to more weakly hydrogen-bound water available on the O/T NP surface than on the other two samples (RSC Adv. 2014, 4, 21284).
 - b. We carried out more detailed EC and IR study of MOR and COR on the cubic and O/T Pt NPs with residual PVP. While our data confirmed the enhanced MOR activity on the O/T Pt NPs observed previously, the *in situ* IR data of much higher quality provided strong indications that the underlying reason for the MOR enhancement on the O/T Pt NPs was highly likely related to the enhanced no-CO-generating reaction pathway(s), as evidenced by much lower CO generation during the MOR on these Pt NPs (Electrocatal. 2014, 5, 248).
2. On the chemistry of activation of PtRu NPs for the MOR. While potential cycling has been widely used to activate PtRu NPs for MOR, little is known about the chemistry and what constitutes the optimal activation. *In situ* ATR-SEIRAS study of the activation–deactivation process in PtRu/C, which was corroborated by TEM, EDS, and XRD data, revealed that the commonly used catalyst activation procedure caused a dynamic redistribution of surface Pt and Ru that moved the catalyst surface from the initial alloyed distribution of Pt and Ru to more segregated distributions of each element. The best activation corresponded to achieving an equal amount of segregated surface Pt and Ru ensembles, presumably to maximize the Pt–Ru boundaries. However, over-activation led to the deactivation of the catalyst, largely caused by the substantial loss of surface Ru (Chem Commun 2014, 50, 12963)

Molecular-Level Design of Heterogeneous Chiral Catalysts

Institution: Wisconsin-Milwaukee, University of
Point of Contact: Wilfred Tysoe

Email: wtt@uwm.edu
Principal Investigator: Wilfred Tysoe
Sr. Investigator(s): Andrew Gellman; Carnegie Mellon University
Nisha Shukla; Carnegie Mellon University
Francisco Zaera; California-Riverside, University of
Students: 5 Postdoctoral Fellow(s), 8 Graduate(s), 1 Undergraduate(s)
Funding: \$650,000 (2014)

PROGRAM SCOPE

The goal of this project by the Chiral Catalysis Group is to understand the interactions of prochiral reactants or chiral products on chirally modified surfaces that lead to the preferential formation of one enantiomer over the other, with the goal of understanding the principles that govern the operation of heterogeneous chiral catalysts. While catalysis research has focused on improving activity, the focus has shifted to improving the selectivity or the atom efficiency of catalytic processes. Enantioselectivity, the ability of a catalyst to select between the two enantiomers of a chiral product, is one of the subtler forms of selectivity and is one of the most challenging problems in chemistry because it seeks to discriminate between two enantiomeric products that are identical in all respects except for their mirror reflection symmetry. Enantioselectivity is also central to catalytic processes that are at the heart of the pharmaceutical and agrochemical industries. The research focuses on three types of enantiospecific interactions of chiral molecules with chiral catalytic surfaces: interactions with naturally chiral surfaces; interactions with chirally templated surfaces; and one-to-one interactions of prochiral molecules with chiral surface modifiers. The specific goals are to: determine the structures of chiral surfaces, prochiral reactants, chiral products and chiral modifiers; understand the enantiospecific interactions that occur between prochiral reactants and chiral products with chirally modified surfaces; develop methods for detection of enantiospecific surface phenomena; elucidate enantioselective reaction pathways and the effects and interactions that control them; and develop novel chiral catalytic materials. The range of expertise within the Chiral Catalysis Group includes molecular-scale theory, surface science experiments in vacuum and under more-realistic liquid- and gas-phase environments, materials synthesis, and catalytic measurements.

FY 2014 HIGHLIGHTS

1. Measured enantiospecific adsorption equilibria for amino acids on chiral Cu(3,1,17)^{R&S} demonstrating enantiomeric separation on a naturally chiral surface.
2. Observed adsorption-induced auto-amplification of enantiomeric excess of aspartic acid (Asp) on Cu(111).
3. Demonstrated that D- and L-Asp mixtures undergo steady-state catalytic decomposition on Cu(111) and Cu(643)^{R&S}.
4. Used XPS to map rates of tartaric acid (TA) and Asp decomposition on a Cu(111) structure spread single crystals.
5. Quantified enantiospecific adsorption of propylene oxide and propranolol on chirally modified, tetrahexahedral (24-sided) Au nanoparticles.
6. Identified differences in adsorption of enantiopure versus mixed-enantiomer propylene oxide (PO) on Pt(111), explained by a kinetic effect analyzed using Monte Carlo simulations to model kinetic and STM data.
7. Demonstrated that NEA adsorption on Pt in a CCl₄ solution is dominated by interactions with the amine, not via the aromatic ring as commonly believed.

8. Correlated cinchona adsorption with catalytic activity for alpha-keto ester hydrogenation, influenced by concentration, nature of the solvent, and dissolved gases.
9. Demonstrated that the chemistry of tethered chiral modifiers is affected by the non-selective catalytic activity of the oxide surface, the activity of the OH species generated by hydrolysis of Si-alkoxy groups, and the tethered chiral modifier.
10. Demonstrated the use of glycidol as a chiral probe on Pd(111).
11. Characterized the surface chemistry of TA on Pd(111) showing that TA on Pd(111) is not a chiral modifier for PO but is for glycidol, due to the hydrogen-bonding interactions with $\bar{\text{O}}\text{H}$ groups on glycidol and TA.
12. Identified the tetramers and dimer rows formed from alanine (Ala) on Pd(111) and demonstrated that the amino acid tetramer forms chiral templates.
13. Identified docking complexes between MP and NEA on Pd(111) showing preferential enol binding accounting for enhanced MP hydrogenation.

Development of Catalytic Alkylation and Fluoroalkylation Methods

Institution: Lehigh University
 Point of Contact: David Vivic
 Email: vivic@hawaii.edu
 Principal Investigator: David Vivic
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
 Funding: \$155,000 (2014)

PROGRAM SCOPE

The objectives of this project are to understand at the molecular level the details of metal-mediated transformations involving alkanes and fluoroalkanes so that better alkylation/fluoroalkylation methods and reagents may be developed. The proposed research focuses on using cheap, readily available, and environmentally benign metals in efforts to overcome certain obstacles and to make the new methods as universal as possible. The alkyl-alkyl cross-coupling methodology we are developing can help understand how to convert natural gas feedstocks to useful chemicals. Fluorination has become popular for its known ability to increase the oxidative and thermal stability of new materials, and its role in supporting new energy technologies is expected to grow. Also of growing importance are the applications of fluorination reactions and various fluorides to energy conversion materials for lithium batteries, fuel cells, solar cells, etc. Fluoroalkyl groups are known to be one of the most challenging fluorine-containing functional groups to manipulate synthetically, and understanding how to control their reactivity can lead to better methods to prepare a diverse array of products such as fluorinated refrigerants, surfactants, polymers, liquid crystals, aerosol formulations, and lubricants. Controlling additions and eliminations of fluoroalkyl groups are also expected to lead to new “greener” ways to prepare high-performance fluoroalkyl polymers and coatings that do not rely on the chemistry of fluoroalkenes, which are becoming increasingly unavailable to purchase due to the explosion hazards associated with their handling. Such polymers are of high value because they are chemically inert and stable at extreme temperatures. Fluoropolymers can also be used as oxidizers in metal-based pyrolant designs for the preparation of energetic materials, owing to the favorable enthalpy of formation of the metal-fluorine bond.

FY 2014 HIGHLIGHTS

For the fiscal year 2014, we have developed new synthetic routes to zinc-based perfluoroalkyl dinucleophiles that could be used in a variety of chemical transformations of interest to the Department of Energy such as perfluoroalkyl co-polymerizations, metathesis-like reactions, and cross-coupling reactions. Traditionally, these types of perfluoroalkyl nucleophiles prepared have problematic issues associated with their use. For instance, the related di-Grignard reagents must be used at low temperatures because they have a half-life of only two hours at -50 degrees Celsius in THF. We observed that 87 percent of our dizinc reagents persist in acetonitrile solution after 300 hours at room temperature. The dizinc reagents we have developed are operationally simple to prepare using inexpensive and easy to handle zinc metal. The zinc reagents are also critical for preparing new types of high-valent nickel complexes, which are key targets for developing alkylation and perfluoroalkylation reactions. The difficult step in metal-mediated perfluoroalkylations is the reductive elimination of R-Rf. We have prepared a Ni(III) fluoroalkyl species in order to obtain the first structure/reactivity parameters that will help us understand how to facilitate reductive eliminations at nickel. This complex has been structurally and spectroscopically characterized, and represents the first example of a well-defined paramagnetic fluoroalkyl complex of nickel. The complex is a key find because in order to understand how to use the more naturally abundant first-row metals in catalysis, a more detailed knowledge of the reactivity patterns of the less-commonly studied paramagnetic redox states is required. Cyclic voltammetry studies also suggest that the rarely seen Ni(IV) redox state is also accessible.

Surface Science Studies of Nano-Crystalline Metal Oxide and Metal-Metal Oxide Core-Shell Catalysts

Institution: Pennsylvania, University of
Point of Contact: John Vohs
Email: VOHS@SEAS.UPENN.EDU
Principal Investigator: John Vohs
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

In this project we are attempting to bridge the materials gap between fundamental surface science studies of metal-oxide, single-crystal model catalysts, and high surface catalysts that are used industrially by measuring structure-activity relationships for thin films of well defined, metal oxide nanoparticles. The research program is concentrating on systems that are of interest for use as catalysts for complete-, selective- and photo-oxidation of organic oxygenates and builds upon our group's extensive experience in using surface-sensitive spectroscopic techniques to elucidate structure-activity relationships for oxide surfaces. The goals of this work are (1) to determine the role that highly undercoordinated edge and corner sites play in catalysis on oxides, (2) determine if control of oxide nano-crystalline size and shape can be used to design highly active and selective catalysts for specific reactions, and (3) determine how crystallite size and shape affect the photocatalytic properties of semiconducting oxides such as TiO₂. In addition to studies of nanocrystalline oxides, the research program will also include studies of hierarchal structured core-shell materials in which a metal nanoparticle is encased in a porous nano-crystalline oxide shell. Such materials have interesting catalytic properties and our goal in this work will be to use these unique model systems to study synergistic interactions between a metal and a reducible metal oxide support.

FY 2014 HIGHLIGHTS

Research during the 2014 focused on exploring structure-activity relationship for small organic oxygenates on catalytic titanium dioxide anatase nanocrystals. Methanol, ethanol, acetaldehyde, and acetic acid were used as probe reactants. Experiments were conducted across a range of reactant coverages, nanocrystal geometries and sizes, and photochemical conditions. These studies have provided new insight into the active sites for specific reactions and how the densities of these sites can be controlled by crystallite size and shape. Methanol reactivity studies provide a good example of the types of insight we have obtained. The thermally induced reaction of methanol on anatase TiO₂ nanocrystals produces primarily dimethylether and by comparison to what has been reported in previous in studies using macroscopic single crystals and powders we have been able to determine that this coupling reaction must either take place on (001) surfaces which are exposed in the nanocrystals or at edge sites. In contrast for the photochemically-induced oxidative coupling of methanol to produce methyl formate, (101) anatase surface planes have been identified as the active surface. Our studies have also provided new insight into the mechanisms of photochemical reactions on TiO₂. For the photochemical reaction of methanol to methyl formate it was observed that the methyl formate production increased at the expense of dimethylether production with increasing UV photon flux thereby demonstrating the central role of adsorbed methoxide groups in the photochemical reaction and that this reaction also occurs on the exposed (101) planes. The fact that the overall reactivity for the photochemical reaction was found to be independent of nanocrystallite size also supports this latter conclusion. Interestingly, size effects have been observed for the bimolecular ketonization of acetic acid, suggesting that edge in corner sites may be required for this reaction.

Theoretically Relating the Surface Composition of Pt Alloys to Their Performance as the Electrocatalysts of Low-Temperature Fuel Cells

Institution: Pittsburgh, University of
Point of Contact: Guofeng Wang
Email: guw8@pitt.edu
Principal Investigator: Guofeng Wang
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The main objective of this project is to gain fundamental knowledge about the relation between surface composition and catalytic performance of Pt alloy catalysts for electro-chemical reactions relevant to renewable energy technology.

Specific objective 1: Develop and improve a first-principles based multiscale computation approach to predict equilibrium surface composition of Pt alloy surfaces.

Specific objective 2: Evaluate the surface electronic structure and catalytic activity of Pt alloy catalysts.

Specific objective 3: Relate the surface composition and surface structure to the catalytic performance of Pt alloy catalysts.

FY 2014 HIGHLIGHTS

The project was launched on September 15, 2009. The research progress in this year includes the first-principles density functional theory (DFT) study of reaction energies and reaction mechanisms for

oxygen reduction reaction on Pt-based alloys and strained Pt surfaces as well as adsorption free energy of chemical species involved in methanol oxidation reaction on Pt-base alloys. The significant research achievements are: (a) our DFT results suggest that both ligand effect (subsurface transition metal such as Fe, Ni, and V) and strain effect (-2 to -3 % compressive strain) could lead to enhanced catalytic activity for ORR on surface-segregated Pt alloy catalysts as compared to pure Pt surface, and (b) the Pt/Co(111) surface, which was predicted to have the lowest onset potential in indirect pathways among the four Pt-based catalysts studied, could be a promising catalyst for CH₃OH oxidation to form CO₂. At this moment of the project, fifteen journal articles have been published from this grant.

Enabling Catalytic Strategies for Biomass Conversion

Institution: Stanford University
Point of Contact: Robert Waymouth
Email: waymouth@stanford.edu
Principal Investigator: Robert Waymouth
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$380,000 (2014-2016)

PROGRAM SCOPE

The goal of the proposed research is to investigate the fundamental science related to the development of selective catalytic processes for converting renewable bio-feedstocks into new classes of value-added chemicals and thermoplastics. We have discovered a cationic Pd catalyst ligated by neocuproine (2,9-dimethylphenanthroline) that catalyzes the selective oxidation of glycerol to dihydroxyacetone, the selective oxidation of sugar-derived polyols to alpha-hydroxyketones, and the oxidative carbonylation of diols to cyclic carbonates. Investigations into the fundamental chemistry of the selective oxidation of glycerol has both illuminated some key insights on the origin of high selectivities of this reaction and opened up new opportunities for the selective catalytic oxidations of biomass-derived polyols. Specific objectives for the proposed work are to: (1) Investigate the basic science and mechanistic origin of selective catalytic oxidation reactions, particularly of biomass-derived polyols and carbohydrates; (2) Expand the scope of selective catalytic oxidation reactions for the synthesis of new renewable monomers and polymers and (3) Develop integrated catalytic strategies for conversion of biomass wastes to useful chemical intermediates and polymers. This research program embraces a mix of fundamental investigations of catalytic reactivity with targeted approaches for the catalytic synthesis of monomers and renewable polymers. We are investigating the mechanisms of selective aerobic oxidation of polyols and carbohydrates with Pd catalysts with a special focus on the role of hydrogen peroxide and peroxy intermediates in an effort to increase catalyst lifetime. We have also extended our studies on the selective oxidation of sugars to ketoses and the oxidative lactonization of 1,5-diols to generate new families of lactone monomers.

FY 2014 HIGHLIGHTS

Kinetic and mechanistic studies of the aerobic oxidation of alcohols with cationic (neocuproine)Pd catalysts led to the identification and characterization of a novel trinuclear Pd oxo complex, which was shown to be a competent catalyst precursor for alcohol oxidation. The formation of this complex implicates a new mechanism for the activation of oxygen by reduced Pd species. Recent studies of this complex implicate its role in the disproportionation of hydrogen peroxide, a key reactive intermediate that is responsible for the oxidative degradation of the catalyst. These studies led to the development of

sacrificial phenol additives that increased the catalyst lifetime and provided experimental protocols for aerobic oxidations with high turnover numbers at much lower Pd loadings. The scope of the Pd-catalyzed alcohol oxidations were extended to the oxidative lactonization of substituted diethanolamines to generate new families of morpholinones (aza lactones), which have used as monomers to generate highly functionalized degradable polyesters. The scope of selective oxidations with these Pd catalysts were also extended to carbohydrates, specifically the 6-carbon glucopyranosides and deoxy fucopyranosides as well as the 5-carbon ribopyranosides. In some cases, the catalytic oxidation of these sugars occurs selectively at the 3-hydroxyl position to generate 3-keto sugars. Significantly, these selective oxidations of sugars can be carried out in the absence of protecting groups in aqueous solution or mixed organic/aqueous media. The origin of the high selectivities of these oxidation reactions are a subject of ongoing investigations.

Alkane Activation and Oxidation on Pd-Pt Oxide Surfaces

Institution: Florida, University of
Point of Contact: Jason Weaver
Email: weaver@che.ufl.edu
Principal Investigator: Jason Weaver
Sr. Investigator(s): Aravind Asthagiri; Ohio State University
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

Surface chemical reactions on Pd and Pt oxides play a central role in catalytic applications under oxygen-rich conditions, including the catalytic combustion of methane, the remediation of exhaust gases from automobiles and power plants and fuel cell catalysis. Unfortunately, however, difficulties in oxidizing Pd and Pt surfaces in ultrahigh vacuum (UHV) have limited the fundamental understanding of the properties and surface chemistry of Pd and Pt oxide phases. In this project, we are performing experimental and molecular modeling investigations of the growth and chemical reactivity of oxide phases generated on crystalline Pt and Pd surfaces in UHV using oxygen atom beams. We have been focusing particularly on characterizing the mechanisms governing the activation and oxidation of alkanes on pure and Pt-modified PdO(101) thin films. This focus is motivated by our discovery that alkanes adsorb as strongly-bound sigma-complexes on PdO(101) and that the sigma-complexes serve as precursors for facile C-H bond activation. The major goals of our work are to elucidate atomic-level steps involved in the oxidation of alkanes and CO on Pd oxide surfaces, and to develop microscopic models that can ultimately be used to predict reaction rates under practical conditions.

FY 2014 HIGHLIGHTS

During the 2014 period, we investigated the steady-state oxidation of methane on Pd(100) using ambient-pressure X-ray photoelectron spectroscopy (AP-XPS). This work shows that the formation of a multilayer PdO(101) film coincides with enhanced catalytic activity toward the complete oxidation of methane, whereas single layer PdO(101) is relatively unreactive. The high activity of the multilayer PdO(101) film observed under ambient pressure conditions agrees well with our prior UHV studies of alkane activation on this surface. Quantum chemical calculations reveal that multiple layer PdO(101) films are more reactive toward methane C-H bond cleavage than single PdO(101) layers due to electronic differences induced by the subsurface bonding partner. The effect that we discovered is analogous to ligand effects in organometallic complexes, and may be broadly applicable to

understanding the surface chemical properties of thin-film oxides. We also extensively investigated the oxidation of CO on Pd oxide phases using surface vibrational spectroscopy and density functional theory (DFT) calculations. Our results provide detailed insights into the mechanisms for CO oxidation on PdO(101), and reveal that surface oxygen vacancies created during reaction serve to promote further oxidation of CO. Additionally, our work shows that surface oxygen atoms are rapidly replenished by the bulk oxygen reservoir during CO oxidation at temperatures as low as 400 K, demonstrating a dynamic coupling between the creation and annihilation of surface oxygen vacancies during reaction.

Design and Characterization of Novel Photocatalysts with Core-Shell Nanostructures

Institution: California-Riverside, University of
Point of Contact: Francisco Zaera
Email: zaera@ucr.edu
Principal Investigator: Francisco Zaera
Sr. Investigator(s): Yadong Yin; California-Riverside, University of
Christopher Bardeen; California-Riverside, University of
Students: 6 Postdoctoral Fellow(s), 8 Graduate(s), 0 Undergraduate(s)
Funding: \$250,000 (2014)

PROGRAM SCOPE

The overall goal of this project has been to develop new a new and novel class of well characterized nanostructured Metal@TiO₂ core-shell and yolk-shell photocatalysts to address two fundamental issues presently limiting this field: (1) the fast recombination of electron-hole pairs once generated by light absorption, and (2) the recombination of H₂ and O₂ on the metal surface once produced. These model samples are also used to study the fundamentals of the photocatalytic processes. The specific objectives for this year have been to continue in our advances toward the three directions assigned to the three main members of the group. From a synthetic point of view, we continue to look for improved ways to make core-shell and yolk-shell materials with control on their key structural parameters. In terms of the characterization of the samples, the mass transport of the cells continues to be measured under realistic photocatalytic conditions, namely, in liquid phase by using infrared absorption spectroscopy. Finally, the photophysical behavior is being mapped out by using time-resolved measurements of transient light absorption and fluorescence and also the evolution of plasmon resonances over time, and correlated with photochemical activity. Correlations are being sought between those properties and structural parameters within the nanostructured samples.

FY 2014 HIGHLIGHTS

In terms of synthesis, we have made advances in several fronts: (1) we further improved our protocol for metal/TiO₂ core/shell composite nanostructures. A controlled sol-gel process has been recently developed to directly coat gold nanoparticles with a relatively thin layer of TiO₂ to produce Au@TiO₂ core-shell catalyst particles, which can be rendered crystalline via calcination at high temperatures. (2) The synthetic strategy for hollow TiO₂ shells has been extended to other catalytically relevant oxides such as zirconium. (3) We have developed a photocatalytic strategy for the synthesis of colloidal Ag-TiO₂ nanorod composites, in which each TiO₂ nanorod contains a single Ag nanoparticle on its surface. (4) We have studied the contribution of the hollow geometry to the enhancement in photocatalysis. (5) We have also explored the use of photocatalyst for designing a novel photoreversible color switching system. Regarding the photophysical and photocatalytic characterization of the catalysts, we continue to

use both time-resolved photoluminescence and diffuse reflectance femtosecond transient absorption spectrometer to probe charge transfer dynamics in organic charge transfer crystals and nanostructured oxide compounds. Those studies are correlated with photocatalytic activity measurements in terms of hydrogen production from aqueous solutions. Last year we identified clear correlations among the lifetime of the fluorescence decay, the rate at which hydrogen is produced in photocatalysis, and the crystallinity of the titania shells using well-defined Au@Void@TiO₂ yolk-shell nanostructures. Our photophysics results suggests an alternative pathway to that commonly reported for the role of the metal that does not involve electron transfer to the metal but requires it to act as a catalyst for the recombination of the hydrogen atoms made via the reduction of protons on the surface of the semiconductor instead.

DOE National Laboratories

Metal and Metal Oxide-Supported Platinum Monolayer Electrocatalysts for Oxygen Reduction

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: Radoslav Adzic
Sr. Investigator(s): Jia Wang; Brookhaven National Laboratory
Kotaro Sasaki; Brookhaven National Laboratory
Miomir Vukmirovic; Brookhaven National Laboratory
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$699,000 (2014)

PROGRAM SCOPE

This project contributes to resolving major problems in electrocatalysis important in chemical-to-electrical energy conversion in fuel cells, or electrical-to-chemical energy conversion in water electrolysis or carbon dioxide (CO₂) reduction. It focuses on the study and control of the electronic, structural and reactivity properties of promising nanostructured electrocatalysts. Great success has been achieved using platinum monolayer electrocatalysts, whose monolayer shell properties can be tuned by interactions with an underlying core to improve activity and durability for difficult reactions such as oxygen reduction or alcohol electro-oxidation, while reducing noble metal content to reduce cost. Efforts in 2014 continue to address the long-lasting challenge of shifting oxygen reduction reaction potentials close to thermodynamic reversible values. Such efforts include use of fluorinated chain molecules to decrease H₂O activity on Pt and increase near-surface O₂ concentration to enhance splitting the O-O bond (“dry cave” effect). We are also examining onion-structured nanoparticles with cores of multiple metal layers to facilitate reaching this goal, supported by DFT calculations. A broad study of enhanced kinetics and reaction mechanisms of the oxidation of alcohols (methanol, ethanol) on Pt monolayers under tensile strain is underway. Studies of ordering at the core-shell interface to increase stability and activity of electrocatalysts will be continued, as well as the design of a micro-reactor for electron microscopy studies of catalysts. Nitriding of non-noble components of core-shell catalysts will be explored to increase their catalytic activity and stability. By kinetic modeling and computational methods, we will obtain deeper insight into the kinetics and mechanisms of the O₂ reduction reaction, and alcohol oxidation.

FY 2014 HIGHLIGHTS

A distinct class of oxygen reduction (ORR) core-shell electrocatalysts comprised of nitride metal cores enclosed by thin Pt shells has been synthesized. Our theoretical analysis and the experimental data indicate that metal nitride nanoparticle cores significantly enhance the ORR activity in the order of PtNiN/C > PtFeN/C > PtCoN/C as a consequence of combined geometrical, electronic and segregation effects on the Pt shells. DFT calculations have shown a volcano type behavior with PtNiN/C at the top of the curve revealing the fact that, among the catalysts investigated, it has the best combination of both the surface strain and d-band center shifts. A structurally ordered Au₁₀Pd₄₀Co₅₀ catalyst exhibits comparable activity to Pt/C in both acid and alkaline media. Electron microscopic techniques demonstrate that via addition of Au atoms PdCo nanoparticles undergo an atomic structural transition from core-shell to a rare intermetallic ordered structure with twin boundaries forming stable {111}, {110} and {100} facets. The stability superior to Pt/C in alkaline media is attributed to the atomic structural order of PdCo nanoparticles along with protective clusters of Au atoms on the surface. This new strategy of making ordered Pd intermetallic alloy nanoparticles can be used in varied heterogeneous catalysis where size and structural stability matters. The splitting of the C-C bond in ethanol oxidation was observed on Pt monolayer under tensile strain on Au nanoparticles, while that was not observed with extended surfaces. Further work is needed to explain this difference. We demonstrated the effect of oxide co-catalysts on Pt/Au surfaces that helps oxidation and removal of CO that enhances the ethanol oxidation rate.

EARLY CAREER: Adsorbate Interactions in Catalytic Trend Studies

Institution: SLAC National Accelerator Laboratory
Point of Contact: Jens Norskov
Email: norskov@stanford.edu
Principal Investigator: Thomas Bligaard
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

There is a constant drive toward more energy- and resource-efficient technologies, for example related to the use of natural gas or biomass, and new sustainable energy processes. A key element in most novel energy technologies is the need for new, efficient catalysts made from Earth-abundant materials. The atomic-scale design of catalytic materials with tailored properties thus represents a grand challenge for science and technology. Computational catalyst search approaches leveraging electronic structure theory-based atomic-scale simulations coupled with kinetic models provides a promising avenue for accelerating catalyst discovery efforts. To reliably address detailed catalytic properties, such as for example product selectivity, the currently available simulation accuracy needs to be significantly improved. The absence of suitable models for reliably including interactions between adsorbates on a catalyst surface presents a leading contribution to the inaccuracy in computational catalysis trend studies. This project aims to improve the fundamental understanding of the interactions between adsorbed atoms and molecular fragments on transition metal surfaces and devise models to include these interactions in catalytic trend studies. The scientific insights and the set of tools established in this project aim to create a break-through in obtaining quantitative agreement between theoretical catalysis studies and experimental measurements and could potentially become a cornerstone in establishing an accurate and reliable "Catalyst Genome". The tools will be applied to catalytic processes pertaining to the transformations and eventually the liquefaction (Fischer-Tropsch) of methane. This could ultimately lead to improved processes for utilization of natural gas resources.

FY 2014 HIGHLIGHTS

In earlier work a model for differential adsorption energies was established and used to analyze catalytic trends in the methanation and the steam reforming reactions. In FY14 we have developed a more complete model for integral adsorption energies in the presence of adsorbate-adsorbate interactions. This model can then be differentiated to obtain appropriate models of differential adsorption energies to be used in microkinetic trend studies. Whereas the accurate description of differential adsorption energies is the key ingredient in microkinetic models, the integral adsorption energy is essential for accurately describing for example adsorption-corrections to surface free energies. This makes the integral adsorption energy model a key ingredient in the accurate modeling of the morphology of transition metal catalyst nanoparticles in reactive environments. Another highlight has been the extension of the model for adsorbate-adsorbate interactions to multi-site surface facets of higher complexity than the close-packed fcc(111) facet. As many (if not most) interesting catalytic reactions take place on steps, defects or other under-coordinated surface sites, we have worked on devising a model, which adequately describes the interactions between ensembles of different sites on transition metal surfaces. The combined integral-multisite adsorption model has been used to re-analyze trends for methanation, synthetic natural gas synthesis, steam reforming, and for dry reforming of methane. This strengthens the foundations under the future analysis of the more complex selectivity issues present in the Fischer-Tropsch synthesis reaction.

Catalysis Science Program

Institution: Argonne National Laboratory
Point of Contact: Emilio Bunel
Email: ebunel@anl.gov
Principal Investigator: Emilio Bunel
Sr. Investigator(s):
Students: 8 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$2,098,000 (2014)

PROGRAM SCOPE

The unifying theme in our research is the investigation of catalytically active metal centers whose nuclearity is limited to single metal atoms. The molecular uniformity of metal complexes studied in the field of homogeneous catalysis has been a major factor for the success of the field in the elucidation of reaction mechanisms and the understanding of catalytically active sites. We demonstrated previously the ability to synthesize isolated, ionic metal sites immobilized on hard supports such as SiO₂ and designer porous organic polymers (POPs) containing catechol and binol groups. Through the study of these catalysts we have shown that highly stable single-atom sites can be prepared and are catalytic for a variety of C-H activation and other catalytic transformations. For example, robust single-atom sites are highly selective and stable for alkane dehydrogenation at high temperature, but with low rates. By changing the ligand environment of the same transition metal, we have recently demonstrated much higher rates at lower temperatures while retaining high selectivity. We are interested to understand the factors which lead to higher activity by changes in the coordination environment around the metal, for example, the support type, redox active surface bonds, and changes in the metal-ligand bond strength tuning. In order to demonstrate enhanced rates and compare catalysts with differing thermal stability, we are determining the kinetics for alkane activation via dehydrogenation at high temperature and olefin-alkane hydrogen transfer at low temperature. State of the art *in situ* and *operando*

characterization using infrared, Raman and X-ray absorption spectroscopy, will provide information on the local structure of the site (number and type of metal-ligand and metal-support bonds, their distances, etc.), the oxidation state, and the intermediates formed under reaction conditions.

FY 2014 HIGHLIGHTS

Five different 1st row transition metal precursors (V^{III}, Cr^{III}, Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}) were successfully incorporated into a catechol POP (catPOP A₂B₁) support and characterized using ATR-IR and XAS analysis. The resulting metallated POPs were then evaluated for catalytic alkyne hydrogenation using high-throughput screening techniques. All six POPs were unexpectedly found to be active and selective catalysts for alkyne semi-hydrogenation. Three of the POPs (V, Cr, Mn) are the first of their kind to be active single-site hydrogenation catalysts. These results highlight the advantages of using a POP platform to develop new catalysts that are otherwise difficult to achieve through traditional heterogeneous and homogeneous routes. *Angewandte Chemie International Edition* 2014, 126, 12251-12254

Strategic Design of Novel Catalysts for the Selective Synthesis of Fuels and Chemicals

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: John Hartwig
Sr. Investigator(s): Alexis Bell; Lawrence Berkeley National Laboratory
Robert Bergman; Lawrence Berkeley National Laboratory
Christopher Chang; Lawrence Berkeley National Laboratory
Michelle C Chang; Lawrence Berkeley National Laboratory
Enrique Iglesia; Lawrence Berkeley National Laboratory
Kenneth Raymond; Lawrence Berkeley National Laboratory

T. Don Tilley; Lawrence Berkeley National Laboratory
Students: 7 Postdoctoral Fellow(s), 17 Graduate(s), 0 Undergraduate(s)
Funding: \$1,969,000 (2014)

PROGRAM SCOPE

The present program is focused on the strategic design of novel catalysts of potential interest for the production of fuels and chemicals in an energy-efficient and environmentally acceptable fashion. Of particular interest are the conversion of alkanes to alkenes and functionalized products, and the synthesis of fuels and chemicals from carbon monoxide and carbon dioxide. To achieve these goals a molecular understanding of catalytically active centers is used together with knowledge of how to synthesize unusual chemical and physical environments at such centers. The program involves a synergistic combination of efforts in the areas of catalyst synthesis, characterization, and evaluation. Quantum chemical simulations of catalytically active centers help guide the interpretation of experimental findings and suggest novel structures to be attempted synthetically. The seven principal investigators - Alexis T. Bell (ATB), Robert G. Bergman (RGB), Christopher Chang (CC) Enrique Iglesia (EI), Kenneth N. Raymond (KNR), Gabor Somorjai (GAS), and T. Don Tilley (TDT) pursue independent research goals while extensively collaborating via joint supervision of graduate students and postdoctoral associates, and by extensively sharing instrumentation.

FY 2014 HIGHLIGHTS

Showed that dianionic square planar cobalt(II) complex activates dioxygen to produce reactive intermediate that cleanly cleaves range of C-H bonds likely through cobalt(IV) oxo. Prepared dantalum center supported by silsesquioxane ligand that models selective silica-supported epoxidation catalysts and provides correspondingly selective homogeneous epoxidation catalysts. Devised strategy to control electron density at metal center via remote chemical trigger involving second-sphere Lewis acid binding. New examples of appropriate ligand-Lewis acid pairs developed for triggering reductive elimination and C-H activations at Pt center. Showed that self-assembled supramolecular host catalyzes Nazarov cyclization with rates over a million times faster than that of background reaction. Showed that supramolecular host catalyzes substitutions at secondary benzylic carbon with retention of configuration as opposed to inversion of configuration in bulk solution. Such control of stereochemistry is unprecedented with supramolecular host-guest catalysis. Generated water-soluble iron-oxo complexes supported by polypyridine ligands; evaluated their reactivity for C-H oxidations. Prepared and characterized series of new iron-based catalysts for CO₂ and proton reduction. Developed hybrid cell-nanoparticle system for electrochemical CO₂ reduction. Developed genetic selection for increasing fuel titers in engineered bacteria. Isolated and sequenced strains with improved fuel production efficiency under production conditions. Showed that proximity between Pt metal clusters and Brønsted acid sites at nanometer scale within confined environments leads to much higher turnover rates for bifunctional cascades leading to hydrodeoxygenation of butanols and alkyl phenols than on solids of similar composition but with intersite distances in micron scale. Identified evidence for strain effects on activity of isolated tungstate species supported on silica used for metathesis of propene.

Studies on Homogeneous Catalysis for Efficient Synthesis from Chemical Feedstocks

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: John Hartwig
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$485,000 (2014)

PROGRAM SCOPE

This FWP strives to establish the foundation upon which to design new catalysts and catalytic processes for chemical synthesis. The research has encompassed reactions catalyzed by transition metal catalysts that form both carbon-carbon and carbon-heteroatom bonds in products that have typically required multi-step syntheses from common chemical feedstocks. This program addresses several goals of the Basic Energy Sciences mission. It will create fundamental understandings that elucidate catalyst structure-reactivity relationships needed to design future systems, will use this information to develop new catalytic reactions that make more efficient use of energy resources and carbon feedstocks, and will address the need to develop chemical reactions that have reduced environmental impact. The current application includes proposed work to continue fruitful studies on additions of amines and alcohols to alkenes, as well as to investigate new topics related to the additions of C-H and X-H bonds to alkenes and new approaches to the discovery of catalytic reactions. The proposed studies include Specific Aims to 1) identify amido and alkoxo complexes that insert alkenes under mild conditions and to understand the factors that control the rates of these reactions; 2) develop iridium and enzymatic systems that catalyze the additions of N-H and O-H bonds to unactivated alkenes; 3) develop new

catalysts for the addition of aromatic C-H bonds to alkenes; and 4) expand the scope of our studies on high-throughput evaluation of catalyst activity to identify new transformations catalyzed by complexes of underutilized classes of ligands and first-row metals.

FY 2014 HIGHLIGHTS

Completed initial studies and reported the first hydroarylations of unactivated alkenes occurring with high anti-Markovnikov regioselectivity. Discovered and reported the oxidative olefination of furans with unactivated alkenes. Discovered the first intermolecular addition of indole N-H bonds to unactivated alkenes. Characterized the first single-site artificial organometallic protein and observed the first reaction of an organometallic protein to both cleave and form a metal-carbon bond. Developed an automated algorithm to search for reaction products within a pool of reactants and catalyst components.

Multifunctional Catalysis to Synthesize and Utilize Energy Carriers

Funding: \$7,157,000 (2014)

PROGRAM SCOPE

The central goal of this research program is to develop a fundamental understanding of catalytic processes for hydrogen management in the conversion of biogenic resources and CO₂ directly to energy

carriers, to use this knowledge to synthesize new catalysts, and to design new catalytic routes to energy carriers. We surmise the need for multi-functional catalytic sites, as well as for sterically assembling various sites to enable cascade strategies for effecting complex transformations. Throughout the organization of this program we integrate heterogeneous and homogeneous catalysis, surface science and computational methods. The research will focus on the grand challenges described in this quote from the U.S. Department of Energy (DOE) Basic Energy Sciences (BES)-sponsored report Basic Research Needs: Catalysis for Energy: "To realize the full potential of catalysis for energy applications, scientists must develop a profound understanding of catalytic transformations so that they can design and build effective catalysts with atom-by-atom precision and convert reactants to products with molecular precision."

FY 2014 HIGHLIGHTS

- Catalysts, containing both acid and metal active sites, for lignin conversion were investigated in reactions involving model substrates such as phenolic ethers, phenols, alcohols and olefins. Individual steps of these reactions were studied to understand the guiding principles for further catalyst design at both atomic and mesoscale level.
- An unexpected bimolecular dehydrogenation reaction pathway for diols on TiO₂(110) was uncovered. H₂ formation from this unusual reaction arises from hydroxyl groups of adjacently-adsorbed diols and, as such, is highly sensitive to the steric environment around these ⁻OH groups.
- Using fundamental thermodynamic data, a catalyst for CO₂ hydrogenation was designed based on molecular cobalt complexes. This new catalyst has a higher catalytic performance than the fastest precious metal analogs. We are now extending this concept to aqueous catalysis for CO₂ hydrogenation.
- Carbonates were established as major intermediates in heterogeneous phase catalytic hydrogenation of CO₂ on multifunctional metal/metal-oxide catalysts. Further, a low temperature/pressure CO₂ conversion via alkylcarbonate intermediates was demonstrated in a carbon capture solvent.
- Mechanistic studies of water and simple probe molecules were completed on TiO₂(110) and RuO₂(110) using a variety of experimental and theoretical approaches. We focused on the roles of defects, coadsorption, site specificity and reaction dynamics on single electron transfer photochemical events.
- Capabilities and expertise were developed to provide the first experimental measure of reaction rates, turnover frequencies and thermodynamic driving force for the catalytic hydrogenation of imines, olefins, aldehydes and ketones. We have carried out the first quantitative measurements of the reactivity of frustrated Lewis pairs, as nonmetallic hydrogenation catalysts.

Predictive Theory of Transition Metal Oxide Catalysts

Institution: SLAC National Accelerator Laboratory
Point of Contact: Jens Norskov
Email: norskov@stanford.edu
Principal Investigator: Jens Norskov
Sr. Investigator(s): Todd Martinez; SLAC National Accelerator Laboratory
Harold Wang; SLAC National Accelerator Laboratory
Anders Nilsson; SLAC National Accelerator Laboratory
Thomas Bligaard; SLAC National Accelerator Laboratory
Aleksandra Vujvodic; SLAC National Accelerator Laboratory
Charles Campbell; Washington, University of
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)

Funding: \$970,000 (2014)

PROGRAM SCOPE

The work focusses on establishing a predictive theory for transition metal oxide catalysis. It addresses the fundamental challenges associated with the electronic structure description of transition metal oxide surfaces, such as the electron localization in oxides and its effect on adsorption properties. The goal is to combine experimental and theoretical methods to establish an accurate theory for transition metal oxide surfaces, which potentially could create the foundation for tailoring new oxide catalysts.

FY 2014 HIGHLIGHTS

As a first step towards a database of adsorption and activation energies for oxide surfaces, we performed a theoretical investigation of surface properties and energetics of molecules and oxygen chemistry on low-Miller index surfaces of alkaline-earth metal oxides (MgO, CaO, SrO, BaO). The accuracy of commonly used xc functionals and RPA was evaluated and compared to experiments. All considered functionals qualitatively predict similar adsorption energy trends and the calculated and experimental adsorption energies lie within the bounds of LDA (too high) and RPBE (too low). The ordering between adsorption energies on different surface facets is attributed to the local geometrical and electronic surface structure of the metal constituent of the oxide. We have worked to extend the *ab initio* nanoreactor to problems involving heterogeneous catalysis with the first target to explore the Fischer-Tropsch reaction on iron and iron/silica for direct nonoxidative conversion of methane to ethylene, aromatics and hydrogen (Nature Chem. 6, 1044 (2014)). The basic idea of the nanoreactor is to use *ab initio* molecular dynamics to sample the space of chemical reactions, which are monitored by pattern recognition algorithms. We added effective core potentials (ECPs) to describe the metal atoms to our GPU-based code, which required development of a GPU-based algorithm for the ECP integrals. We also incorporated fractional occupation in the self-consistent field procedure to be able to sample several spin states, necessary when modeling metal clusters. Finally, we incorporated new boundary conditions for a surface nanoreactor – augmenting the spherical nanoreactor with a disc-shaped region representing the surface not subject to periodic confining potential. A key element in testing new computational approaches for oxide surface chemistry is to compare their results to accurate experimental adsorption energies for well-defined systems.

SUNCAT Center for Interface Science and Catalysis

Institution: SLAC National Accelerator Laboratory
Point of Contact: Jens Norskov
Email: norskov@stanford.edu
Principal Investigator: Jens Norskov
Sr. Investigator(s):
Students: 11 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$2,425,000 (2014)

PROGRAM SCOPE

The SUNCAT Center for Interface Science and Catalysis seeks to develop a fundamental understanding of the electronic and structural factors determining the catalytic properties of solid surfaces. The ultimate aim and test of success is to provide design tools for new catalysts. We propose to further develop the SUNCAT-FWP to include new levels of complexity: more complex molecules and processes, more

complex multi-functional active sites and support effects, more complex bonding types, and more complex electronic structure methods. Our strategy will be to develop concepts that reduce the complexity to manageable descriptor-based models and enable an understanding of trends from one catalyst system to the next. The concepts are tested on a number of processes for energy transformations: Higher alcohol synthesis from syngas, direct conversion of methane to methanol, and metal-air batteries.

FY 2014 HIGHLIGHTS

Highlight from 2014 include the development of a first method to include uncertainty in the calculation of complex properties like catalytic reaction rates (Science 445, 197), new insights into limitation in electrochemical performance due to charge transport in insulating catalysts (Nano Lett. 14, 5853), new ideas for ammonia synthesis catalysis at low temperature and pressure (Chem Phys. Lett. 598, 108), discovery of a new class of catalysts for CO₂ reduction to methanol (Nature Chem. 6, 320), new insight into electronic structure effects in surface reactivity of transition metals (Phys. Rev. B 89, 115114), the first analysis of trends in selectivity and activity of catalysts for higher alcohol synthesis from CO and H₂ (Top. Catal. 57, 135), theoretical predictions and direct experimental observation of intermediates in the electrochemical oxygen reduction reaction (Nature Comm. 4, 2817), and new catalysts for the oxygen reduction reaction (ChemElectroChem 1, 67).

Fundamentals of Catalysis and Chemical Transformations

Zili Wu; Oak Ridge National Laboratory
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$2,289,000 (2014)

PROGRAM SCOPE

The overarching goal of this proposal is to understand molecular interactions and reactions at the surfaces of catalytically active oxides and functionalized oxides. There is particular emphasis on oxygenated molecules and their thermal chemistry, surface chemistry and catalytic conversion which links all tasks of the proposal. Catalytic systems of interest include cerium oxide as a model crystalline, reducible oxide, other oxides with controlled morphologies, and Au in various forms including nanoparticles, well defined clusters (Au_n(SR)_m) and single sites. Model oriented thin films of CeO₂ with (100) and (111) surface terminations are compared to uniformly structured CeO₂ nanoshapes (cubes, octahedra) which manifest these surface terminations. These surfaces and nanoshapes are used to explore the effect of site geometry on catalytic behavior as a basis for learning how to tailor catalytic selectivity via structural differentiation. Selectivity and rates of catalytic reactions of C₁ and C₂ alcohols,

aldehydes and acids are compared to learn how surface sites geometry and cooperativity between cation and anion sites affect reaction pathways. Surface reactions on oriented films are probed in UHV by synchrotron based electron spectroscopies. Nanoshapes are used directly in flow reactors to probe catalytic behavior and explore reaction pathways using operando Raman and IR spectroscopies and a variety of temperature programmed and catalytic measurements. Reactions are modeled computationally using DFT. Studies are underway to explore the how functionalization with acidic or basic sites affects surface adsorption and catalytic properties. The effects of the stabilizing ligands upon stability of Au clusters and the structural changes that occur upon ligand removal are being studied. The proposed research is aligned with the grand challenges described in the BES Basic Research Needs Workshop Report on Catalysis for Energy.

FY 2014 HIGHLIGHTS

We have pursued three focus areas. First, catalytic reactions of small oxygenates on model CeO₂ surfaces were explored to obtain a fundamental understanding of reaction pathways and the relationship between surface structure and catalytic function. It was shown that CO₂ adsorbs on a CeO₂(100) in a flat-lying tridentate configuration. This novel bonding is unexpected since carbonates are usually thought to form mono- or bi-dentate adsorption configurations. Reaction of acetaldehyde over CeO₂ nanoshapes produce crotonaldehyde and various other products. Selectivity can be attributed to the variation in the basicity of the surfaces, defects densities, coordination numbers of surface atoms, and reducibility. DFT calculations clarified the origin of the selectivity differences between the CeO₂(100) and (111) surfaces for the ethanol selective oxidation. Transition states computed for α - and β -CH bond cleavage explained the experimentally measured selectivity. In the second focus area, we have explored supported molecular Au clusters of well-defined sizes. We have studied the stability and reactivity of Au cluster compounds on uniformly structured CeO₂ supports as a route to structurally defined metal catalysts. Ligands play a key role in stabilizing the Au clusters, but are found to poison the activity of the Au catalytic sites. Cationic Au sites are found to play a major role in CO oxidation, which proceeds predominantly via a redox mechanism where CeO₂ activates O₂ while CO is activated on the de-thiolated gold sites. In the third focus area, we have explored synthetic routes to achieve selectivity in catalysis. A lab-in-a-shell strategy was developed for the preparation of multifunctional core-shell nanospheres consisting of a core of metal clusters and an outer microporous silica shell. Pd clusters encapsulated in hybrid core-shell structures exhibit size-selective catalysis in allylic oxidations of substrates with the same reactive site but different molecular size.

Homogeneous and Interfacial Catalysis in 3-D Controlled Environments

Institution:	Ames Laboratory
Point of Contact:	Cynthia Jenks
Email:	cjenks@ameslab.gov
Principal Investigator:	Marek Pruski
Sr. Investigator(s):	Andreja Bakac; Ames Laboratory Aaron Sadow; Ames Laboratory Igor Slowing; Ames Laboratory
Students:	2 Postdoctoral Fellow(s), 12 Graduate(s), 0 Undergraduate(s)
Funding:	\$1,254,000 (2014)

PROGRAM SCOPE

This program brings together the best features of homogeneous and heterogeneous catalysis by designing novel single-site mesoporous interfacial catalysts with controlled, nanostructured morphology and surface properties. The control of specific chemical properties, spatial distribution, and concentrations of various catalytic functional groups on the pore walls is achieved by a synthetic approach referred to as multifunctionalization, where some of the anchored groups serve as a catalyst, while others are designed to modify the selectivity or activity of the system. We seek to advance the physico-chemical characteristics of mesoporous scaffolds, understand and address the effects of transport and confinement on catalytic transformations, and develop improved organometallic ligands for energy-related catalytic transformations. These new single-site heterogeneous catalysts are amenable to precise characterization by a combination of chemical, physical and computational methods. Solid-state NMR methodology is developed and applied as the primary analytical tool for studying their structure and functioning. The catalytic activity is being examined in several distinct classes of chemical reactions, including enantioselective hydrogenation, hydrolysis, polymerization and oxidation. Detailed mechanistic studies are carried out in an effort to recognize the key factors that determine selectivity, reactivity and kinetics in both homogeneous and heterogeneous catalytic chemistry. Our team gains fundamental knowledge about the influence of the 3-D environment on catalysis. In the long term, such fundamental knowledge will create a basis for the design of efficient, stable, and highly selective catalytic systems that for specific applications in the production of fuels and chemicals.

FY 2014 HIGHLIGHTS

We developed, characterized and tested a new silica-supported zirconium catalyst for the hydroboration of aldehydes and ketones. This novel material remained catalytically active upon recycling or exposure to air, showing that these single-site zirconium centers are robust catalytic sites for carbonyl reduction. Most importantly, this system highlights the possibility of using abundant oxophilic early metal catalysts for the conversion of highly oxidized substrates relevant to new chemical feedstocks. The mechanistic details of carbon-carbon coupling reactions catalyzed by amine-modified mesoporous silica nanoparticles were investigated using theoretical models, kinetic measurements and solid-state NMR spectroscopy. These studies led to the assembly of multicatalytic systems that performed tandem reactions for upgrading the molecular weight of alcohols. The general strategy consisted in the assembly of two site-isolated catalysts: the first enabling low temperature oxidation of alcohols to aldehydes, and the second facilitating aldol condensation between the intermediate aldehydes. Site-isolation was achieved by immobilizing one catalyst inside of the pores, while the other catalyst was bound to the external surface of the particles. This isolation prevented mutual poisoning of the catalysts. The versatility of this method of assembly was proven by combining an organocatalyst with a second organocatalyst, an enzyme, or a metal nanoparticle.

Catalysis Science for Advanced Fuels

Institution: Brookhaven National Laboratory

Sr. Investigator(s): Dario Stacchiola; Brookhaven National Laboratory
Ping Liu; Brookhaven National Laboratory
Sanjaya Senanayake; Brookhaven National Laboratory
Michael White; Brookhaven National Laboratory
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)

Funding: \$1,645,000 (2014)

PROGRAM SCOPE

This program pursues an improved understanding of chemical catalysis for advanced fuels synthesis and energy conversion processes by elucidating catalytically important properties of well-defined surfaces, powders and nanostructures. Complexities stemming from the inherent multi-component aspects of heterogeneous catalysis are explored using both ultra-high-vacuum surface science investigations of well-defined model systems, and powder diffraction and x-ray absorption studies of 'real-world' systems. Two subtasks bring distinct methods to common reaction themes in fuel synthesis such as desulfurization, hydrogen production and oxygenate synthesis. The subtask Catalysis: Reactivity and Structure develops and applies new approaches for the in-situ characterization of heterogeneous catalysts using facilities available at the National Synchrotron Light Source for X-ray diffraction, X-ray absorption and photoemission. Quantum-chemical computation plays an essential role for basic understanding of catalytic reactions and interpretation of experimental results. The subtask Nanostructured Materials for Catalysis focuses on the preparation, characterization and reactivity of metal nanostructures. Its goals are to identify and characterize the catalytically active sites of supported nanocatalysts and to investigate the influence of particle size, morphology and support on nanostructure reactivity. Nanostructure synthesis and characterization benefit from collaboration at the Center for Functional Nanomaterials. Nanocluster preparation techniques include soft-landing of size-selected clusters and reactive layer deposition.

FY 2014 HIGHLIGHTS

The research themes in this FWP are inspired by challenges in the production and use of chemical fuels. In the last year important contributions have been made in areas related to (1) the cleaning of oil-derived fuels through hydrodesulfurization, (2) the reforming of alcohols, (3) the synthesis of higher (C_1 - C_4) alcohols by the hydrogenation of CO_2 or CO, and (4) CO oxidation. The last two topics are associated with C_1 chemistry. These research efforts were also linked by an interest in the properties of oxides, carbides and sulfides, materials which may be able to replace scarce noble metals in energy-related catalysis. In many of our studies, the catalytic processes took place on multifunctional catalysts which contained metal-oxide, metal-carbide or metal-sulfide interfaces developed in the subtask on Nanostructured Materials. A paper was published in Science describing a novel and highly active catalysts, $Cu/CeO_x/TiO_2$, for the hydrogenation of CO_2 to methanol. In addition, it was shown that Au deposited on carbide supports such as TiC and MoC is an excellent catalyst for desulfurization reactions, the oxidation of CO and the transformation of CO_2 to methanol. Studies were performed examining the properties of a highly efficient non-expensive Ni-CeO₂ catalyst active for the production of hydrogen through the reforming of ethanol. The development of techniques for characterizing the structural properties of catalysts under the high-pressure conditions of industrial processes is a top priority for this project. In the last year, the Catalysis Group at BNL has been very active in developing instrumentation for the characterization of catalysts with PDF analysis and the integration of XAFS and XRD or XAFS and IR or Raman. The integration of IR and Raman with XAFS allows a simultaneous determination of the reaction intermediates on the surface and the chemical state and structure of the catalyst.

Mechanisms for Water Gas Shift Reaction

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov

Principal Investigator: Jose Rodriguez
Sr. Investigator(s): Ping Liu; Brookhaven National Laboratory
Dario Stacchiola; Brookhaven National Laboratory
Sanjaya Senanayake; Brookhaven National Laboratory
Jonathan Hanson; Brookhaven National Laboratory
Michael White; Brookhaven National Laboratory
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$631,000 (2014)

PROGRAM SCOPE

The water-gas shift reaction (WGS: $\text{CO} + \text{H}_2\text{O} = \text{H}_2 + \text{CO}_2$) is a critical process in providing pure hydrogen for fuel cells and other applications. Improved air-tolerant, cost-effective WGS catalysts for lower temperature processing are needed. Ceria-, titania- and molybdena-based catalysts are expected to be the next generation of WGS catalysts for industrial applications. The design and optimization of these WGS catalysts depends on a better understanding of their structures and functions. This project involves a coordinated research program to understand the active sites and reaction mechanism for the WGS on these promising metal/oxide catalysts. Our goal is to develop the ability to predict, and ultimately design, improved cost-effective WGS low temperature catalysts. Our approach exploits a uniquely powerful combination of synthetic and characterization methods for both model systems and industrially relevant powder catalysts. It utilizes unique capabilities for in-situ studies using time-resolved X-ray diffraction, X-ray absorption spectroscopy, photoemission, infrared spectroscopy and transmission electron microscopy. Most experiments are closely coupled to theoretical studies on the chemisorption of the reactants, the stability of possible intermediates, and activation barriers for elementary reaction steps, providing critical guidance in developing a complete picture of the links between catalyst structure and reaction mechanism in this important process for the production of pure hydrogen.

FY 2014 HIGHLIGHTS

More than ten papers in topics related to the water-gas shift reaction were published. There were important advances in six general areas.

- 1) Systematic studies using a suite of in-situ techniques (XRD, PDF, XAFS, AP-XPS, IR) showed that the structure and composition of metal/oxide catalysts used for the water-gas shift are dynamic entities that change with the system temperature and the pressure of the reactants.
- 2) New type of metal-support interactions were discovered while examining the behavior and properties of metal/oxide and metal/carbide catalysts. These metal-support interactions can be quite useful for the rational design of low-temperature water-gas shift catalysts.
- 3) It was shown that the metal and support phases of metal/oxide and metal/carbide catalysts must be taking into consideration when designing highly-efficient catalysts for the water-gas shift.
- 4) Theoretical studies showed that a HOCO species, formed at metal-oxide and metal-carbide interphases, is a key intermediate during the water-gas shift.
- 5) Highly active powder catalysts that combine Au or Pt on $\text{CeO}_x/\text{TiO}_2$ and MoC_x substrate were prepared and fully characterized.
- 6) The scientists in the project participated in the development of new tools or techniques for the in-situ characterization of water-gas shift catalysts, helping in the design of a new instrument that will combine PDF or XAFS with infrared or Raman spectroscopy. This new instrumentation will allow us to perform unique mechanistic studies.

EARLY CAREER: Catalyst Biomimics: A Novel Approach in Catalyst Design

Institution: Pacific Northwest National Laboratory
Point of Contact: Bruce Garrett
Email: bruce.garrett@pnl.gov
Principal Investigator: Wendy Shaw
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$2,500,000 (2010-2014)

PROGRAM SCOPE

The objective of the proposed research is to incorporate a rationally designed proton channel into homogeneous catalysts using advanced enzyme design methodology combined with superior molecular catalyst design. Proton channels are essential for the rapid rates of hydrogen production/oxidation observed in enzymes and small molecule catalysts are notably unable to match these rates. We propose to design synthetic catalysts with an enzyme-like proton channel while maintaining a relatively small catalyst. Using Rosetta, energy minimized computational structural models will be generated to develop peptide ligands with positioned proton relays. The computationally determined “best” ligands will be synthesized and incorporated into nickel based catalysts. The catalyst will be characterized using electrochemistry, NMR, IR, XAFS and X-ray crystallography. Attributes such as the pK_a , distance, structural flexibility and number of the relays will be probed. The multistate empirical valence bond approach will be used to predict which stabilized structures might perform better than others based on pK_a values and preferred proton transport pathways. This molecular level approach will allow us to develop a detailed understanding of proton relays, revealing insights into how they can enhance homogeneous catalysts, as well as how they function in enzyme systems, with potential applications to energy and fuel storage.

FY 2014 HIGHLIGHTS

In the past year, we have achieved several key accomplishments. We successfully incorporated a structured peptide into a hydrogen production catalyst and demonstrated its function. While the resulting complex was twice as fast as the parent catalyst with no peptide, the most important result is that this complex can serve as a foundation upon which to develop a more complex outer coordination sphere, whose features can be tested to provide a mechanistic understanding of its role. We also reported on development of the first water soluble hydrogen oxidation catalyst, where solubility was enabled by an attached amino acid (glycine), which also served to create a two-relay proton channel. Modifying glycine to an arginine resulted in the fastest H_2 oxidation catalyst reported to date at room temperature, and exceeding the rates of enzymes by several orders of magnitude at elevated pressures of H_2 . This remarkable performance is thought to be due to the arginines controlling the active site structure. This complex was further found to be truly reversible while maintaining fast rates in both directions, something only ever observed before in enzymes and representative of achieving the highest efficiency attainable. The reversible behavior was found to be due to a combination of the outer coordination sphere, the solvent and the thermodynamic matching of the 1st and 2nd coordination spheres.

Nanoscience and Nanoparticles for 100% Selective Catalytic Reactions

Institution: Lawrence Berkeley National Laboratory

Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Gabor A Somorjai
Sr. Investigator(s): Heinz Frei; Lawrence Berkeley National Laboratory
Miquel B. Salmeron; Lawrence Berkeley National Laboratory
F. Dean Toste; Lawrence Berkeley National Laboratory
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$776,000 (2014)

PROGRAM SCOPE

Heterogeneous catalysts are nanoparticles. They are utilized in most industrial chemical processes in the form of metal clusters dispersed on high surface area oxide supports. Recent breakthroughs in nanotechnology have created the ability to control material structures on scales that are relevant for catalyst design (e.g., the diffusion length of molecular intermediates in a bifunctional catalyst, ca. 5 nm). The goal of this project is to explore the molecular and nanoscale variables, structure, composition and dynamic properties of catalysts to achieve 100% selectivity in multipath surface catalyzed reactions. The three main areas of emphasis that are combined in this program: to fabricate 3-dimensional or 2-dimensional catalyst systems with complete control of catalyst nanoparticle location, structure, thermal and chemical stability; to characterize these nanoscale systems by a combination of steady-state and time-resolved and spectroscopic techniques that identifies their size, location, electronic structure and composition during and after fabrication and under reaction conditions; to carry out multipath chemical reactions and correlate reaction selectivity with the physical-chemical variables of nanoparticle catalyst fabrication with in-situ probes of the catalyst surface, if possible.

FY 2014 HIGHLIGHTS

Studied hydrogenative isomerization of hexane and methylcyclopentane over Pt nanoparticles (2.5nm) supported in mesoporous oxides (e.g. V, Nb, Sn and Al modified silica) and zeolites of BEA and ZSM-5 framework structures. Conducted hydrogenation of CO and CO₂ to produce hydrocarbon fuels using size-controlled Co nanoparticles (3-10nm) supported in mesoporous metal oxides such as TiO₂, Co₃O₄ and MnO₂. Oxidative conversion of simple alcohols (methanol, ethanol and propanol) was studied in both liquid-solid and gas-solid interfaces over size-controlled Pt nanoparticles in the 1-5nm range. Detected a transient intermediate of gold-catalyzed arylative ring expansion under reaction conditions in solution by rapid-scan FT-IR spectroscopy; elucidated kinetic behavior. Determined structure of this intermediate based on identification of 6 vibrational modes revealing chemical bond rearrangements during rate limiting step. (Specifically, the intermediate features an expanded ring and the step involves transfer of aryl group from Au center to the alkyl side chain under expulsion of Au moiety to form final product under regeneration of free catalyst). Determined the efficiency, lifetimes and mechanisms of several light driven Ru and Ir redox sensitizers by combined transient FT-IR and optical spectroscopy for pulsed activation of catalysis in solution through redox activation of catalyst (soluble Au catalysts and supported Au clusters are first application). Spectral mapping of a multistep gold-catalyzed rearrangement in a flow microreactor performed with a spatial resolution of 15 micrometers, employing micrometer-sized synchrotron-based IR and X-ray beams. *In situ* synchrotron-sourced IR microspectroscopy detected conversion of reactant into primary product which was catalytically transformed into secondary product. By tuning residence time of reactants in flow microreactor, performed detailed an analysis of reaction kinetics.

Understanding Electron Transfer in Plasmon-Enhanced Photocatalysis using Nonadiabatic Electron Dynamics

Institution: Kansas State University
Point of Contact: Christine Aikens
Email: cmaikens@ksu.edu
Principal Investigator: Christine Aikens
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$359,950 (2014-2016)

PROGRAM SCOPE

Plasmon-enhanced photocatalysis is a promising method for the generation of solar fuels. In plasmon-enhanced photocatalysis, noble metal nanoparticles (NPs) are interfaced with a semiconductor, and the combined system has increased photocatalytic yields when irradiated with visible light. However, there is currently a lack of understanding of the fundamental physical principles that underlie these systems. The goal of this work is to develop an essential understanding of the origin of plasmon-enhanced photocatalysis and the conditions that increase its enhancement. This investigation will involve studies of the electron and electron-nuclear dynamics in pure NPs as well as in systems that incorporate an interface between a metal NP and a metal oxide layer. To accomplish our goals, our investigation will begin at the first instance when solar photons interact with a metal nanoparticle and progress to systems that incorporate an interface between a large metal NP and a metal oxide layer. This requires a variety of theoretical techniques depending on the size and complexity of the system and the time scale of the processes involved. Initially, we will examine the electron dynamics in pure metal NPs using quantum mechanical methods including time-dependent Hartree-Fock and time-dependent density functional theory methods. In the next step of the research, we will examine how electron dynamics couple with nuclear dynamics to permit the excited electronic states generated by solar excitation to decay to lower energy states. In addition, we will examine how electrons transfer between a gold nanoparticle and a titanium oxide surface, which will likely depend on the linker between the NP and the surface, features of the surface such as defects, and the excitation wavelength. To treat some of the largest systems of interest in this work, we will develop and test a new nonadiabatic density functional tight binding approach.

FY 2014 HIGHLIGHTS

This project has just come online in the last couple months of FY 2014. Our group has installed the CPMD code and has begun examining how the memory requirements of TDDFT calculations increase with the size of the system. We have found that the memory requirements do not scale as N^3 or N^4 , where N is the number of basis functions in the system; we will continue to examine the memory requirements in order to learn more about the scaling. In addition, our group has begun to use the time-dependent Kohn-Sham approach to examine the electron dynamics of thiolate-stabilized nanoparticles including $\text{Au}_{18}(\text{SH})_{14}$, $\text{Au}_{25}(\text{SH})_{18} \dots \text{NH}^+$, and $\text{Au}_{38}(\text{SH})_{24}$. The Au_{18} system has recently been reported as a good sensitizer for photocatalysis, so we have added it to our original scope of work.

Theoretical Studies of Elementary Hydrocarbon Species and Their Reactions

Institution: Georgia, University of
Point of Contact: Wesley Allen

Principal Investigator: Wesley Allen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 8 Graduate(s), 0 Undergraduate(s)
Funding: \$285,000 (2014-2015)

PROGRAM SCOPE

This research program carries out both methodological development and computational applications of *ab initio* quantum chemistry, as directed toward the fundamental chemical physics of combustion. To build and refine the world's database of thermochemistry, spectroscopy, and chemical kinetics, next-generation electronic structure methods are needed to achieve very high accuracy (0.1-0.2 kcal/mol) in theoretical predictions. Toward this ambitious goal, our work focuses on rigorous single- and multireference coupled cluster methods, executed to the level of triple or quadruple excitations and pushed to the complete basis set limit via new explicitly correlated techniques or more established extrapolation schemes. Another hallmark of this research is the treatment of molecular vibrational anharmonicity.

FY 2014 HIGHLIGHTS

Representative research topics recently pursued are as follows:

- (1) Radical-radical hydrogen abstractions in combustion chemistry are disproportionation reactions that are generally exothermic with little or no barrier, yet are underappreciated and poorly studied. These reactions usually begin with two free radicals and end with two closed-shell products, and thus the electronic transformation is intrinsically multireference in nature. Such challenging electronic structure problems have been tackled using our recently developed state-specific multireference coupled cluster methods Mk-MRCCSD and Mk-MRCCSD(T). The rigorous Mk-MRCCSD(T)/CBS results demonstrate unequivocally that the prototypical methyl + ethyl, H + ethyl, and H + HCO reactions are facile, proceeding with no barrier in the entrance channel.
- (2) The ubiquitous reactions of alkyl radicals with molecular oxygen rapidly become more complex as the radical grows in size. Isomerizations to hydroperoxyalkyl radicals (QOOH) are in competition with concerted elimination of HO₂. In a herculean investigation, all chemically relevant minima and transition states of the *n*-propyl, *i*-propyl, and *n*-butyl + O₂ systems are being mapped out using CCSD(T)/cc-pVTZ theory, and focal point analyses targeting the complete basis set limit of CCSDT(Q) are being executed to obtain definitive energetics.
- (3) The abundance of HOOO in combustion and atmospheric chemistry and the role of this poorly understood species as a sink for hydroxyl radicals has been a subject of recent debate. In a collaboration with the experimental group of Professor Gary Douberly, inertial dipole moment components were obtained from Stark spectra of the trans-HOOO radical in superfluid helium nanodroplets, and computations at the composite all-electron CCSDT(Q)/CBS level of theory were used to resolve the controversy over the structure of this species.

Towards 3rd Generation Organic Tandem Solar Cells with 20% Efficiency: Accelerated Discovery & Rational Design of Carbon-Based Photovoltaic Materials

Institution: Harvard University
Point of Contact: Alan Aspuru-Guzik
Email: aspuru@chemistry.harvard.edu
Principal Investigator: Alan Aspuru-Guzik
Sr. Investigator(s):
Students: 5 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$341,056 (2014)

PROGRAM SCOPE

The goal of this research effort is to expand the capabilities of the Harvard Clean Energy Project— our automated, high throughput screening framework for the virtual design and screening of potential organic photovoltaic materials – in order to accelerate development towards a material displaying 20% power conversion efficiency. In order to understand and characterize the electronic structure of these materials, CEP utilizes first principles quantum chemical calculations for multiple low energy geometries of each of the generated molecules – resulting in what we believe to be the world’s largest database of quantum chemical information. From the data that we collect, we aim to establish structure-property relationships which will aid the rational design of novel photovoltaic materials by identifying combinations of fragments which result in increased performance. These relationships will aid in the development of enriched libraries, allowing us to efficiently search chemical space, and focus computational resources on molecules which have high potential for displaying desirable properties. We augment this data-mining based approach with machine-learning techniques, which affords additional feedback, helping us to both improve the design of these molecules and predict the potential of newly generated molecules. This allows us to extend our search far beyond the scale which is feasible with an all-quantum-chemical approach. By distributing our calculations over thousands of volunteer computers using the World Community Grid, we can calculate properties for around 30,000 molecules a week. We estimate this resource to correspond to a 6-7,000 core computer cluster. The development of organic photovoltaic materials is one of the most exciting frontiers of renewable energy, and we believe that our high throughput approach has the potential to provide important contributions, as well as changing how science equips itself to answer such questions in the future.

FY 2014 HIGHLIGHTS

1. Expansion of the Harvard Clean Energy Project. Over 3 million compounds have now been screened, which has required over 300 million quantum-chemical calculations. This represents the largest known database of such information, and the data provided affords significant insight into factors determining the efficacy of molecules for use in OPVs. The project has thus far harvested over 29,000 CPU years from the World Community Grid.
2. Analysis of pairwise fragment frequencies from the CEP. A library of 2.1 million molecules was built from 26 fragments suggested by the Bao group and examined with quantum chemical calculations on the World Community Grid. High performing candidates have been extracted and used to aid in the design on new libraries. Pairs of fragments which were particularly effective, and those whose inclusion would result in poor device performance have been identified.
3. Generation of synthetically accessible libraries. One of the learning points from the initial round of investigation was of the importance of generating synthetically accessible libraries. This has

been achieved by investigating molecular reactivity, and by generating libraries of molecules with specific restraints. Molecular reactivity was investigated by data-mining the Reaxys database and correlating these results with calculated descriptors. Measures of accessibility have been calculated for libraries which have symmetry constraints placed upon the combinatorial growth, and these indicate improved synthetic accessibility.

4. Inclusion of machine learning techniques to the CEP. We have developed methods which combine molecular fingerprinting with neural networks and Gaussian processes to enable the fast screening and prioritization of molecules. Currently, Gaussian processes are able to predict the PCE to within $\pm 1\%$ - which is enough to vastly reduce the number of molecules screened. A multi-layer perceptron has been trained which can reduce this error.

Density Functional Based Tools for Simulation of Photo-Induced Charge Transfer

Institution: Texas-El Paso, University of
Point of Contact: Tunna Baruah
Email: tbaruah@utep.edu
Principal Investigator: Tunna Baruah
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$390,000 (2014-2016)

PROGRAM SCOPE

The project concerns development and applications of efficient density functional theory based methods that can provide a framework to study the light-harvesting molecular systems. The goal is to gain the predictive capability of quantum mechanical computational methods, which could be used for high-throughput material screening. Such a framework needs to be efficient enough to handle large system sizes for molecular calculations since most of the interesting light-harvesting molecular systems contain hundreds of atoms. We have earlier demonstrated the predictive power of a density functional method for charge transfer excitations. It was shown that even using pure generalized gradient approximation to exchange-correlation functionals such systems could be described both efficiently and accurately. Further developments include calculation of other parameters such as electronic coupling from first principles which combined with the previous developments can be used to gain insight into photoinduced charge transfer process. Other related developments are based on incorporation of recent advanced density functionals, which are shown to better predict certain properties into our code. While our interest is mostly in the light harvesting systems, such developments will also help in describing other interesting systems. Application of the developed method to light harvesting systems, which are of interest to experimentalists, is another aspect of the project. Another goal is to study the electronic structure of light-harvesting molecular systems in an environment such as on surfaces or in the presence of spectator molecules where the effects due to morphology and polarization can be large.

FY 2014 HIGHLIGHTS

We have applied our method to two novel acceptor systems, which are being tested in the laboratories of our collaborators at UTEP and UCSB. We have shown that using trimetallic nitride endohedral C_{80} fullerene in a donor-acceptor dyad can enhance the charge transfer excitation energies by about 25% compared to C_{60} . Another application to a dye-attached fullerene showed that the linker addition site strongly influences the electronic structure of the dye-attached molecule resulting in higher electron

affinities for some of the systems. The charge transfer exciton binding energy in the dye-functionalized fullerene:P₃HT systems is lower than the corresponding value in PCBM:P₃HT system.

Theoretical Studies of Combustion Dynamics

Institution: Emory University
Point of Contact: Joel M Bowman
Email: jmbowma@emory.edu
Principal Investigator: Joel M Bowman
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$129,999 (2014)

PROGRAM SCOPE

Theoretical and computational studies of gas phase reaction dynamics of relevance to combustion. The past year has focused on energy transfer in allyl and hoco in collisions with Ar, using high-level *ab initio* potential energy surfaces in classical trajectory calculations. Mode specific tunneling in unimolecular reactions was another research area. Code development of MULTIMODE was planned. This unique code performs high-level rovibrational calculations of molecules.

FY 2014 HIGHLIGHTS

Several publications resulted from this research. Three were on the energy transfer in the allyl radical and the hoco radical in collisions with Ar atoms. The dominant role of rotational energy transfer was highlighted. These calculations also showed the limitations of the widely-used pairwise models to describe the intermolecular interactions. The tunneling lifetime of trans-hydroxymethylene to formaldehyde was shown to decrease dramatically upon excitation of the bending mode of trans-hydroxymethylene. This study made use of a new highly accurate full-dimensional potential energy surface for the cis/trans-HOCH and H₂CO parts of the full potential.

Advanced Modeling of Ions in Solutions, on Surfaces, and in Biological Environments

Institution: Princeton University
Point of Contact: Roberto Car
Email: rcar@princeton.edu
Principal Investigator: Roberto Car
Sr. Investigator(s): Weinan E; Princeton University
Xifan Wu; Temple University
Michael L. Klein; Temple University
Esmond Ng; Lawrence Berkeley National Laboratory

Lin Lin; California-Berkeley, University of /
Lawrence Berkeley National Laboratory
Students: 5 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$372,130 (2014)

PROGRAM SCOPE

This proposal combines expertise from academe and National Labs to advance the state of molecular modeling of water with empirical and ab-initio techniques. Neat water and hydrated ions in situations relevant for future research applications dealing with energy and the environment will be studied. To achieve these goals community codes will be elaborated and augmented to incorporate new theoretical concepts and recent algorithmic advances. The project complements on-going experimental effort at the DOE Labs to probe water and its solutions using advanced spectroscopic techniques.

FY 2014 HIGHLIGHTS

Princeton (Car, E):

1. Car studied the ST2 model of water with advanced free energy methods finding that two metastable liquid phases and a stable crystal phase exist at the same deeply supercooled thermodynamic condition, a result with important implications for our understanding of the water anomalies (published in Nature)
2. Car showed that the collective effects of exact exchange and non-local van der Waals/dispersion interactions are crucial for predicting a microscopic structure of ambient liquid water in quantitative agreement with experiment (published in the Journal of Chemical Physics).
3. E designed new multi-scale numerical algorithms that probe the free energy landscape obtaining rather detailed understanding of the melting mechanism of simple solids (published in Science). An extension of this work to model ice melting and nucleation is underway.

Temple (Wu, Klein):

1. Wu (in collaboration with Car) studied the effect of advanced functional approximations on the structure of water (published in the Journal of Chemical Physics).
2. Wu and Klein extended this study (in collaboration with Car) to investigate how functional approximations affect the solvated water ions (hydroxyl and hydronium) and the hydroxyl radical. The progress made in describing these defect complexes has far reaching consequences on the chemistry and physics of autoprotolysis.

LBL (Ng, Yang, and Lin):

Significant progress was made in the development of the parallel pole expansion and selected inversion (PEXSI) method (<http://www.pexsi.org/>). A paper on the parallel selected inversion of large sparse matrices was submitted to ACM Trans. Math. Software. PEXSI was integrated with SIESTA for electronic structure calculations on large cells (published in the Journal of Physics Condensed Matter). Work to integrate PEXSI with CP2K is ongoing. This will allow us to perform large-scale ab-initio molecular dynamics simulations in collaboration with the Princeton and Temple teams.

Quantum Mechanical Evaluation of CZTS Photovoltaic Materials

Institution: Princeton University
Point of Contact: Emily Carter
Email: eac@princeton.edu
Principal Investigator: Emily Carter
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$166,000 (2014)

PROGRAM SCOPE

Solar energy conversion via photovoltaics to produce carbon-neutral electricity offers tremendous promise but wide-scale deployment is impeded by a lack of sunlight absorbers that simultaneously offer high efficiency and low manufacturing costs. The novel semiconductor $\text{Cu}_2\text{ZnSnS}_4$ (CZTS) promises both: all of its constituent elements are abundant and non-toxic; it has an ideal band gap with a large absorption coefficient; and it can be easily manufactured as a thin film by spraying suitable inks. However, CZTS is still limited by comparatively low efficiencies and difficulties synthesizing the desired crystallographic phase. We propose to use first-principles quantum mechanics methods to explore potential routes to selectively grow the preferred phase (kesterite). Excited states will be treated with many-body Green's function methods, as well as embedded correlated wavefunction (ECW) theory, to evaluate trapping propensity of defects. Off-stoichiometry surface modifications will be explored to identify compositions that improve band alignments at interfaces and reduce recombination. The CdS layer currently used in the CZTS modules is environmental unfriendly, so we will interrogate interface properties of alternative buffer layers with the aim to replace it. We also propose to search for dopants or defects that will induce intersystem crossing between singlet and slightly lower-energy triplet excited states, as the longer lifetime of the triplet states could effectively prevent recombination. We will develop our ECW theory to calculate singlet and triplet electron-hole pair, as well as charged defect states, which are difficult to study within periodic calculations. Finally, we propose to go beyond the traditional planar architecture and consider whether nanostructures could improve CZTS performance. By using these state-of-the-art techniques, we hope to contribute to the development of a cheap, abundant, and non-toxic material for efficient solar energy conversion.

FY 2014 HIGHLIGHTS

We began our work by computing effective Hubbard (U_{eff}) parameters for the 3d electrons of Cu(I), Zn(II), and Sn(IV) via our UHF-based embedded cluster methodology, which we showed was much more robust than the conventional constrained DFT scheme for closed shell metal ions. Subsequent use of these *ab initio* U_{eff} parameters within DFT+U theory accurately reproduced experimental lattice parameters and bulk moduli for relevant metal oxides and CZTS. After this validation study, we utilized this *ab initio* DFT+U approach to study the thermodynamic stability of all three phases of CZTS (kesterite, stannite and wurtzite) and most common secondary compounds. We confirmed that even though formation of CZTS itself is very exothermic, the kesterite and stannite phases of CZTS are very close in free energy. Consequently, secondary phase formation and the associated Cu/Zn sublattice disorder is very difficult to avoid. We next evaluated the cleavage energies of a variety of low-index surfaces of all phases of CZTS. We found that for a few ((100)/(001)) orientations, the desired kesterite phase has lower cleavage energies compared to the stannite phase. These "beneficial surfaces" might provide extra stability for the kesterite phase to form in nanoscale thin films. However, these beneficial surfaces are not observed during bulk synthesis, so external templates will be needed to control the growth direction of the crystal. We therefore studied interactions between a potential growth template, namely a zincblende ZnS (001) substrate, and ultrathin films of kesterite and stannite CZTS. We found significantly enhanced relative stability of the kesterite phase grown on the ZnS (001) substrate, especially in the initial stage of crystallization. We thus propose using a ZnS (001) substrate as a potential means to synthesize high-quality, single-phase kesterite CZTS thin films.

Multiscale Investigation of Thermal Fluctuations on Solar-Energy Conversion

Institution: Houston, University of
Point of Contact: Margaret Cheung

Principal Investigator: Margaret Cheung
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$120,000 (2014-2015)

PROGRAM SCOPE

One source of inspiration in the quest to identify new materials capable of converting solar energy into chemical fuels is to learn from plants and bacteria about the mechanism of photosynthesis. One of these light-harvesting materials is the molecular triad that consists of a fullerene (C_{60}) that acts as an electron acceptor, a chromophore that absorbs visible light, and a carotenoid that acts as an electron donor. This charge-separated state can potentially catalyze water into hydrogen, or carbon dioxide into methane when it absorbs sunlight. However, because the molecular triad is a structurally complex molecule in solvent and its charge-separated state is transient, it is challenging to adapt a triad molecule into real-world applications. The objective is to characterize the dynamics and structures of a charge-separated triad in polar/apolar solvents by theory, modeling, and large-scale computer simulations. To achieve this objective, first I plan to develop a multiscale model that enables computer simulations to investigate the thermal effects on the optical properties of a molecular triad in solution at a sub-microsecond time scale. The major effort is to effectively coarse-grain the solvent molecules that are far away from the core region around a triad where the interactions will be evaluated quantum mechanically. Second, I aim to develop a statistical-mechanical view of the rate relaxation for a triad molecule in solution. I plan to compute the rates of relaxation from a photo-excited state to a charge-separated state on several triad structures that are dominant in solutions of varying polarities. These relaxation pathways will be weighed by the population size of these triad structures and dependent on the thermal effect and the solvent polarity. The outcome of our research is important because of a far-reaching impact on the application of solar energy conversion.

FY 2014 HIGHLIGHTS

I have been collaborating with Professor Barry Dunietz from the Kent State University to further understand the impact of structural variety of the molecular triad on its charge-transfer (CT) mechanism. It took two years of training the postdocs from each lab to learn new computational tools and developing the protocols for understanding the complexity of the triad. We successfully established the relationship of the CT kinetics and the triad conformation using both quantum mechanics calculations and molecular dynamics simulations. We computed the rate of CT at two distinctive conformations of the triad of linear and bent geometries. The linearly extended conformation, in which the donor (carotenoid) and the acceptor (fullerene) are separated by nearly 50 angstroms, enables charge separation through two sequential CT steps, following an excitation localized on the porphyrin. A representative structurally bent conformation, however, attenuates the CT, although the donor and the acceptor are spatially closer in space. Our computed rates of CT at the linear conformation are in good agreement with experimentally measured values. Our work provides a fundamental understanding of the photo-induced CT process in the molecular triad. This work was recently submitted to the PNAS (1). Dr. Balamurugan who was supported by this award accepted an offer as a Scientific Computing Consultant, at the Computation Institute, University of Chicago last summer. Dr. Oleg Starovoytov who

started in January 2015 as a postdoc will continue this line of research. He will develop and apply the polarizable force fields to the molecular dynamics simulations of molecular triad. We expect it will improve the computational outcome.

Developing Electron-Correlated Methods for Excited State Structure and Dynamics in the NWChem Software Suite

Institution: Minnesota, University of
Point of Contact: Christopher Cramer
Email: cramer@umn.edu
Principal Investigator: Christopher Cramer
Sr. Investigator(s): Laura Gagliardi; Minnesota, University of
J. Ilja Siepmann; Minnesota, University of
Donald Truhlar; Minnesota, University of
Students: 7 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$481,567 (2014)

PROGRAM SCOPE

A suite of new theoretical methods is being developed and implemented in the NWChem computational chemistry software suite in order to provide improved capabilities for excited-state dynamics in the gas phase and to add the capability to perform electronically excited-state dynamics in solution. Successful implementation will be transformative for the study of photochemical reactions with levels of accuracy similar to those commonly available for ground-state thermal reactions. Developed methods will have a broad impact as they will be implemented in a robust, widely available, actively supported software environment. The implementation will benefit from the expertise of the NWChem development team and infrastructure at the Environmental Molecular Science Laboratory and from dedicated 'guinea pig' end users. It will also benefit from the expertise of people at the SciDAC Institute for Frameworks, Algorithms, and Scalable Technologies for Mathematics (FASTMATH) and at the SciDAC Institute for Sustained Performance, Energy, and Resilience (SUPER).

FY 2014 HIGHLIGHTS

The most recent version of NWChem was released (ver 6.5). This newest release incorporates analytic time-dependent density functional theory gradients for a wide variety of functionals, the continuum solvation model based on the electron density (SMD), and the vertical electrostatic model (VEM) for the state-specific inclusion of solvatochromic effects on excited-state energies. Prior to incorporation into NWChem, significant progress has been made on coupling real-time time-dependent density functional theory with nuclear dynamics on adiabatic potential energy surfaces with plans to add non-adiabatic couplings in the future. Speed-up of key algorithms using Kernel Polynomial Methods and the Lanczos algorithm has been accomplished along with implementation of a thread-level OpenMP parallelization scheme designed more effectively to exploit future many core architectures. Progress has been made on the rapid selection of representative configurations from simulations including explicit solvent around large chromophores and the mapping of that information to a coarse-grained simulation model. Progress has also been made on paradigmatic photochemical reactions taking place on high-dimensional potential energy surfaces through efficient diabaticization and identification of privileged coordinate schemes. A new multiconfiguration pair density functional theory has been developed to extend the

range of conventional density functional theory to chemical systems characterized by high degrees of multideterminantal character.

EARLY CAREER: Multiple Coupled Potential Energy Surfaces with Application to Combustion

Institution: Missouri University of Science
Point of Contact: Richard Dawes
Email: dawesr@mst.edu
Principal Investigator: Richard Dawes
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project combines developments in the areas of PES fitting and multistate multireference quantum chemistry to allow spectroscopically and dynamically/kinetically accurate investigations of key molecular systems, many of which are radicals with strong multireference character and have the possibility of multiple electronic states contributing to the observed dynamics. A main goal is to develop general strategies for robustly convergent electronic structure theory for global multichannel reactive surfaces. Combining advances in *ab initio* methods with automated interpolative PES fitting allows the construction of high-quality PESs incorporating thousands of high level data to be done rapidly through parallel processing on high-performance computing (HPC) clusters. New methods and approaches to electronic structure theory will be developed and tested through applications. Some effort will be applied to the development of Quantum Monte Carlo (QMC) and working to apply these methods in the context of global PESs. The feasibility of capturing a larger fraction of the correlation energy than is possible with traditional electronic structure approaches will be tested on suitable combustion related systems. Strategies will be developed to generate QMC data in the context of a distributed high-throughput computing model in which tens or even hundreds of kiloprocessors are used.

FY 2014 HIGHLIGHTS

The high temperature spin-forbidden kinetics of the $\text{CO} + \text{O} \rightarrow \text{CO}_2$ reaction was studied using the coherent switches decay of mixing (CSDM) semi-classical trajectories method. Three coupled PESs at the MRCI/CBS level (1 singlet and 2 triplets) were constructed including geometry dependent couplings. The total rate coefficient obtained is 7–35 times larger than the values often used in combustion kinetic models. A multireference (MRCI-F₁₂) data set of ~100,000 symmetry unique points was computed for methane. A potential energy surface (PES) of benchmark quality ($r_{\text{mse}} < 1 \text{ cm}^{-1}$) was obtained using a permutation invariant PIP-IMLS scheme. The PES was confirmed (by full dimensional variational calculations) to be spectroscopically accurate in the methane well, and is now being extended to include the $\text{CH}_3 + \text{H}$ and $\text{CH}_2 + \text{H}_2$ channels for future use in dynamics studies. We worked with a developer of GAMESS to successfully interface multiconfigurational trial wavefunctions from GAMESS to the CASINO Quantum Monte Carlo (QMC) code. Some benchmark potential energy curves were computed using QMC that are comparable to high level traditional quantum chemistry and show promise for capturing large fractions of the dynamic electron correlation.

Dynamics of Peroxy and Alkenyl Radicals Undergoing Competing Rearrangements in Biodiesel Combustion

Institution: New York-Syracuse, State University of
Point of Contact: Theodore Dibble
Email: tsdibble@esf.edu
Principal Investigator: Theodore Dibble
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$80,000 (2014-2015)

PROGRAM SCOPE

The ignition of diesel fuel depends on isomerization of peroxy radicals ($\text{ROO}\bullet$) via a hydrogen shift reaction to produce hydroperoxy alkyl radicals ($\bullet\text{QOOH}$). Production of multiple OH radicals (chain branching) in the chemistry following reaction $\bullet\text{QOOH}$ production leads to autoignition. Processes such as elimination of HOO terminate the organic radical chemistry that leads to autoignition. Experimentalists face several difficulties in gaining an understanding of this chemistry, and, until 2014, no QOOH species had ever been detected by experiment! This has inspired many computational studies of these processes. Biodiesel fuel is increasingly being used worldwide. Although we have a fair understanding of the molecular details of the chemistry of peroxy radicals derived from alkanes, biodiesel fuels contain ester and olefin groups which significantly impact the thermodynamics and kinetics of biodiesel ignition. The broader goal of this research is to carry out systematic computational studies of the elementary kinetics of this chemistry for compounds that are models for biodiesel ignition. This includes not only the reactions described above, but also reactions leading from $\bullet\text{QOOH}$ to chain branching. Another aspect is that the olefin groups in biodiesel fuels lead to carbon-centered radicals that have yet another available reaction pathway. Consider a linear carbon chain with a carbon-carbon double bond and a radical centered on a carbon atom. This linear species can cyclize by forming a bond between the radical center and either one of the two carbons of the double bond. The cyclic radical thus produced can revert back to the initial, acyclic radical, or decyclize to form a branched carbon chain with a double bond and a carbon-centered radical. The formation of the branched radical changes the competition between chain branching and termination in diesel autoignition.

FY 2014 HIGHLIGHTS

Methyl butanoate (MB) is composed of a methyl ester group and a short alkyl group. MB oxidation mechanisms have been studied as the starting point for understanding biodiesel combustion for a decade. The CBS-QB3 composite method is used to determine reaction energies and activation barriers to reactions of peroxy radicals and the corresponding QOOH species. We find peroxy radical interconversions of $\bullet\text{OOQOOH}$ radicals from methylbutanoate commonly possess the lowest barriers of any unimolecular reaction of these radicals, despite that they proceed via 8-, 10- and 11-member ring transition states. At temperatures relevant to autoignition, these peroxy radical interconversions are dominant or significant reaction pathways. This means that $\bullet\text{OOQOOH}$ radicals that were expected to be produced in negligible yields are, instead, major products in the autoignition of methyl butanoate. These reactions have not previously been considered for OOQOOH from MB, and will require revision of models of autoignition of methylbutanoate and other esters. We examined exo- and endo-cyclization of a number of isomers of the straight chain unsaturated C_8H_{15} (n-octenyl) radical using the CBS-QB3 level of theory. Endo-cyclizations lead to the carbon radical center being part of the ring while exo-cyclization leads to the carbon radical center being on a substituent of the ring. The exo cyclization and

decyclization reactions are strongly favored, kinetically, over the endo cyclizations, even though the enthalpy changes for the exo and endo processes are almost identical. At combustion temperatures, it seems likely that the n-alkenyl radical could achieve quasi-equilibrium with the product of exo reactions. Moreover, the cyclization reactions seem to have lower barriers than the H-shift reactions of the same isomer. Those H-shift reactions are commonly included in detailed combustion mechanisms, but the exo- and endo-cyclization reactions are usually not included.

Electron Transport Modeling of Molecular Nanoscale Bridges Used in Energy Conversion Schemes - Transfer Balance from UM

Institution: Kent State University
Point of Contact: Barry Dunietz
Email: BDunietz@kent.edu
Principal Investigator: Barry Dunietz
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$305,576 (2012-2015)

PROGRAM SCOPE

The goal of the research program is to reliably describe electron transport and transfer processes at the molecular level. Such insight is essential for improving molecular applications of solar and thermal energy conversion. We develop electronic structure models to study (1) photoinduced electron transfer and transport processes in organic semiconducting materials, and (2) charge and heat transport through molecular bridges. We seek fundamental understanding of key processes, which lead to design new experiments and ultimately to achieve systems that demonstrate improved properties.

FY 2014 HIGHLIGHTS

In one thrust, we investigate charge and heat transfer processes in molecular bridges that are candidates for thermoelectric applications. We analyzed the role of anchoring groups in the reorganization of frontier molecular orbitals (JPCL, 2013). In another project, we showed that molecular bridges can function as spin filters to actively control the heat flow using a magnetic field (PRB, 2013). In the second thrust we study photoinduced charge transfer (CT) processes through interfaces of organic semiconducting materials. We developed a fully quantum mechanical protocol to compute CT kinetics, that implements a Fermi-Golden rule picture of CT (first reported in a JPCB 2013 paper). We showed that a fully quantum mechanical scheme is necessary for reliable modeling of the CT processes, whereas the pervading semiclassical Marcus picture grossly underestimates their rates. In follow up studies we study important aspects of the molecular interfaces. For example, we show that molecular-scale means can tune the kinetics through stabilization of CT states affected by the polar environment (JCP comm, 2014). Our electronic structure approach combines charge constraint DFT and range separated based DFT to study CT properties in condensed organic materials. In a related study we investigated a high profile solvated tri-nuclear complex (two Fe and one Pt bridged centers). We find that the solvated complex differs substantially in structure from the resolved crystal one. We point out that the measured spectroscopies and indicated CT processes are substantially different than widely accepted (JACS, 2014). In an on-going collaboration with Prof. Cheung (Houston) we investigate the relationships of conformational flexibility and photoinduced CT in a molecular triad system

EARLY CARRER: First Principles Modeling of Metal-Electrolyte Systems: A Novel Approach to the Study of the Electrochemical Interface

Institution: New York-Stony Brook, State University of
Point of Contact: Maria-Victoria Fernandez-Serra
Email: mvfernandezs@ms.cc.sunysb.edu
Principal Investigator: Maria-Victoria Fernandez-Serra
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The role of surface polarity is explored and linked to the structure of the interfacial water. In particular the research examines how ferroelectric surfaces can enhance the dissociation and deprotonation of surfaces. Project goals are to model a realistic ferroelectric/water interface, and understand: (i) The screening of polar ferroelectric surfaces by bulk liquid water. (ii) The nature of the electrical double layer formed by the water molecules while screening surfaces with different polarities. (iii) The modification of the electron and hole states at the water/surface interface. (iv) The relation between water dissociation and proton diffusion to the polar nature of the semiconductor surfaces. A second main research thrust is to model the proton affinity of polar surfaces. The acidity of a surface plays a central role in the chemical reactions happening at the water semiconductor interface. One of the main objectives of current project is to evaluate the pK_a values for polar surfaces, both oxides (ferroelectric oxides) and GaN based. This entails an initial search for surfaces with high dissociative potential, and then, among the ones found, subsequent *ab initio* molecular dynamics simulations (AIMD) at room temperature will be performed to monitor deprotonation events, together with fluctuations in local surface charges. The results of this study will allow for the evaluation of the contribution to the proton affinity of the fluctuations of the local charges at the semiconductor surface and their coupling to surface solvent fluctuations.

FY 2014 HIGHLIGHTS

A. This work is based on the use of density functional theory (DFT) to understand the effects of zero-point motion in water and ice. Water exhibits a very rich phase diagram which is partially due to protonic order-disorder phase transitions. Local density functional theory calculations have been used to evaluate the accuracy of a commonly used classical method for describing water. The latter model includes the role of polarization. After taking zero-point nuclear quantum effects, within both models, and using a quasi-harmonic approximation to determine free-energies, it has been demonstrated that the more accurate quantum-mechanical methods must be used to determine the most stable phase. The DFT approach predicts the proton ordered ice XI as the most stable phase and a predicts a phase transition at 91K. We have also analyzed the structural properties (stability and bulk modulus) of both ice phases in detail, and we have carefully studied both the isotropic and anisotropic compressibilities. The study shows a link between the isotope effects in liquid water and the compressibility anomaly of liquid water and the phase diagram of ice, and shows that nuclear quantum effects in liquid water can be used to shed light into the origin of the anomalies of both liquid water and ice.

B. Density-Functional-Based electronic structure methods have been used to predict the properties of an alloy composed of a mixture of gallium arsenide and zinc oxide. The random alloy has been generated using cluster expansion models from previous work.

Water Dissociation, Electronic Structure and Proton Diffusion Dynamics at Photo-Catalytic Surfaces

Institution: New York-Stony Brook, State University of
Point of Contact: Maria-Victoria Fernandez-Serra
Email: mvfernandezs@ms.cc.sunysb.edu
Principal Investigator: Maria-Victoria Fernandez-Serra
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 3 Undergraduate(s)
Funding: \$157,001 (2014-2015)

PROGRAM SCOPE

The research objective of this proposal is the computational modeling of the metal-electrolyte interface purely from first principles. The accurate calculation of the electrostatic potential at electrically biased metal-electrolyte interfaces is a current challenge for periodic *ab-initio* simulations. It is also an essential requisite for predicting the correspondence between the macroscopic voltage and the microscopic interfacial charge distribution in electrochemical fuel cells. This interfacial charge distribution is the result of the chemical bonding between solute and metal atoms, and therefore cannot be accurately calculated with the use of semi-empirical classical force fields. We will study in detail the structure and dynamics of aqueous electrolytes at metallic interfaces taking into account the effect of the electrode potential. The electrode potential will be set by using the methodology already developed for the study of electronic transport in nano-structures. The *ab-initio* molecular dynamics (AIMD) simulations will be performed with the SIESTA program. An interface for the combination of both methods in AIMD simulations will be developed. Methods based on Density Functional Theory will be adapted and tuned for efficient and accurate AIMD calculation of metal-electrolyte interfaces. The PI has a well-established record of applying DFT to this problem and has already successfully developed a formalism within the Siesta program to accelerate molecular dynamics simulations of metal-water interfaces. The PI also has a broad experience in the field of electronic transport in nanostructures, with 4 high profile articles published in this area.

FY 2014 HIGHLIGHTS

We have studied the structure and dynamics of liquid water in contact with Pd and Au (111) surfaces using *ab initio* molecular dynamics simulations with and without van der Waals interactions. Our results show that the structure of water at the interface of these two metals is very different. For Pd, we observe the formation of two different domains of preferred orientations, with opposite net interfacial dipoles. One of these two domains has a large degree of in-plane hexagonal order. For Au, a single domain exists with no in-plane order. For both metals, the structure of liquid water at the interface is strongly dependent on the use of dispersion forces. The origin of the structural domains observed in Pd is associated to the interplay between water/water and water/metal interactions. This effect is strongly dependent on the charge transfer that occurs at the interface and which is not modeled by current state of the art semi-empirical force fields. *J. Chem. Phys.* 142, 034706 (2015)

Non-Adiabatic Molecular Dynamics Methods for Materials Discovery

Institution: California-Irvine, University of
Point of Contact: Filipp Furche
Email: filipp.furche@uci.edu
Principal Investigator: Filipp Furche
Sr. Investigator(s):

Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$183,159 (2014)

PROGRAM SCOPE

The rate of breakthrough discoveries in energy-related materials sciences depends crucially on our ability to predict and control non-adiabatic transitions between electronic states. For example, efficient sensitizer dyes for solar cells should exhibit large transition probabilities from the initial absorbing state to the charge-injecting state and minimal losses through other decay channels. Non-adiabatic molecular dynamics (NAMD) simulations are the method of choice to attack these problems. However, predictive NAMD simulations are extremely demanding, and the theoretical and the computational machinery to tackle non-adiabatic processes in real materials is woefully inadequate. The goal of this project is to provide robust, predictive, and broadly applicable computational tools enabling NAMD simulations in real materials with unprecedented accuracy and realism. We are well on our way to developing a general-purpose code enabling 10-100 picosecond ensemble NAMD simulations for molecules and nano-sized clusters with 100 or more atoms at the level of hybrid time-dependent density functional theory (TDDFT). Our implementation uses atom-centered Gaussian basis sets and rigorously treats non-adiabatic couplings between all relevant states. Tully's fewest switches surface hopping algorithm is to be employed for nuclear dynamics. The availability of these tools will dramatically accelerate the discovery of new energy-related molecular materials. We are combining the latest developments in excited state methods, response and analytical derivative theory, functional development, and sampling methods with efficient iterative algorithms and parallel computing, including acceleration by graphics processing units. The code developed in this project will be rapidly and widely distributed through the Turbomole package, and parts have already been released. We are validating our methodology by comparison to accurate experiments and calculations.

FY 2014 HIGHLIGHTS

A highlight in FY 2014 was the development of improved iterative subspace algorithms for large-scale response calculations which lie at the heart of materials simulations. The simple but effective idea underlying this method is to exploit the reduction of the residual norms as convergence is reached. The method is particularly successful when Coulomb and exchange portions of the linear response equations are separated and in combination with fast factorization techniques such as the resolution-of-the-identity (RI) approximation. Up to five-fold speedups were observed in TDDFT calculations, with larger benefits for larger systems. This significantly extends the scope of NAMD simulations, where solution of the TDDFT response equations is a rate-determining step. Another important accomplishment was the extension of TDDFT-based NAMD simulations to open-shell systems. This has enabled us to tackle homolytic bond breaking, which is very common in photochemical reactions. Previously, homolytic dissociation could only be addressed by multi-reference calculations, which are limited to molecules with few atoms. The present developments make it possible to obtain a qualitatively complete picture of photochemical reactivity for systems with up to 100 atoms for the first time. Finally, we have completed the derivation and a first implementation of first-order non-adiabatic couplings between two excited states in the hybrid TDDFT framework. The result is consistent with time-dependent response theory, but also reveals an incorrect pole structure of the quadratic TDDFT response within the adiabatic (zero frequency) approximation for the exchange-correlation kernel. This result highlights the importance of frequency-dependent kernels for NAMD simulations. In the meantime, an approximate version of the couplings that becomes exact at conical intersections is the most promising candidate for applications.

Nanoporous Materials Genome: Methods and Software to Optimize Gas Storage, Separations, and Catalysis

Funding: \$1,770,000 (2014)

PROGRAM SCOPE

The Nanoporous Materials Genome Center (NMGC) discovers and explores microporous and mesoporous materials, including metal-organic frameworks (MOFs), zeolites, and porous polymer networks (PPNs). These materials find use as storage and separation media and catalysts in many energy-relevant processes and their next-generation computational design offers a high-payoff opportunity. Towards that end, the NMGC develops state-of-the-art predictive modeling tools, databases, and web-based repositories, and employs them to increase the pace of materials discovery. The goals of the NMGC are advanced by a tight collaboration between leading experimental groups in the synthesis and characterization of nanoporous materials and of computational groups with experience in molecular simulation, electronic structure calculations, and theory. The majority of the completed projects resulted from iterative feedback where computational modeling was instrumental for understanding the function of specific nanoporous materials or for discovering materials with optimal properties for subsequent synthesis.

FY 2014 HIGHLIGHTS

The NMGC research efforts have already led to more than 40 publications. Here, we highlight the key achievements of five application projects and one web tool that are central to the goals of the NMGC.

- a. The computation-ready, experimental (CoRE) MOF database contains ~5000 porous structures that are derived from experimentally refined crystal structures by removing solvent molecules and

- resolving partially occupied or disordered atoms. The CoRE MOF database is utilized to find materials for methane storage and hexane isomer separation.
- b. A computational methodology is developed that applies known chemical transformations for in silico synthesis of organic linkers to identify MOFs with high methane deliverable capacity.
 - c. Enabled by a multistep screening workflow, efficient sampling algorithms, accurate force fields, and a parallel execution hierarchy utilizing up to 131,072 compute cores on Mira at Argonne, we identify zeolites with exceptional selectivities for ethanol purification from aqueous solution and the transformation of alkanes with 18-30 carbon atoms.
 - d. Enzymatic heme and non-heme high-valent iron-oxos are known to activate very strong C–H bonds; we demonstrate that a MOF featuring site-isolated iron centers in a weak-field ligand environment can convert ethane into ethanol and acetaldehyde using nitrous oxide as the terminal oxidant and elucidate all steps in the mechanism.
 - e. We use quantum mechanical computations to identify a new MOF with open vanadium sites that is of potential utility for the separation of dinitrogen from other light gases and reveal that two types of interactions, the σ donation and π^* backbonding, are responsible for the strong V-N₂ bond. In collaboration with the Materials Project, the NMGC has developed the Nanoporous Materials Explorer. This openly accessible web-based tool aids materials discovery and also serves as repository for computational and experimental data generated by the NMGC.

EARLY CAREER: Many-body Effects in Transport and Energy Transfer

Institution: California-San Diego, University of
Point of Contact: Michael Galperin
Email: micalgalperin@ucsd.edu
Principal Investigator: Michael Galperin
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$152,400 (2014)

PROGRAM SCOPE

Understanding dynamics of systems interacting with baths is crucial in developing memory and logic molecular devices, molecule based sensors, photovoltaics for solar conversion, and optoelectronics. Strongly correlated resonant inelastic electronic transport is particularly relevant for application purposes. Sensitivity of molecular electronic and vibrational structures to oxidation/reduction/excitation calls for the development of approaches capable of treating molecular response in the language of many-body states, in contrast with the effective single-particle formulations employed in most *ab initio* schemes today. My goal is to formulate a truly non-equilibrium many-body theory capable of retaining universality and exactness of scattering theory in the treatment of on-the-bridge interactions, which will retain junction information, and will allow to incorporate sophisticated methods of equilibrium quantum chemistry and molecular spectroscopy in the transport calculations. Another important goal is to introduce non-adiabatic molecular dynamics (in particular, fewest-switches algorithm of the surface-hopping method) into molecular junction setup. The proposed research considers fundamental problems of molecular transport theory with potential impact on possible technological applications. Proposed theoretical developments are of multidisciplinary nature – the consideration encompasses problems and methods of quantum chemistry, computational and many-body physics, non-equilibrium statistical mechanics, and molecular spectroscopy. Within the proposed approach, the non-equilibrium state of the system is described in the language of molecular states. This means that all on-the-molecule correlations are taken into account from the very start, and that well developed methods of quantum

chemistry and equilibrium molecular spectroscopy can be employed for description of transport and optical response of molecular devices.

FY 2014 HIGHLIGHTS

We focused on the development of methods of the nonequilibrium atomic limit and on their application to transport and optical response of molecular junctions.

1. Methods development for the nonequilibrium atomic limit:
 - a. An invited feature article was published [A. J. White *et al.*, *J. Phys. Chem. C* 118, 11159-11173 (2014)] reviewing the methods developed within the project and their applications to model and ab initio simulations
 - b. A paper on PO-NEGF EOM method was published [M.A.Ochoa *et al.*, *J. Phys.: Condens. Matter* 26, 455301 (2012)], where solid methodological proof of viability (something which was questioned in the literature) of the Hubbard NEGF approach was presented.
2. Molecular optoelectronics: A first many-body approach to Raman spectroscopy in open nonequilibrium devices within the PP-NEGF (one of the methods of the nonequilibrium atomic limit) was formulated and applied to describe within ab initio simulation experimentally observed shift in position of the Stokes line under bias [A. J. White *et al.* *Nano Lett.* 14, 699-703 (2014)].
3. Quantum interference and coherent control in junctions: Preferability of the methods of the nonequilibrium atomic limit for describing processes involving coherent transfer of both charge and energy was demonstrated in a publication [A. J. White *et al.*, *Phys. Rev. B* 205424 (2013)]. We employed the PP-NEGF in a search for measurable effects in combined coherent charge and energy transfer in molecular junctions. In particular, inspired by the known charge and spin fluxes separation effect, we demonstrated that tuning parameters of the external laser field (amplitude and/or frequency) lead to coherence-induced spatial separation of charge and energy (electron excitation) fluxes in multi-terminal molecular junctions. Note that this observation may be relevant also for a technically similar consideration of propagation of vibrational excitation in junctions and hence to constructing low-heating molecular devices.

EARLY CAREER: Interfacial Electrocatalytic Processes from First Principles

Institution: Purdue University
Point of Contact: Jeffrey Greeley
Email: jgreeley@purdue.edu
Principal Investigator: Jeffrey Greeley
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This program develops and applies electronic-structure based methods to the study of electrocatalytic processes at solid/liquid interfaces. We are simultaneously pursuing two general goals: a) the development of detailed electrocatalytic reaction mechanisms for electrochemical denitrification processes, an effort in which we are adopting techniques from electronic structure analyses of traditional heterogeneous catalytic reaction processes to complex electrocatalytic environments, and b) the optimization of electronic structure methods to treat the structural and catalytic complexity found at multifunctional metal/oxide interfaces in alkaline electrochemical environments. Both efforts also

involve use of ab-initio molecular dynamics simulations to describe the structure of water near the electrocatalyst surfaces.

FY 2014 HIGHLIGHTS

We have determined the elementary reaction mechanisms of electrochemical denitrification, a process that is of importance for purification of biologically-contaminated wastewater streams and that also serves as a model system on which to develop appropriate computational techniques. We have considered reduction of NO to N₂O, NH₂OH, and ammonia on different single crystal platinum surfaces and have identified new mechanistic pathways for these conversion processes, including the formation of a previously unknown trans dimer of NO that serves as a precursor to N₂O formation. We are in the process of generalizing these results to produce predictions of both NO and nitrate reduction kinetics over a variety of transition metal alloy surfaces, with an ultimate goal of developing a general, systematic toolkit of techniques to permit the rapid and efficient elucidation of complex reaction networks on similar metal surfaces. Additionally, we have developed an approach to accurately describe the oxidation state and geometric structures of thin (1-2 ML) oxyhydroxide films on precious metal substrates, and we have, for the first time, related the detailed structural characteristics of these films to their electrocatalytic activity for hydrogen production in alkaline solutions. The results have revealed a complex and stimulating interplay between the local geometric structure, the oxidation state, and the electrocatalytic activity.

Quantum Dynamics of Elementary Chemical Reactions

Institution: New Mexico, University of
Point of Contact: Hua Guo
Email: hguo@unm.edu
Principal Investigator: Hua Guo
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$120,001 (2014)

PROGRAM SCOPE

The goal of this grant is to develop theoretical and computational methods that will allow us to understand the dynamics of gas phase bimolecular reactions, particularly those involved in combustion.

FY 2014 HIGHLIGHTS

The focus of our research was on the reactions between H₂O and several atomic species such as F, Cl, and O(³P). In order to understand the reaction dynamics of these prototypical tetra-atomic systems, we have constructed highly accurate potential energy surfaces from large numbers of high-level *ab initio* data over a large configuration space. The resulting full-dimensional global potential energy surfaces allowed us to carry out full-dimensional quantum dynamical and quasi-classical trajectory calculations. Mode specificity and product state distributions shed valuable light on the reaction dynamics. A good example of our work is the photodetachment of FH₂O⁻, which is published in Science in 2014. In collaboration with Bob Continetti at UCSD, we provided theoretical insights into the photoelectron-photofragment coincidence spectra, which sheds valuable light on the transition state and the post-reaction hydrogen bonded well of the potential energy surface.

Development of Accurate and Affordable Electronic Structure Methods for the Condensed Phase

Institution: Ohio State University
Point of Contact: John Herbert

Funding: \$148,205 (2014)

PROGRAM SCOPE

The goal of this project is to develop fragment-based electronic structure methods to facilitate efficient and accurate condensed-phase *ab initio* calculations. By exploiting the 'embarrassingly parallel' nature of fragment-based approaches, these methods will leverage the power of massively-parallel computer architectures to reduce wall clock times dramatically, relatively to conventional electronic structure algorithms. As compared to other efforts along these lines, our approach is distinguished by a focus on achieving consistent, sub-kcal/mol accuracy with respect to the best available benchmark calculations. The initial stages of this project focus on non-covalent interactions (molecular clusters, aggregates, and liquids), that is, systems that suggest a very natural fragmentation pattern based on molecular monomer units. This strategy will allow us to isolate and evaluate what is necessary to achieve high accuracy in intermolecular interactions, without introducing errors due to the need to fragment the system across covalent bonds. In later stages of the project, we will attack macromolecular problems where fragmentation across covalent bonds is necessary; in these cases, we will employ a novel overlapping-fragment scheme developed previously in the PI's group. Excited states in molecular aggregates, in which the excitonic wave function is delocalized across multiple chromophore units, will also be addressed. Ultimately, this work will facilitate calculations at 'chemically accurate' levels of theory in systems of unprecedented size, harnessing the power of parallel computing in conjunction with physics-based fragmentation approximations.

FY 2014 HIGHLIGHTS

We continue our development of the 'extended' version of symmetry-adapted perturbation theory (XSAPT). XSAPT extends the traditional SAPT approach, in a naturally parallelizable way, and thus facilitates affordable calculations of intermolecular interactions in non-covalent assemblies. Using 'tuned' long-range corrected density functionals, we have shown that (contrary to conventional wisdom), Kohn-Sham orbitals can be used directly in (X)SAPT calculations without ill effects, and this provides a low-cost means to introduce monomer electron correlation into SAPT calculations. An efficient atomic-orbital implementation of (X)SAPT has been developed, which reduces the memory footprint of the algorithm and facilitates calculations on systems where the monomer units are quite large, e.g., a C₆₀ buckyball bound to an even larger molecule, or various fragments of graphene (e.g., coronene). Whereas we had previously benchmarked XSAPT only against high-level *ab initio* calculations, we are now benchmarking against experimental enthalpies and (in conjunction with simple entropic corrections) against experimental free energies of association, for difficult systems including room-temperature, solution-phase ionic complexes. Preliminary results are still of sub-kcal/mol accuracy. We have also begun to address the relative conformational energies of macromolecules (fragmenting across covalent bonds), using a two-body expansion after tessellating the system into overlapping fragments. These results suggest that we can accurately reproduce supersystem conformational energies across isomers spanning an energetic range of more than 100 kcal/mol, using

subsystem calculations no larger than 20-30 atoms. Finally, we have introduced an *ab initio* version of the Frenkel-Davydov exciton model, an approach that holds great promise for understanding excitonic energy transfer in molecular aggregates.

Breakthrough Design and Implementation of Electronic and Vibrational Many-Body Theories

Institution: Illinois-Urbana Champaign, University of
Point of Contact: So Hirata
Email: sohirata@illinois.edu
Principal Investigator: So Hirata
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$390,000 (2014-2016)

PROGRAM SCOPE

The goal is to develop novel many-body theories and algorithms that are systematically accurate, diagrammatically size consistent and thus applicable to molecules of all sizes and solids, capable of describing electronic and vibrational structures at zero and nonzero temperatures and chemical potentials, and scalable with respect to both the number of particles and the number of processors. We aim at solving the following three specific problems:

- (1) Finite-temperature full configuration interaction. We will formulate, implement, and test finite-temperature FCI. Here, the target quantity is no longer the energy eigenvalue of the Schrödinger equation, but the canonical and grand-canonical electronic partition functions. It serves as the benchmarks for finite-temperature many-body perturbation and coupled-cluster methods.
- (2) General-order, relativistic Monte Carlo MP2. MC-MP2 simultaneously achieves parallel scalability, negligible memory consumption, capacity to directly compute molecular properties (often difficult with QMC), and near-linear size dependence of cost even in small molecules. We will automate the generation of diagrams, their algebraic interpretation, and code synthesis. They will be combined with a Dirac–Hartree–Fock reference wave function to account for relativistic and correlation effects.
- (3) Monte Carlo size-extensive vibrational self-consistent field (MC-XVSCF) and vibrational MP2 (MC-XVMP2). We will explore a stochastic evaluation of anharmonic frequencies and zero-point energies with the size-extensive version of VSCF and VMP2 developed in this project. We will thus eliminate the expensive, non-scalable step of high-rank force constant calculations.

FY 2014 HIGHLIGHTS

We have essentially completed the proposed developments of both Monte Carlo XVSCF and Monte Carlo XVMP2 methods. The latter has been reported in J. Chem. Phys. and the former under review by J. Chem. Phys. They, along with their deterministic counterparts, are summarized in an invited review, which is under consideration by Int. Rev. Phys. Chem. Furthermore, we realized that a normal-ordered Hamiltonian for molecular vibrations, which underlies both of these methods, is hardly discussed in the literature. We, therefore, reported such a Hamiltonian, which we consider to be fundamental progress in equilibrium quantum dynamics. The development of a diagrammatic theory of vibrational coupled-cluster (XVCC) methods is underway. We continue to make significant advance in a novel algorithm of MP2 for electrons. Specifically, we have developed a stochastic algorithm of the explicitly correlated MP2 or MP2-F12 in collaboration with Professor Edward F. Valeev and his postdoctoral researcher, Dr. Jinmei Zhang, of Virginia Tech. This work has been published in J. Chem. Phys. as a Communication. An

important reason why we base our developments on the MP methods is their size consistency. In a Theor. Chem. Acc. paper, we put forth a conjecture of mutual exclusion between size consistency and variability. This paper has produced a strong reaction in a recent conference presentation. During March-September 2014, 9 papers have been published or submitted with support of this grant.

Elucidating positive quantum effects for efficient energy and charge transfer dynamics in soft solar energy conversion systems

Institution: New York-Queens College, City University of
Point of Contact: Seogjoo Jang
Email: seogjoo.jang@qc.cuny.edu
Principal Investigator: Seogjoo Jang
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$120,000 (2014)

PROGRAM SCOPE

Fast and directed migration of excitons and charge carriers across 100 nanometer or larger length scales in soft environments is an issue of fundamental importance in developing efficient biomimetic or organic solar energy conversion devices. The primary goal of PI's research is to identify and understand novel and robust quantum effects making significant positive contribution to such exciton and charge flow dynamics. This is pursued through application of theories developed by PI's group, which can account for important quantum effects that have not been well addressed before, while also making thorough theoretical investigation of the effects of molecular level factors and the disorder. Applications are being made to generic model systems, models of photosynthetic light harvesting complexes, and to organic conjugated molecular systems in collaboration with experimental groups. Outcomes of these efforts will provide new theoretical insights, help more quantitative and reliable interpretation of spectroscopic data, and can ultimately contribute to experimental realization of efficient and robust solar energy conversion devices.

FY 2014 HIGHLIGHTS

- i. Major effort during this funding period was devoted to theoretical investigation of the photosynthetic light harvesting 2 (LH2) complex of purple bacteria. LH2 is an efficient natural excitation energy carrier with high fold symmetry (N=8-10), but the molecular level design principle governing its functionality is unknown. The PI's group has constructed an all-atomistic model of a natural LH2 based on reported X-ray crystal structure (N=9), and also constructed non-natural analogues with different fold symmetries (N=5-8 and 10-12). Molecular dynamics (MD) simulations of these models confirmed that all complexes can be formed and remain stable. However, distinctively different features were observable for different sizes in their final structures. Close examination of bonding characteristics revealed that the main source of such difference is the variation in the pattern of the hydrogen bonding (HB) between the pigment molecule and protein residues. Stable and consistent formation of HB is possible only near naturally occurring sizes (N=9,10), leading to significantly smaller disorder than non-natural ones. Simulation of the exciton transfer dynamics between two LH2s based on a recently developed theoretical approach called generalized master equation for modular exciton density (GME-MED) clearly demonstrated that the average inter-LH2 exciton transfer rates are close to the maximum for N=9 and 10. These results suggest that natural sizes of LH2 have been indeed optimized for the maximum inter-LH2 exciton

transfer rate, for which formation of stable HB and quantum delocalization of the exciton plays a critical role.

- ii. The effects of quantum environments on charge transport were studied for a one dimensional chain with energetic Gaussian disorder. Time dependent variances of populations were calculated by solving the master equation numerically. The results show the importance of using reliable quantum rate expressions for quantitative modeling.

Design of Stratified Functional Nanoporous Materials for CO₂ Capture and Conversion

Institution: Pittsburgh, University of
Point of Contact: J Karl Johnson
Email: karlj@pitt.edu
Principal Investigator: J Karl Johnson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$266,000 (2014-2015)

PROGRAM SCOPE

Efficient capture and conversion of carbon dioxide from various emission sources into valuable chemicals could be accomplished with highly tailored multi-functional catalytic sorbent materials. We utilize first-principles computational methods to investigate the fundamental interactions between carbon dioxide and hydrogen with functionalized nanoporous materials with the ultimate goal of designing materials for selective capture and reaction of carbon dioxide with hydrogen to produce chemical feedstocks or fuels. We initially focus on the simplest reduction reaction to produce formic acid from a two-electron reduction with hydrogen. We study metal organic frameworks (MOFs) as a catalytic platform for these reactions because they can be readily functionalized with a wide variety of chemically active functional groups. We initially study UiO-66 as a candidate MOF due to its high chemical and thermal stability and because it can be functionalized post-synthetically to imbue it with catalytic properties. We target Lewis acid and base sites as potential catalytic functional groups for binding and chemically activating both hydrogen and carbon dioxide. We primarily use periodic density functional theory to identify the catalytic pathways for carbon dioxide reduction within functionalized MOFs. We are able to screen different functional groups and develop predictive relationships through characterizing the properties that control binding energies and transition state geometries and energetics. We examine a variety of different chemical descriptors using computational methods in order to characterize the key properties that control the binding energy, reaction pathway, transition state energetics, and product states of the reaction. These descriptors include atomic charges, frontier orbitals, acidity, basicity, d-band centers, and electronegativity. Our calculations can ultimately be used to guide experimental synthetic efforts to design materials.

FY 2014 HIGHLIGHTS

We have designed and evaluated a variety of different Lewis pair moieties for binding carbon dioxide and heterolytically dissociating molecular hydrogen within the functionalized pores of UiO-66. The idea of using a functional group with both Lewis acid and Lewis base site on the same moiety is inspired by recent work with frustrated Lewis pairs used in solution chemistry. Our calculations show that Lewis pairs that are covalently bound to sites within a MOF retain their chemical activity for chemically binding carbon dioxide and heterolytically dissociating hydrogen even though they are not sterically hindered. We have demonstrated that the geometric constraint of being bound to the MOF makes steric

hindrance unnecessary. We have computed the reaction pathways for carbon dioxide reduction with hydrogen on several different Lewis pair functional groups bound within UiO-66. We have identified 1-(difluoroboranyl)-4-methyl-1*H*-pyrazole as the best Lewis pair functional group out of nine different groups we have screened. The reaction with this material proceeds with low barriers to produce HCOOH when hydrogen is first chemically activated by the Lewis pair in the pore. Carbon dioxide then reacts with the activated H atoms, the hydridic hydrogen binding to carbon and the protic hydrogen binding to one of the oxygens, in a single step concerted reaction resulting in a two-electron reduction. We have demonstrated that the MOF serves to reduce the reaction barrier relative to the gas phase reaction on the same Lewis pair. We ascribe this additional catalytic effect to the geometric constraint of the MOF pore, making the interaction between the activated hydrogens and carbon dioxide more favorable due to the binding of carbon dioxide to the pore walls. In this way, the functionalized MOF mimics a complex enzyme by bringing two substrates together to form an activated complex.

Electronic Structure of an Organic/Metal Interface: Pentacene/Cu(110)

Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$119,905 (2014)

PROGRAM SCOPE

Organic molecule adsorption on metal substrates is of continuing interest as thin films and self-assembled monolayers open the way toward functionalization. Interaction of small hydrocarbons with transition metal surfaces has been extensively studied by surface science methods to gain a fundamental understanding of problems relevant to heterogeneous catalysis. We have also witnessed intense efforts to employ organic molecules as the basic components in electronic devices for molecular electronics with the hope that they become an alternative to the available technology. So far, organic molecules have demonstrated the ability to be used as functional units in such devices as diodes, photo-voltaics, molecular switches, and field-effect transistors. Describing accurately the atomic and electronic characteristics of the interface between organic materials and metal surfaces is the main purpose of the present proposal. In recent years, evaluating the effect of van der Waals (vdW) forces for many physical systems, including the adsorption of small organic molecules on metal surfaces became possible thanks to the continuous improvements in vdW density functional theory (DFT). In my work, I employ a self-consistent implementation of the vdWs effects to DFT, namely the vdW-DF. I evaluate the performance of various vdW functionals by examining the equilibrium adsorption geometries and energies, and comparing the results with those available experimental and computational data. I also extract valuable information for determining the performance of organic devices. Such information includes charge transfer and charge redistribution at the interface, changes in the work function, interface dipoles and interface electronic states. I study a variety of molecules on several metal surfaces with different orientation and chemistry. Molecules such as acenes, thols and others with CN groups are studied on transition metal surfaces with orientations (111), (100), (110) and vicinals.

FY 2014 HIGHLIGHTS

I have continued my research on assessing the role of van der Waal (vdW) interactions on a variety of molecules and substrates (benzene, thiophene, sexithiophene, 1,4-benzenedimethanethiol (BDMT), 9,10-anthracenedicarbonitrile (DCA), and a cyano-substituted triarylamine (HBQUAT)). I also included van der Waals interactions in 2D materials such as silicene, the counterpart of graphene. The goal of these studies is first to assess the accuracy of the newly developed vdW functionals within the density functional theory for molecular adsorption characteristics on varying substrate chemistries, and coordination. This information will then help to extract the transferability, strengths, weaknesses of the available functionals, and provide insights into the development of new vdW functionals. Some of the work is also performed in collaboration with experimentalists. The specific work done during the reporting period between October 1st 2013 and September 30th 2014 includes (all the work is done using density functional theory with the inclusion of vdWs effects):

- 1) Adsorption characteristics of a sexithiophene molecule on Ag(110): JCP 140, 144703 (2014)
- 2) Adsorption characteristics of a thiol molecule on Cu, Ni and Pd (100): paper in preparation.
- 3) Adsorption characteristics of BDMT on Au(111): paper submitted to JPCC
- 4) Adsorption characteristics of benzene on Cu, Au, Ag, Ni, Pd, Pt, and Rh (110) surfaces: paper accepted for publication at JPCC.
- 5) In-Depth Atomic Structure of the Pentacene/Cu (110) Interface in the Monolayer Coverage Regime: Theory and X-ray Diffraction Results: JPCC 118, 27815 (2014)
- 6) Atomic and electronic structures of the sqrt(13) R13. 9° of silicene sheet on Ag (111): App. Surf. Sci. 303, 61 (2014)
- 7) Cyano-Functionalized Triarylamines on Coinage Metal Surfaces: Substrate Influence on Molecular Self-Assembly: to be submitted to Chem. Eur. J.

Dynamical Analysis of Highly Excited Spectra

Institution: Oregon, University of
Point of Contact: Michael Kellman
Email: kellman@uoregon.edu
Principal Investigator: Michael Kellman
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Highly excited vibration-rotation dynamics of small molecular species, including those approaching the threshold of reaction, are crucial to understanding fundamental processes important for combustion. Our goal is to develop theoretical tools to analyze spectra and dynamics of these highly excited systems. A persistent theme is the use of effective spectroscopic fitting Hamiltonians to make the link between experimental data and theoretical dynamical analysis. There are three areas currently under investigation:

- 1) The role of bifurcations and the “birth of new modes in bifurcations from the low energy normal modes.”
- 2) A more recent focus has been systems approaching and undergoing intramolecular isomerization reactions. We have been developing new generalizations of the effective Hamiltonian, called “polyad-breaking Hamiltonians,” to deal with spectra of isomerizing systems. In our most recent

work we have extended these investigations to consider time-dependent dynamics, including the isomerization process.

- 3) Most recently, in a new development in our research program, we have begun an investigation of the “quantum thermodynamics” of a small quantum molecular system immersed in a quantum heat bath.

FY 2014 HIGHLIGHTS

(1) CRITICAL POINTS BIFURCATION ANALYSIS OF EFFECTIVE SPECTROSCOPIC HAMILTONIANS. In a project conducted with Dr. Vivian Tyng, we are completing our first bifurcation analysis for a rotation-vibration effective Hamiltonian, using a recent spectroscopic Hamiltonian for CO₂ fit to experimental data. We have in hand the successful critical points analysis of rotation-vibration dynamics of CO₂ on the effective Hamiltonian fit to experimental data. The analysis gives relatively simple, intelligible dynamics, comparable to but significantly extending what has been obtained with pure vibrational dynamics. At J = 0 there is only the bifurcation tree of normal modes and Fermi resonance modes. Then, as J increases, we find a principal 'Coriolis mode' that bifurcates out of one of the Fermi resonance modes at very low J, with further finer branching of the tree into Coriolis modes with increasing J.

(2) GENERALIZED SPECTROSCOPIC HAMILTONIAN FOR ISOMERIZING SYSTEMS WITH POLYAD BREAKING. This work has been primarily in collaboration with Dr. George Barnes. The recent focus of our work is systems approaching and even surmounting an isomerization barrier, in which the standard effective spectroscopic Hamiltonian breaks down. The Hamiltonian used in virtually all existing spectral fits invokes an approximate conserved quantity known as the polyad or total quantum number. In a recent step we showed that it is possible to construct an effective Hamiltonian to encompass multiple potential energy minima in an isomerizing system. As our exemplar, we used one of the most important elementary combustion species is the hydroperoxyl radical HO₂. A new direction will involve combining the existing bifurcation analysis of our HO₂ effective Hamiltonian with our thrust into entangled system-environment dynamics outlined briefly at the end of the following section.

Combining Novel Simulation Methods and Nucleation Theory to Uncover the Secrets of Gas Hydrates

Institution: Boston University
Point of Contact: Thomas Keyes
Email: keyes@bu.edu
Principal Investigator: Thomas Keyes
Sr. Investigator(s): William Klein; Boston University
Harvey Gould; Clark University
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$158,159 (2014)

PROGRAM SCOPE

First-order phase transitions modulate material properties. Nucleation and growth of a new phase proceeds through a sequence of states with coexisting phases, which are difficult to sample with conventional computer simulation methods. The usual choice of temperature as the control variable is poor, since diverse coexisting states have the same temperature. The project aims to develop and exploit our generalized replica exchange method (gREM), which specifically targets coexisting states, to obtain a new capability of characterizing first-order transitions. We propose a unified approach of gREM simulation, combination of data from different replicas with a non-iterative method we have developed, and a description of the transition via the entropy as a function of enthalpy, the control variable. The

immediate target is gas hydrates, substances of great importance for energy and climate science. In forming hydrates from methane and liquid water, the gREM robustly samples coexisting states at all stages of growth. The mechanism and phase diagram of hydrate formation is under investigation and the action of hydrate inhibitors will be considered. All coexistence involving solid/liquid water is relevant and computationally challenging, and we seek a description with the gREM for stable hexagonal ice and for the metastable β -ice which holds guest molecules in hydrates. The methods developed will advance the study of any material properties influenced by phase transitions, e.g. for nano catalysts surrounded by a lipid envelope with a solid/liquid transition.

FY 2014 HIGHLIGHTS

The theory of constant pressure molecular dynamics algorithms sampling generalized, non-Boltzmann ensembles was derived and our generalized replica exchange method (gREM) was optimized accordingly. A complete test of our approach to first-order transitions was performed, for melting of the methane hydrate scaffolding, β -ice. The states with coexisting phases were sampled, with every structural change identified with a feature in the entropy as a function of enthalpy. The position of a prominent plateau in the statistical temperature, the inverse of the enthalpy derivative of the entropy, was presented as a novel estimator of the equilibrium transition temperature. The upper spinodal gave the limit of superheating, and the Gibbs free energy profile yielded the β -ice/liquid surface tension for the first time, 26.3 mJ/m^2 . A similar new view of the equilibrium of stable hexagonal ice and liquid water was obtained. The pathway of methane hydrate formation from a dilute solution was investigated, using new methods to identify empty and partial hydrate cages. The sequence, with decreasing enthalpy, is: methane solution, piece of perfect hydrate in water, hydrate surrounded by β -ice in water, and hydrate in hexagonal ice. We believe that the catalysis of a relatively large region of β -ice by a small piece of hydrate is a key element of the growth pathway: the empty cages will be filled as more methane becomes available. The basic concept of the gREM was validated by facile observation of coexisting states in several systems.

Magnetic and Tunable Band Gap Cluster Building Blocks for Novel Nanostructure Materials and Electron Transport through their Assemblies

Institution: Virginia Commonwealth University
Point of Contact: Shiv Khanna
Email: Snkhanna@vcu.edu
Principal Investigator: Shiv Khanna
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014-2016)

PROGRAM SCOPE

An important development in nanoscience is the possibility of designing nanoscale materials with chosen atomic clusters as the building blocks. Since the properties of small clusters are found to change with size and composition, such an approach offers the promise of making materials with selected properties. Our DOE program proposes to undertake a comprehensive approach starting from studies of electronic structure and magnetic properties (including magnetic anisotropy energy) of free and supported clusters for identifying magnetic motifs with stable magnetic order and varying band gaps, to investigation of the transport properties of molecules of such motifs, and exploration of synthesis and

properties of larger assemblies of such motifs. The program involves four interrelated areas of study, namely:

- A. investigation of the magnetic anisotropy in free TM_nC_m/TM_nSi_m (TM = Cr, Mn, Fe, Co, Ni) clusters and in TMn clusters supported on Graphene motivated by our preliminary findings of high magnetic anisotropy in such systems;
- B. studies of metal chalcogenide superatoms and Si_nTM_m (TM = Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Nb, Mo, Ru, Rh, Pd) clusters to identify potential semiconducting magnetic building blocks.;
- C. studies of ligated cluster assemblies and supported ligated clusters to explore magnetic assemblies with tunable band gaps.;
- D. development of computational codes to carry out electronic transport studies that incorporate the effect of excess charge, spin ordering and anisotropy. Thereafter, building on our recent collaborations with experimental groups involved in synthesizing nanoassemblies using wet chemical methods, we will work to form similar assemblies of magnetic motifs. The research promises a class of nanoscale materials with potential applications in spintronics and other areas.

FY 2014 HIGHLIGHTS

We had a very successful period where we studied the stability of magnetic motifs that could form the building blocks of novel nanoscale magnetic materials and the emergent properties of such assemblies. Our investigations on Ag_nV^+ clusters (JACS 136, 8229 (2014)) focused on the evolution of bonding and spin magnetic moment in metal clusters while our studies on CrSi₁₂ (J. Phys. Chem. Lett. 118, 8314(2014)) examined the applicability of the 18-electron rule, currently used to account for its stability. We showed that the cluster does not conform to this rule. We are currently developing revised electronic and geometric rules for these classes of clusters. Efficient control of magnetic anisotropy and orientation of magnetization are of central importance for the application of nanoparticles in spintronics. Conventionally, magnetization is controlled directly by an external magnetic field or by an electric field via spin-orbit coupling. We demonstrated (APL 105, 152409(2014)) a different approach to control magnetization. We first showed that the low magnetic anisotropy of a Co₅ cluster can be substantially enhanced by attaching benzene molecules due to the mixing between p states of C and the d states of Co sites. We then showed that the direction of magnetization vector of a Co₅ sandwiched between two benzene molecules rotates by 90 degrees when an electron is added or removed from the system providing a new approach to control the direction of magnetization. Finally, we participated (J. Phys. Chem. 118, 8314(2014)) in the synthesis, isolation, and characterization of the ligand-protected bimetallic cluster, $Ag_4Pt_2(DMSA)_4$ (DMSA=meso-2,3,-dimercaptosuccinic acid) using wet chemical methods where our theoretical studies suggest that the Pt atoms have square planar configuration with a larger crystal field splitting of 5d orbitals than the corresponding 3d orbitals in a similar Ni based assembly. This leads to an optical spectrum that is blue shifted than for Ni.

Quantum Monte Carlo Calculations of Chemical Binding and Reactions

Institution: William and Mary, College of
Point of Contact: Henry Krakauer
Email: hxkrak@wm.edu
Principal Investigator: Henry Krakauer
Sr. Investigator(s): Shiwei Zhang; William and Mary, College of
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014-2016)

PROGRAM SCOPE

The auxiliary field quantum Monte Carlo (AFQMC) method developed by the PIs has been shown to provide the most accurate description of strongly correlated electronic systems, from molecules to solids. Unlike other explicitly many-body approaches, QMC scales as a low order polynomial of systems size, similar to mean-field methods such as density functional theory (DFT). Since the AFQMC algorithm has the form of an entangled ensemble of mean-field calculations, it is significantly more expensive than traditional DFT calculations. This creates a bottleneck for applications to extended systems, such as large molecules and solids. One principal objective of this proposal is to develop new AFQMC computational strategies to achieve improved scaling with system size, using downfolding and localization schemes, without sacrificing the predictive power of the calculations. A second goal is to extend the reach of AFQMC to calculate excited states. The project will first be focused on building this computational infrastructure. We will implement quantum chemistry localization methods in both the occupied and virtual sectors. Then as our first application we will carry out calculations of the chemistry of two-dimensional layered transition metal dichalcogenide nanosheets, which have possible applications in a variety of fields, including catalysis, energy storage, sensing and electronic devices. The development of this theoretical capability will have cross-cutting impacts beyond specific systems, with the potential to deliver breakthrough science. The techniques and codes we will develop are very general and applicable to many other problems, for example strongly correlated transition metal oxides and materials with lanthanide and actinide elements. By establishing highly accurate benchmark calculations, the results will validate less computer intensive methods. The capability of these tools will allow a new level of prediction and understanding of nano-structured materials.

FY 2014 HIGHLIGHTS

Frozen orbital and downfolding method with auxiliary-field quantum Monte Carlo (AFQMC): We demonstrated an approach that can provide great computational savings, downfolding high-energy basis states to a physically relevant low-energy sector, which allows a systematic approach to produce realistic many-body model Hamiltonians. As a by-product, we obtain a way to effectively eliminate the error due to single-projector, norm-conserving pseudopotentials in AFQMC. [Wirawan Purwanto *et al.*, *Journal of Chemical Theory and Computation*, 2014 DOI: 10.1021/ct4006486.]

Stability, Energetics, and Magnetic States of Cobalt Adatoms on Graphene: We investigate the stability and electronic properties of single Co atoms on graphene with near-exact many-body calculations. A frozen-orbital embedding scheme was combined with auxiliary-field quantum Monte Carlo calculations to increase the reach in system sizes. Several energy minima are found as a function of the distance h between Co and graphene. The findings provide an explanation for recent experimental results with Co on free-standing graphene. [Yudistira Virgus *et al.*, *Phys. Rev. Lett.*, 2014, DOI: 10.1103/PhysRevLett.113.175502. (Paper Received 2 July 2014; published 23 October 2014).]

Quantum Monte Carlo calculations in solids with downfolded Hamiltonians: We applied the downfolding approach to extended systems. Many-body calculations operate on a simpler Hamiltonian which retains material-specific properties. The Hamiltonian is systematically improvable and allows one to dial, in principle, between the simplest model and the original Hamiltonian. [Submitted to *Phys. Rev. Lett.* Dec 2014.]

Theoretical Modeling of Spin-Forbidden Channels in Combustion Reactions

Institution: Southern California, University of
Point of Contact: Anna I Krylov
Email: krylov@usc.edu

Principal Investigator: Anna I Krylov
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$125,000 (2014)

PROGRAM SCOPE

The goal of our research is to develop predictive theoretical methods, which can provide crucial quantitative data (e.g., rate constants, branching ratios, heats of formation), identify new channels and refine reaction mechanisms. Specifically, we are developing tools for computational studies of spin-forbidden and non-adiabatic pathways of reactions relevant to combustion, and applying these tools to study electronic structure and reactions of open-shell and electronically excited species involved in these processes.

FY 2014 HIGHLIGHTS

During the past year, we conducted several computational studies of open-shell and electronically excited species. The common theme in these studies is interactions between states of different character and intersections between the corresponding potential energy surfaces. We also continued to develop and benchmark computational methods for modeling electronic structure and spectroscopy of open-shell species. Particular emphasis was placed on determining spectroscopic signatures of transient species, to facilitate comparisons with experimental data. In 2014-2015, the DOE support has been acknowledged in six papers. Two more papers are being prepared for the publication. The highlights include investigations of conical intersections, developing protocols for calculating redox properties and energetics of hydrate transfer reactions, developing an validating codes for Dyson orbitals and cross section calculations (including condensed phase), as well as developing formalism and codes for efficient calculations of spin-orbit couplings.

Computational Design of Metal Organic Frameworks for Photocatalytic Reduction of Carbon-Dioxide

Institution: West Virginia University
Point of Contact: James Lewis
Email: james.lewis@mail.wvu.edu
Principal Investigator: James Lewis
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$269,832 (2014-2015)

PROGRAM SCOPE

The utilization of light as a direct means of energy production and as an aid to catalyze chemical reactions are examples of key technological applications depending on the interaction of light with matter. There is an urgent need to understand light-matter interactions to determine fundamental processes in photoactive materials with an ultimate goal of optimizing materials for various applications. Developments of new simulation methodologies are required to contribute abundantly to the discovery and innovation process in partnership with advances in synthesis and characterization. In this project, our research team will continue to develop advanced methods to examine excitation dynamics and light-matter interactions in materials. More specifically, as outlined in the project narrative, we will utilize computational tools in a high-throughput search for porous coordinated polymers that

incorporate organic linkers that undergo photo-isomerization, that is, conformation changes as a result of light irradiation; azobenzene is a well-studied example of a molecule with photo-isomerization properties. Porous coordinated polymers (PCPs) that utilize stimuli response, such as light absorption, are shown to be potentially highly efficient sorbents, particularly for carbon dioxide uptake.

FY 2014 HIGHLIGHTS

More recently, we have been investigating the photo-isomerization processes in azo-functional organic linkers through non-adiabatic molecular dynamics. We are exploring the impact of R-groups on the optical properties, isomerization reaction time, and quantum yield and we find that these properties are strongly dependent on the functional groups attached to the azobenzene derivative. We will report on non-adiabatic molecular dynamics simulation results for a few model azobenzene derivative systems and we will discuss our theoretical understanding of the trans- to cis- transformation mechanisms, and timescale variations, resulting from different functional groups. Our long term goal is to use high-throughput calculations to rationally design highly efficient photo-isomerization response in porous coordinated polymers for gas separation. Two publications regarding this research have been accepted and are currently in print.

Time-Dependent Density Functional Theory: Introducing First-Principles Electron Friction in Time-Domain

Institution: Washington, University of
Point of Contact: Xiaosong Li
Email: li@chem.washington.edu
Principal Investigator: Xiaosong Li
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$90,000 (2014)

PROGRAM SCOPE

Excited state multi-electron dynamics is fundamental to describing the electronic behavior of molecules in photochemical reactions, dynamics at metal or semiconductor surfaces, and electron transfer in molecular, biological, interfacial, or electrochemical systems. Providing accurate and experimentally meaningful descriptions of excited state electronic dynamics within the real-time time-dependent density functional theory (RT-TDDFT) framework has been the focus of our research during this funding period. Our research supported by this DOE award has been focusing on extending the capability of RT-TDDFT electronic dynamics to probe excited state dynamics in response to external perturbations such as solvent and molecular vibrations. In a real physical/chemical system, multi-electron wave function decoherence arises from bath-induced fluctuations in the system. From the perspective of electrons, the bath can be the collective solvent degrees of freedom or the molecular vibrations. Within the framework of first-principles electronic dynamics, we have developed several different techniques to address the electronic decoherence arising from interactions with solvent and molecular vibrations. New methods include a real-time, time-dependent polarizable continuum model (RT-TDPCM) method to model electron-solvent interactions with an open-system framework, a first-principles friction/dissipation formalism to model thermalized electronic equilibration processes, and a concept of mixed quantum/classical molecular dynamics that combines surface-hopping and an excited Ehrenfest potential to model electron-phonon coupling.

FY 2014 HIGHLIGHTS

In this funding period (Oct13 - Sept 14), we have published four peer-reviewed papers. Highlights of our recent work of RT-TDDFT electronic dynamics funded by this DOE award include: A plasmon-like phenomenon, arising from coinciding resonant excitations of different electronic characteristics in 1D silver nanowires, has been proposed based on theoretical linear absorption spectra. Such a molecular plasmon holds the potential for anisotropic nanoplasmonic applications. However, its dynamical nature remains unexplored. Recently, we have carried out the real-time time-dependent density functional theory to study the quantum dynamics of longitudinal and transverse excitations in 1D silver nanowires. The anisotropic electron dynamics confirm that the transverse transitions of different electronic characteristics are collective in nature and oscillate in-phase with respect to each other. Analysis of the time evolutions of participating one-electron wave functions suggest that the transverse transitions form a coherent wave packet that gives rise to a strong plasmon resonance at the molecular level. "In-Chain Donor/Acceptor block copolymers" comprised of alternating electron rich/poor moieties are emerging as promising semiconducting chromophores for use in organic photovoltaic devices, but a mechanistic understanding of the relevant charge diffusion pathways is lacking. To elucidate the mechanisms of electron and hole transport following excitation to optically accessible low-lying valence states, we utilize RT-TDDFT to explicitly track the evolution of these photo-accessible states. From the orbital pathway traversed in the dynamics, p and n type conductivity can be distinguished. The electronic dynamics for the studied polymers show the time-resolved transitions between the initial photoexcited state, a tightly-bound excitonic state that is dark to the ground state, and a partially charge separated state indicated by long-lived, out-of-phase charge oscillations

Hydration Mechanisms in Nanoparticle Interaction and Surface Energetics

Institution: Virginia Commonwealth University

Email: aluzar@vcu.edu
Principal Investigator: Alenka Luzar
Sr. Investigator(s): Dusan Bratko; Virginia Commonwealth University
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$127,196 (2014)

PROGRAM SCOPE

Emerging nanoparticle technologies require new techniques to control surface properties of a material. In many applications, surface thermodynamics and interactions between nanoparticle surfaces are determined by solvation in electrolyte solutions. The long-term objective of this research is to develop molecular level understanding of energetics, kinetics and hydration in nanoparticle solutions, and ionic solutions in particular. The program focuses on modulating surface free energy and hydration effects in prototypical nanoscale systems through surface functionalization or applied electric field in the presence of conducting (ionic) solution. A further goal concerns molecular mechanisms and the intricate role of salt in surface energy storage in a nanoporous medium controlled by an externally applied electric field. The project relies on a combination of theoretical and computational approaches using atomistic and coarse-grained models to span different length and time scales. The efforts involve development of optimized algorithms for molecular simulations of nanoscale surface phenomena, focusing on the interplay of applied and ion-induced electric field and hydrogen bond interactions. Theoretical studies of the new effects this project is uncovering will likely inspire future experiments. Understanding of basic molecular mechanisms involved in solvation of nanoparticles represents an important step in creating

new materials, harvesting energy from nature and storing energy. In nanotechnology, this understanding is essential for effective control of surface interactions and nanocolloid phase behavior. It also underlies the development of novel separation techniques in ionic systems, exemplified by water desalination and soil decontamination.

FY 2014 HIGHLIGHTS

Salt partitioning and phase behavior of electrolytes in porous media can be efficiently modulated by ionic patterning and by applying electric field. Our molecular modeling studies reveal new and unexpected features in both the fast and slow responses of aqueous and solution interfaces to electric stimuli. Specifically, we uncover a strong and nonmonotonic polarity dependence of reorientation dynamics at aqueous interfaces. Order of magnitude acceleration can be achieved in a narrow window of applied field strengths provided the field is pointing toward the solid phase. We developed new computational algorithms for multiphase electrolyte system to capture the slow response, which involves transport of salt and solvent under the influence of the field. Using a novel, self-consistent formulation of the heterogeneous field problem, we show an unambiguous contraction of the solution relative to surrounding bath. This resolves an open literature debate on the role of the external field and provides a route to studies of the electrolyte influence on static and dynamic partitioning of solution components. Of particular importance for materials and energy technologies, we identified a range of conditions where electrolyte solution manifests revertible permeation/expulsion transitions, allowing material flow and storage of surface energy subject to voltage regulation. Nanoscale porosity is mandated for successful operation. We quantify the extent of salt depletion and concomitant weakening of the substrate/solution adhesion. The counterbalancing effect of the rise in solution surface tension stabilizes the permeated state, an outcome of immense importance because of ubiquitous materials exposure to saline solutions.

Electron-Ion Dynamics with Time-Dependent Density Functional Theory: Towards Predictive Solar Cell Modeling

Institution: New York-Hunter College, City University of
Point of Contact: Neepa Maitra
Email: nmaitra@hunter.cuny.edu
Principal Investigator: Neepa Maitra
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$86,249 (2014)

PROGRAM SCOPE

The overall goal is to develop accurate and reliable practical methods to model dynamical processes in solar cells, and eventually be used in their design. Purely electronic aspects of the problem (electronic dynamics and excitations), as well as the coupling of the electron motion to the nuclear motion, need improvement over their present-day treatments. From the electronic side, the usual approximations in time-dependent density functional theory (TDDFT) perform poorly for charge-transfer processes, and little is known about how the adiabatic approximations used perform when simulations begin after the initial photo-excitation (in theory they are not supposed to be applied here). Studying exactly-solvable model systems enables us to find features of the exact exchange-correlation potential that are essential for accurate dynamics, and compare with approximations. In particular for real-time dynamics, such as involved in a transfer of a photo-excited electron from a donor to acceptor, one must go beyond the

linear response regime, and it is unclear whether approximations known to be accurate for excitation spectra perform well. Turning to the problem of coupling with ions, more needs to be understood about the reliability of using TDDFT in conjunction with surface-hopping, yet Ehrenfest provides an inadequate description of the coupling. Originally I had proposed a method coupling semiclassical nuclei to TDDFT electrons, and, in working towards this, exploring different aspects of the exact factorization approach to coupled electron-ion dynamics, in collaboration with the Halle group. This approach has a rigorous foundation, and is the correct starting point for approximations. The potentials of the theory contain new terms that exactly account for electron-ion coupling, and we are studying their main features for non-adiabatic dynamics in the absence and presence of external fields, comparing them to the potentials used in surface-hopping and Ehrenfest.

FY 2014 HIGHLIGHTS

We showed that propagating with the adiabatically-exact functional (i.e. the best possible adiabatic approximation) fails to transfer charge across a long-range molecule, despite capturing nonlocal ground-state step features relevant to dissociation and often accurately capturing charge-transfer (CT) excitations. The dynamics is highly non-perturbative, and calls for functionals beyond the ones developed for excitations. A second result is a new exact condition we proved that has particular implications for time-resolved spectroscopy. A fundamental property of a system driven by an external field is that when the field is turned off, the response frequencies are independent of the time at which the field is turned off. The Kohn-Sham potential typically continues to evolve, leading to time-dependent Kohn-Sham response frequencies. The exchange-correlation kernel must cancel out this time-dependence, yielding an exact condition based on generalized response theory. The condition is typically violated, but we showed a simple functional on a 2-electron model of photo-excited CT satisfies the condition, and consequently fully CTs accurately. Regarding coupled electron-ion dynamics, with collaborators from MPI Halle, we found that quasiclassical propagation of an ensemble of nuclear trajectories on the exact time-dependent potential energy surface is extremely accurate in describing branching of a nuclear wavepacket in a model non-adiabatic CT problem. Further, we related features of the exact surface to aspects of surface-hopping, like velocity renormalization. We see hints of a force-induced decoherence, but more care is needed to fully analyze this aspect. We used the exact factorization to define the exact potential acting on the electronic system, and compared this to traditional potentials used to study laser-induced electron localization, a technique developed for attosecond control of electrons. Important differences found give different localization asymmetries.

Ultrafast Processes in Atoms and Molecules: Integrated Treatment of Electronic and Nuclear Motion in Ultrashort XUV Pulses

Institution: California-Davis, University of
Point of Contact: C. William McCurdy
Email: cwmccurdy@lbl.gov
Principal Investigator: C. William McCurdy
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: Research was supported with prior fiscal year funding. (2014)

PROGRAM SCOPE

This project addresses the physics of new kinds of short laser pulse spectroscopy for studying the dynamics of electrons in atoms and molecules. We are developing and applying a new theoretical and

computational method for describing the response of atoms and diatomic molecules to intense ultrashort pulses of electromagnetic radiation. The project has refined and extended a new computational implementation of the Multiconfiguration Time-Dependent Hartree Fock (MCTDHF) approach to solving the time-dependent Schrödinger equation in which all electrons are treated dynamically on the same footing. This computer code is being used to predict and study the dynamics of population transfer between electronic excited states of molecules in femtosecond pulses of ionizing radiation and to the interpretation of transient absorption and multidimensional spectra of atoms and diatomic molecules.

FY 2014 HIGHLIGHTS

This year our efforts have focused on applications and development of the Multiconfiguration Time-Dependent Hartree Fock (MCTDHF) method in three areas:

- 1) Population transfer between valence states using autoionizing states as intermediates. Our work on this subject appeared this year in Physical Review A, and it demonstrates the remarkable result that roughly 40% of the population of the ground state of the NO molecule can be transferred within 1 femtosecond to a wave packet of valence states through autoionizing states 400 eV above the ground state.
- 2) MCTDHF applications to attosecond transient absorption in the ionization continuum of atoms and molecules: An attosecond transient absorption experiment is one in which a time delayed, intense near infrared (NIR) pulse is used to modify the absorption of a weaker, attosecond UV pulse that came before it or overlapped with it. We have discovered that there exists a way to use this idea to probe the electron dynamics driven by the intense NIR pulse in intensity regimes where it generates high harmonics. This could be a new way to investigate the intense field dynamics that are responsible for high harmonic generation in molecules.
- 3) The development of a new capability for using MCTDHF in a non-perturbative approach to XUV multidimensional spectroscopy, including 3 and 4 wave mixing: We implemented a way to apply the macroscopic phase matching condition that determines the final signal in a multidimensional spectroscopy experiment with several short pulses. During this phase of the project we have made a discovery that these ideas can be applied to transient absorption, and that experiments with two pulses, an IR and an XUV pulse, that have the pulses propagating in different directions could be used to decompose transient absorption spectra into contributions of different numbers of IR photons.

Theoretical Studies of Chemical Reactions Related to the Formation and Growth of Polycyclic Aromatic Hydrocarbons and Molecular Properties of Their Key Intermediates

Institution: Florida International University
Point of Contact: Alexander Mebel
Email: mebela@fiu.edu
Principal Investigator: Alexander Mebel
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$220,000 (2014-2015)

PROGRAM SCOPE

We investigate complex chemical mechanisms of PAH formation and growth via theoretical studies of their critical elementary reactions. Our primary objectives include (i) to unravel reaction mechanisms

through detailed, accurate, and reliable calculations of pertinent potential energy surfaces (PESs); (ii) to compute rate constants for individual reaction steps and total absolute reaction rate constants and product branching ratios depending on reaction conditions, such as collision energy or temperature and pressure; (iii) to characterize molecular, energetic, and spectroscopic parameters of various possible reaction intermediates and products including their enthalpies of formation, geometric structure, vibrational frequencies and rotational constants, as well as photoionization and photoexcitation spectra. To achieve these goals, we employ chemically accurate *ab initio* and density functional calculations (using CCSD(T)/CBS, G3, and explicitly correlated methods) of the PESs of these reactions which are then utilized for statistical (TST and RRKM/Master Equation) computations of absolute reaction rate constants and product branching ratios. In the current project period we study the reactions of dicarbon C_2 with unsaturated hydrocarbons producing resonance-stabilized free radicals (RSFR), which in turn can contribute to the formation of aromatic species, the isomer-specific growth of various PAH and CP-PAH molecules beyond the second aromatic ring, and the oxidation of PAH radicals. The studies of the reactions of the p-tolyl radical with isoprene, 1,2-butadiene, and C_3H_4 isomers, and the reaction of the phenyl radical with isoprene leading to the formation of methyl-substituted PAH molecules indene and naphthalene are performed in conjunction with crossed molecular beams experiments in Kaiser's group. Another collaborative project is underway with Arthur Suite's group on the studies of Cl atoms with alkenes occurring via a Cl-addition-radical-roaming mechanism.

FY 2014 HIGHLIGHTS

We elucidated the chemical dynamics of the formation of toluene through a single collision event of the ethynyl radical C_2H and isoprene in the gas phase. The reaction has no entrance barrier, is exoergic, and all transition states are located below the energy of the separated reactants and hence can lead to toluene not only in high-temperature combustion flames, but also in low-temperature environments. The substitution of the methyl group at the C_2 carbon atom of isoprene by any alkyl group might lead to the synthesis of alkyl-substituted benzene molecules. This reaction class presents a facile alternative to the formation of alkyl benzenes through reactions of benzene with alkyl radicals underscoring the importance of ethynyl-radical-mediated formation of aromatic molecules in combustion flames from acyclic precursors through barrierless and strongly exoergic reactions from noncyclic precursor molecules. Similarly, we discovered that the reaction of triplet dicarbon with isoprene forms the aromatic and resonantly stabilized free radical benzyl providing a barrierless pathway via a single collision event from acyclic, non-aromatic reactants. The reaction of triplet C_2 with isoprene may form benzyl both in combustion flames and in low temperature astrochemical environments. We performed VRC-TST/RRKM-ME calculations of total rate coefficients and product branching ratios for the oxidation of phenyl and naphthyl radicals with O_2 at temperatures relevant to combustion (1500, 2000, and 2500 K) and pressures of 0.01, 0.1, 1.0, and 10 atm. The results gave the rate coefficients in the range of $3.0\text{--}5.5 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ with slightly positive temperature dependence. The dominant reaction channel is elimination of the O atom from peroxy complexes leading to the phenoxy and naphthoxy radical products. Chemically-activated phenoxy and naphthoxy radicals either decompose to the cyclopentadienyl+CO and indenyl+CO products, respectively, or undergo thermal equilibration.

Testing the Applicability and Potential Impact of Rigorous Quantum Embedding Methods for the Study and Characterization of Metal Organic Frameworks

Institution: California Institute of Technology
Point of Contact: Thomas Miller
Email: tfm@caltech.edu
Principal Investigator: Thomas Miller

Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: Research was supported with prior fiscal year funding. (2014)

PROGRAM SCOPE

The PI develops theoretical and computational methods to understand a variety of molecular processes, including enzyme catalysis, solar energy conversion, dendrite formation in lithium batteries, and the dynamics of soft matter and biological systems. An important aspect of this challenge is that many systems exhibit dynamics that require a means for embedded density functional theory. This research develops new techniques that can bridge dynamical hierarchies and simulate complex dynamics.

FY 2014 HIGHLIGHTS

A paper reporting accurate and systematically improvable density functional theory embedding for correlated wavefunctions is accepted to the journal of Physical Chemistry. A paper on embedded mean-field theory was accepted for publication in JCTC. The PI won the ACS Physical Division Early-Career Award in Theoretical Chemistry.

Manipulating Light with Transition Metal Clusters, Organic Dyes, and Metal-Organic Frameworks

Institution: Illinois-Chicago, University of
Point of Contact: Serdar Ogut
Email: ogut@uic.edu
Principal Investigator: Serdar Ogut
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014-2015)

PROGRAM SCOPE

The primary goals of our research program are to develop and apply state-of-the-art first principles methods to predict electronic and optical properties of three systems of significant scientific and technological interest: Transition metal clusters, organic dyes, and metal-organic frameworks. These systems offer great opportunities to manipulate light for a wide ranging list of energy-related scientific problems and applications. We focus our investigations on the following areas:

- The development and implementation of many-body Green's function methods (solving the GW-Bethe-Salpeter Equation) to examine excited state properties of transition metal clusters.
- The prediction of optical properties of free-standing and dye-sensitized titania nanocrystals. For free-standing nanocrystals, we examine the size, shape, and exposed surface dependence of the optical properties of passivated TiO₂ nanocrystals and investigate whether or not the bulk-limit can be achieved with a reasonably sized nanocrystal amenable to a first-principles treatment. We will also consider the perylene-diimide based organic dyes on various TiO₂ surfaces to investigate how the optical properties of the combined system emerge from its individual units.
- The pioneering applications of time-dependent density functional theory and many-body perturbation methods to examine the electronic and optical properties of metal-organic frameworks to shed light on whether they can be utilized as materials for light-harvesting applications. In particular, we will focus on two metal-organic frameworks, the so-called MOF 5 and HKUST-1, and their building units, and perform a systematic study of how their optical properties evolve from their

subunits. These studies are expected to lead to significant insights for future design of alternative photovoltaic and photocatalytic materials based on metal organic frameworks.

FY 2014 HIGHLIGHTS

We have modeled rutile TiO₂ nanocrystals (NCs) up to ~1.5 nm in size to study the effects of quantum confinement on their electronic and optical properties. Electronic excitations were obtained via the perturbative GW approximation and Delta-SCF method for NCs up to 24 and 64 TiO₂ formula units, respectively. These demanding GW computations were made feasible by our implementation of a real-space framework that exploits quantum confinement to reduce the number of empty states needed in GW summations. We used TDDFT to predict the optical properties of NCs up to 64 TiO₂ units. Our computations revealed that the largest NCs modeled are still quantum confined and do not yet have quasiparticle levels or optical gaps at bulk values. Nevertheless, we found that classical Mie-Gans theory can quite accurately reproduce the line shape of TDDFT absorption spectra, even for TiO₂ NCs of subnanometer size. We have started a new collaboration with two groups (Chelikowsky at UT Austin and Louie at UC Berkeley) to benchmark a variety of molecules to determine any trends in the accuracy of GW+BSE computations relative to experiment, particularly in reference to (i) the impact of a LDA-derived vertex correction compared to the standard GW calculations without vertex corrections, and (ii) the effect of self-consistency in GW. The set so far includes three inorganic molecules (N₂, H₂O, and NH₃) and six organic molecules (benzene, naphthalene, thiophene, 1,2,5-thiadiazole, benzothiazole and tetrathiafulvalene). Preliminary results were presented at the 2014 APS March meeting in Denver, CO. We have started a new collaboration with the group of Leor Kronik (Weizmann Institute, Israel) on investigating the electronic structure of copper-oxide clusters (Cu_xO_y, x=1-2, y=1-4) using optimally-tuned range-separated hybrid functionals as well as the GW method at various levels of theory. Preliminary results will be presented at the 2015 APS Meeting, San Antonio TX.

Theoretical Studies of Spin Crossover Metal-Organic Frameworks

Institution: California-San Diego, University of
Point of Contact: Francesco Paesani
Email: fpaesani@ucsd.edu
Principal Investigator: Francesco Paesani
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014-2015)

PROGRAM SCOPE

The main goal of our research project is to characterize the physical mechanisms that determine the spin crossover (SCO) behavior of metal-organic frameworks (MOFs). MOFs represent a relatively new class of porous materials consisting of metal ions coordinated to organic ligands. In most cases, the pores are stable to elimination of solvent molecules, which results in open spaces of high surface area suitable for gas storage and purification, separation processes, and heterogeneous catalysis. The presence of transition metal centers with unpaired electrons, such as Fe(II) and Co(II), can also add magnetic properties to the framework. This provides new opportunities for the design of multifunctional MOFs with SCO behavior in which changes in the electronic structure of the metal centers lead to distinctive changes in the overall geometry, color, and magnetism of the material. Although the SCO behavior has been observed in several MOFs, its connection to the physicochemical properties of the framework, the nature of the guest molecules, and the ligand field of the metal centers remain poorly

understood. Our studies aim at providing a molecular-level understanding of the physical mechanisms that affect the SCO behavior of MOFs through the development and application of new theoretical/computational approaches. The specific objectives are:

- Development of a novel computational methodology, which encodes electronic structure data into a molecular mechanics description of the frameworks for simulating both electronic and structural properties of MOFs with SCO behavior.
- Molecular-level understanding of the effects of the framework properties, such as ligands functionality and flexibility, on the SCO behavior of MOFs.
- Identification of the molecular interactions that determine the adsorption of chemically different guest molecules and, consequently, modulate the SCO behavior of MOFs.

FY 2014 HIGHLIGHTS

We have developed a novel hybrid Monte Carlo / molecular dynamics (MC/MD) method that builds upon the ligand field molecular mechanics (LFMM) approach and enables modeling of SCO properties in bulk materials, including MOFs. Within LFMM, conventional molecular mechanics (MM) energy expressions are supplemented with an additional term that effectively represents the ligand field stabilization energy (LFSE) arising from the splitting and different occupation of the d orbitals of the metal centers. LFMM thus explicitly includes energy contributions that depend on both the instantaneous coordination geometry and the electronic structure of the metal centers. To enable direct simulations of the SCO properties of MOF materials, we have improved upon the original LFMM approach and combined it with a Monte Carlo scheme based on the Metropolis acceptance/rejection criterion that is used to model the transitions between different spin states. We then extended our hybrid MC/MD scheme to systems with multiple metal centers in periodic boundary conditions. Our MC/MD approach, implemented in a modified version of the publicly-available DL_POLY Classic software, is thus designed to describe generic SCO materials with an arbitrary number of different metal centers, each with its own set of possible spin states. We carried out hybrid MC/MD simulations for the $[\text{Fe}(\text{pz})_2\text{Pt}(\text{CN})_4]$ MOF, which displays bidirectional chemo-switching of spin states upon adsorption of different guest molecules. The magnetization curve of the SCOF material obtained with our hybrid MC/MD correctly reproduces the sharp transition between the low-spin and high-spin states observed experimentally (Inorg. Chem 2014, 53, 11020). To the best of our knowledge, our hybrid MC/MD method is the first approach that enables direct simulation of spin crossover in bulk materials, effectively capturing electronic-driven processes within a physically-based computational scheme.

Interactions, Phase Equilibria and Self-Assembly in Ionic Systems

Institution: Princeton University
Point of Contact: Athanassios Panagiotopoulos
Email: azp@princeton.edu
Principal Investigator: Athanassios Panagiotopoulos
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Work under this project focuses on studies of activity and osmotic coefficients in salt solutions using atomistic models, self-assembly of ionic surfactants, and analysis of structure, thermodynamics and dynamics of ionomer membranes. For calculations of free energies of salt solutions, we use

thermodynamic integration and staged insertions. Atomistic models that can be used in a fully predictive mode offer distinct advantages over previously available phenomenological and implicit-solvent models; their performance at elevated temperatures, which are important for separation and CO₂ geophysical sequestration applications, has not been previously determined. In the area of polymer electrolyte membranes, which are used in fuel cell applications, the main focus is on the effects of water content on the internal structure, dynamics, permeability, and mechanical properties of the membranes. Finally, in the area of ionic surfactant self-assembly, we are investigating the effects of added salt on the cmc, aggregation number, and aggregate morphology, the effects of temperature, the dynamics of surfactant exchange between micelles and free solution and of micelle breakup and reformation, and the relationship between grand canonical Monte Carlo methods for determining critical micellar concentrations and the methods based on extrapolation with respect to total surfactant loading.

FY 2014 HIGHLIGHTS

Two key components of our work on polymer electrolyte membranes were completed in FY 2014 and have appeared as publications in the Journal of Physical Chemistry. In the first paper (vol. 118, pp 8798-8807, 2014), atomistic molecular dynamics simulations were reported over a wide range of water contents and temperatures to obtain a better understanding of the structural and transport aspects of water sorption in a widely used polymer electrolyte, Nafion. In the second paper (vol. 118, pp. 13981-91, 2014), the mechanical stiffness and structure of Nafion were studied in the limit of a low water volume fraction using molecular dynamics simulations. The viscosity was shown to increase by up to 4 orders of magnitude in response to changes in composition representing as little as 2 wt % of system, specifically with respect to changes in the counterion type. In the area of phase behavior of aqueous electrolytes, simulations have been carried out to obtain thermodynamic and transport properties of the binary mixture H₂O + NaCl at temperatures from T = 298 to 473 K [J. Chem. Phys., 141: 234507 (2014)]. Vapor pressures, liquid densities, viscosities, and vapor-liquid interfacial tensions have been obtained as functions of pressure and salt concentration. Several previously proposed fixed-point-charge models that include either Lennard-Jones 12-6 or exponential-6 functional forms to describe non-Coulombic interactions were studied. While none of the model combinations are able to reproduce simultaneously all target properties, optimal model combinations for specific properties were identified.

A Theoretical Investigation of the Structure and Reactivity of the Molecular Constituents of Oil Sand and Oil Shale

Institution: Richmond, University of
Point of Contact: Carol Parish
Email: cparish@richmond.edu
Principal Investigator: Carol Parish
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our work focuses on the theoretical characterization of the gas phase structures, energies and reactivities of the molecular constituents of asphaltenes contained in oil sand and oil shale. Asphaltenes represent an untapped source of hydrocarbon fuel in North America; however, information about the molecular nature of these deposits has only recently become available and very little is known about the reaction pathways, combustion efficiency and reactivity of these species. We are currently

characterizing the combustion and pyrolysis reaction channels available to asphaltene constituents such as thiophene and methyl thiophene. Initially, we are using DFT to perform conformational surface scans of the reaction space for each system. Once viable reaction channels have been identified, these are further characterized using higher level, explicitly correlated methods.

FY 2014 HIGHLIGHTS

We have been pursuing 3 lines of investigation related to our DOE-funded goal of better understanding radical reactions through theoretical investigation. We have focused our efforts on: 1) characterizing the pyrolysis and combustion pathways of small model compounds of asphaltenes; 2) learning to use properly highly correlated, multi-reference methods such as the Spin-Flip (SF), Multi-reference Averaged-Quadratic Coupled Cluster (MR-AQCC) and Mukherjee Multi-reference Coupled Cluster (Mk-MRCC) methods for describing the multi-configurational character, energies and structures of diradicals; 3) Applying these methods to the characterization of unusual radical species and/or reactions.

Spin-Forbidden Chemical Reactions in Catalysis from First-Principles

Institution: Central Michigan University
Point of Contact: Juan Peralta
Email: peral1j@cmich.edu
Principal Investigator: Juan Peralta
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: Research was supported with prior fiscal year funding. (2014)

PROGRAM SCOPE

When multiple spin states cross in the reaction pathway, spin-orbit interaction allows for non-adiabatic hopping between the spin surfaces and hence leads to spin transfer between reactant and products, making possible reactions that otherwise would be spin-forbidden. The goal of the proposed research is to develop computational tools for the first-principles modeling of these type of reactions, with particular emphasis on catalytic reactions with transition metals and heavy elements. We will employ noncollinear spin density functional theory to optimize the local atomic spin magnetization direction and the nuclear coordinates along the reaction path, including spin-orbit interaction. To this end, we will implement algorithms based on a constrained minimization to search for noncollinear spin states that are expected to emerge close to the spin-crossover region, as well as in transition metal clusters present in the reaction as catalysts. Spin-orbit interaction will be fully included in the search of the reaction path using the all-electron Douglas-Kroll-Hess approximation or, optionally, relativistic effective core potentials. The outcome of the proposed research will enhance our understanding of the basic processes involved in chemical reactions, and lead us to apply our methodology to several practical problems. One of particular interest is the study of nanometer-sized transition metal clusters as non-conventional catalysts for hydrocarbons, a topic that has drawn a lot of attention lately due to its implications for energy and in the chemical industry.

New Single-and Multi-Reference Coupled-Cluster Methods for High Accuracy Calculations of Ground and Excited States

Institution: Michigan State University
 Point of Contact: Piotr Piecuch
 Email: piecuch@chemistry.msu.edu
 Principal Investigator: Piotr Piecuch
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
 Funding: \$144,000 (2014)

PROGRAM SCOPE

This research program focuses on new generations of *ab initio* electronic structure methods and computer codes exploiting the single- and multi-reference coupled-cluster (CC) wave function ansätze, which can provide an accurate description of chemical reaction pathways, molecular electronic excitations, challenging cases of electronic near-degeneracies, and properties other than energy. The goal is to design and apply affordable approaches that enable precise modeling of molecular processes and properties relevant to combustion, catalysis, and photochemistry. The emphasis is on development of methods that offer high accuracy, ease of use, and lower computational costs compared to other approaches that aim at similar precision, so that one can study complex molecular problems with dozens or hundreds of atoms, in addition to smaller systems, in a predictive manner. Among the most successful methods developed to date are the completely renormalized (CR) CC and equation-of-motion CC (EOMCC) approaches, the local, low-order-scaling, CC methods for larger polyatomic systems, and the active-space CC/EOMCC approaches. Substantial progress in genuine multi-reference CC theories has been made as well. The CR-CC methods and their open-shell, local, and excited-state generalizations extend the conventional single-reference theories to multi-reference situations created by radicals, biradicals, bond breaking, and two-electron excitations with an ease of a black-box computation. The active-space CC and EOMCC approaches, their electron-attached and ionized extensions, and the genuine multi-reference CC methods enable practical high-accuracy calculations for a wide variety of closed-shell, open-shell, and strongly correlated electronic states. The most promising approaches developed in this program are shared at no cost with the community through the GAMESS package. Some of the best methods discovered in this program are also available in NWChem.

FY 2014 HIGHLIGHTS

We developed and tested the doubly electron-attached and doubly ionized EOMCC theories with full and active-space treatments of high-order 4-particle-2-hole (4p2h) and 4-hole-2-particle (4h2p) excitations, which are applicable to open-shell species with two electrons outside the closed-shell cores, particularly to electronic spectra of biradicals, without invoking more complex steps of genuine multi-reference CC theories. The resulting DEA- and DIP-EOMCC methods with an active-space treatment of 4p2h and 4h2p excitations reproduce the results of the analogous full calculations at the tiny fraction of the computer effort, while allowing one to determine the singlet-triplet and singlet-singlet gaps in biradicals to within fractions of kcal/mol. We also demonstrated that the DEA- and DIP-EOMCC

approaches with up to 4p2h and 4h2p excitations provide results that are almost insensitive to the choice of the underlying molecular orbital basis, which should be contrasted with the analogous methods truncated at 3p1h/3h1p excitations that are less accurate and sensitive to the orbital choice. As a follow-up of our successful FY13 work on structural, electronic, and catalytic properties of gold nanoparticles using CC methods and codes developed by our group, we used our IP-EOMCC approaches correlating valence and semi-core electrons, accounting for scalar relativistic effects, and including up to 3h2p terms to investigate the photoelectron spectrum of the negatively charged gold trimer, providing an accurate assignment of peaks and shoulders in the experimental photoelectron spectrum for the first time. We also computed potential energy surface (PES) cuts of the ground and several singlet and triplet excited states corresponding to the dissociation of water into the OH and H fragments and demonstrated that our black-box, single-reference CR-CC and CR-EOMCC methods produce PESs that are competitive with those obtained with the expert high-level multi-reference CC approaches.

Investigation of Non-Premixed Turbulent Combustion

Institution: Cornell University
Point of Contact: Stephen Pope
Email: s.b.pope@cornell.edu
Principal Investigator: Stephen Pope
Sr. Investigator(s): Perrine Pepiot; Cornell University
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$153,428 (2014)

PROGRAM SCOPE

LES/PDF approaches are now well developed, and can be applied to turbulent combustion problems involving complex flows with strong turbulence-chemistry interactions. However, the computational cost is quite high, thus limiting the approach to simple fuels with relatively small chemical models. The objective of this project is to develop and validate an adaptive chemistry approach for use in LES/particle PDF methods. The adaptive strategy allows for individual particles to evolve according to a reduced set of kinetic equations tailored for their specific compositions, thereby significantly reducing both the time and memory required for a computation with a given kinetic mechanism, and enabling affordable computations with significantly more detailed chemistry descriptions. Rather than performing chemical reduction at runtime to determine the optimal set of equations to use for a given particle, a time consuming task limiting the benefits of the adaptive approach, an *a priori* analysis of the composition space region likely accessed during the turbulent flow simulation is performed using simple Partially Stirred Reactor computations. Our approach relies on an *a priori* partitioning of the composition space into a user-specified number of regions, over which suitable reduced chemical representations and chemical models are identified automatically. A computational particle in the LES/PDF simulation evolves according to, and carries only the variables present in the reduced representation corresponding to the composition space region it belongs to. This region is identified using a low-dimensional binary tree search algorithm, thereby keeping the run-time overhead associated with the adaptive approach to a minimum. The methodology is coupled with RCCE dimension-reduction techniques and ISAT. The final objective of this project is to demonstrate the computational benefits of this approach in a large-scale LES/PDF simulation of a turbulent jet flame with detailed chemistry.

FY 2014 HIGHLIGHTS

In FY 2014, the research has focused on the following two topics: the development and optimization of the methodology to implement adaptive chemistry in particle PDF simulations; and the coupling of the adaptive chemistry framework with a previously developed RCCE-based dimension-reduction methodology. Major accomplishments include an improved Directed Relation Graph with Error Propagation (DRGEP) algorithm that simultaneously eliminates non-important species and reactions, an extension of the DRGEP concept for kinetic analysis and characterization, a rigorous mathematical formalism to partition the composition space into regions with markedly distinct chemical characteristics, and a fully automatic implementation of the proposed adaptive methodology, which will greatly facilitate the integration with any Computational Fluid Dynamics Simulation software. The methodology has been tested in Partially Stirred Reactor (PaSR) configurations burning a non-premixed mixture of propane and air. Results indicate that for a similar overall computational cost, using a set of reduced models adaptively using the proposed strategy increases accuracy by one to two orders of magnitude compared to a conventional non-adaptive approach, that is, using a single reduced chemical model valid over the entire composition space. Preliminary results also show that combining DRGEP and RCCE reduction methodology may decrease the memory requirements by an additional factor of two. The adaptive chemistry methodology and results have been reported in a manuscript to be submitted to Combustion and Flame. In addition, the improved DRGEP methodology has been used in two additional research articles so far.

Exploring the Random Phase Approximation for Materials Chemistry and Physics

Institution: Temple University
Point of Contact: Adrienn Ruzsinszky
Email: aruzsinszky@temple.edu
Principal Investigator: Adrienn Ruzsinszky
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The project addresses the applicability of the many-body random phase approximation (RPA) for materials science. The RPA has the ability to capture effects beyond standard density functional theory (DFT) approximations. The correlation energy of the RPA is long-ranged, thus it captures van der Waals interactions. RPA also has the exact exchange energy as an ingredient, therefore it is suitable for some dissociation problems, barrier heights and adsorption challenges in condensed matter physics. Despite these attractive features, RPA suffers some shortcomings in its correlation part. These deficiencies can be potentially corrected by 'beyond-RPA' approximations, i.e.; nonlocal kernels or energy corrections. These corrections can boost the accuracy of the RPA for several materials problems, like the dissociation of the H^{2+} molecular ion, the structural phase transition of SiO_2 , and possibly the adsorption of CO on the silver surface. The RPA is related to GW, a many-body approximation which targets band gap calculations. The application or implementation of GW is usually not straightforward in materials science; it is applied mostly in a perturbative way (G_0W_0). Even if there are recently attempts for a consistent input for perturbative GW, the broad applicability of these methods is limited. In the project we want to estimate the effect of the input potential for certain solids and molecules, especially targeting strongly-correlated materials. A potential uniform and computationally affordable input is also the aim.

FY 2014 HIGHLIGHTS

In the past year, my research group was focusing on structural phase transitions with RPA. We have produced two papers in this area (PRB). One of them gives an estimation of the RPA on the structural phase transition in Si crystals. The other work targeted the structural phase transition in strongly correlated VO₂. In this case the sub-projects 'structural phase transitions' also have an overlap with another part of the projects; the 'strongly-correlated materials'. Relying on these results we are working on an implementation of a nonlocal uniform-electron-gas based kernel to RPA. This kernel is currently being implemented in the ABINIT electronic structure code. Tests will be performed at first on the cohesive energies of semiconductors, where the RPA shows significant deficiencies from its correlation contribution. The PI published recently a work in JCTC about the systems with anion- π interactions. This work gives a detailed assessment of RPA and related methods for weak interactions in molecules. Parallel to this work, the PI is working on a benchmark test for 'beyond-RPA' methods on reaction test sets from organic chemistry. This work is close to be submitted. The PI is also working to assess different inputs for perturbative GW on transition metal monoxides.

Surface Plasmon Enhanced Chemistry

Institution:	Northwestern University
Point of Contact:	George Schatz
Email:	g-schatz@northwestern.edu
Principal Investigator:	George Schatz
Sr. Investigator(s):	Mark Ratner; Northwestern University
Students:	3 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$380,000 (2014-2015)

PROGRAM SCOPE

This project is concerned with the development of computational methods and new theory that enables one to describe plasmon excitation in metal nanoparticles, and the interaction of plasmon excited states with molecules and semiconductor nanoparticles that are nearby the metal nanoparticles. Plasmon excitation leads to dramatic modification to the optical and chemical properties of molecules or nanoparticles that are located near the surfaces of these particles, in some cases leading to enhancement in chemical reactivity or optical properties such as extinction, absorption, and Raman (SERS). Also of interest are theories of time-resolved processes such as transient absorption, and the evolution of initial electronic excitation into phonons and solvent. The research program seeks to develop new electronic structure theories that can be coupled to continuum theories such as Maxwell's equations to describe the interaction of light with plasmonic metal particles leading to plasmonically enhanced chemistry and enhanced spectroscopic properties. In addition, the methods being developed will be used to model experiments being done by a number of collaborators.

FY 2014 HIGHLIGHTS

A new theory for describing plasmon enhanced optical properties was developed which combined a previously developed DFT approach for calculating the chemical contribution to the enhancement factor with a coupled QM/electrodynamics calculation. This is the most complete theory developed so far for SERS. We also performed further studies of our real-time TDDFT approach to photoinduced electron transfer, and we summarized past work on plasmonically enhanced dye-sensitized solar cells. We collaborated with experimental groups to characterize plasmons for dimers of silver particles that are

separated by less than 1 nm. Also, we characterized plasmons for many rod segments that are pieced together with small gaps, and we studied plasmons in spherical structures that consist of a dielectric core and a shell of small gold nanoparticles that acts as a continuous shell. In theory work, we discovered that the plasmon width for Al is dominated by radiative effects, which is fundamentally different from that for Ag and Au, providing new opportunities for Al. We demonstrated how the optical properties of arrays of particles can be modified by both the nanoscale properties of the particles and the mesoscale properties of the array. And we develop a theory of refraction at metal-metal interfaces. We discovered plasmon enhanced lasers that combine lattice plasmons in combination with laser dyes to enhance stimulated emission. We also performed detailed studies of the transient absorption behavior of semiconducting nanoparticles that has led to new understanding of thermal flow from electronic excitation to phonons to solvent, including for quantum confinement effects.

Enabling Technologies for High-Throughput Screening of Nano-Porous Materials: Collaboration with the Nanoporous Materials Genome Center

Institution: Wisconsin-Madison, University of
Point of Contact: Jordan Schmidt
Email: SCHMIDT@CHEM.WISC.EDU
Principal Investigator: Jordan Schmidt
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: Research was supported with prior fiscal year funding. (2014)

PROGRAM SCOPE

The objective of this research program is to develop and apply the theoretical framework necessary to generate transferable “physically-motivated” classical force fields for complex systems, with an emphasis on nano-porous materials for gas separation applications. The overarching goal is to develop models which include, by construction, the right balance of all of the relevant “physics” of intermolecular interactions, with the physical properties of interest emerging as a natural consequence. We make use of symmetry-adapted perturbation theory calculations, exploiting the resultant energy decomposition to parameterize force fields which enforce the right balance of exchange, electrostatics, polarization, and dispersion, thus generating robust and transferable force fields that yield the right answer, for the right reason. We find that the resulting force fields exhibit tremendous transferability, allowing simulation of essentially arbitrary compositions (mixtures, heterogeneous systems, etc.) without re-parameterization. This transferability is not coincidental, but, within the context of the approach, arises naturally from the universality of the underlying physical laws governing intermolecular interactions. We have applied this basic methodology to a variety of complex systems, but with a particular emphasis on the development of transferable force fields for nano-porous metal-organic framework (MOF) materials. We have extended the approach outlined above to generate physically-motivated force fields for adsorbate-MOF interactions and a comprehensive “library” of functional group and metal parameters that covers a sizable fraction of all known (or potentially synthesizable) MOFs. More recently, emphasizing the generality of this approach, we showed that the methodology can also generate accurate and transferable models for a wide range of systems ranging from gases, to bulk organics, to strongly interacting ionic liquids.

FY 2014 HIGHLIGHTS

A significant output of our work over the past several years is a “library” of accurate and transferable force field parameters for MOFs, which can be utilized to screen MOFs for their gas adsorption and separation properties using computational approaches. Recently, in collaboration with Randy Snurr (Northwestern), we examined the sensitivity of such high-throughput screenings with respect to the quality of the force field, contrasting our force fields with simpler “standard” models (which have not been optimized for MOFs). Interestingly, we find that although quantitative results may differ substantially (by 100%!), the correlation between predictions accurate and “standard” models is strong, thus suggesting that pre-screening with efficient standard force fields is a feasible strategy. Significantly, we also established the generality of our force field development methodology well beyond MOFs. We showed that, by including appropriate three-body dispersion interactions, our “physically motivated” methodology yields accurate results even for bulk liquids even in absence of empirical refinement. We also showed that we can even extend the approach to strongly interacting ionic liquids (ILs). Here, we developed, for the first time, an entirely first-principles based model for the prototypical [BMIM][BF₄] system which yields essentially quantitative accuracy with a wide range of physical properties. Currently, we are working to extend our approach to systems which interact non-perturbatively (e.g. adsorption on MOFs with open metal sites) using variational energy decomposition methods. We are also working to generalize our methodology to account for highly anisotropic interactions (e.g. lone pairs, hydrogen bonding systems), using a simple, and computationally efficient formalism. These advances will further increase the accuracy and transferability of our approach, while largely maintain compatibility with standard simulation packages.

Accurate Excited States via Symmetry Projected Approaches

Institution: Rice University, William Marsh
Point of Contact: Gustavo Scuseria
Email: guscus@rice.edu
Principal Investigator: Gustavo Scuseria
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$138,779 (2014)

PROGRAM SCOPE

While electronically excited states are of primary importance in many energy-related processes, their theoretical description is quite challenging. Accurate ground state methods cannot generally be used to describe excited states because they cannot enforce the condition that the ground and excited states be orthogonal. Our recently developed projected quasiparticle theory (PQT) and the closely related projected Hartree-Fock theory (PHF), however, have particularly simple structures which makes enforcing this orthogonality condition feasible. In this project we have extended PQT and PHF to the study of excited states, even those with the same spatial and spin symmetries as the ground state. We are planning to apply our techniques to important problems as spin-spin interactions in molecular magnets, singlet-triplet splittings, and photon absorption and energy conversion in dendrimers.

FY 2014 HIGHLIGHTS

This is the second year of this grant. During 2014, there were 8 publications acknowledging support to this grant. We are very happy with the progress achieved in this project. Briefly, the most salient bullets

are: (1) The calculation of excited states for the one-dimensional Hubbard model with different quantum numbers (spin, space group) which can be compared to exact results; (2) The calculation of singlet-triplet energy splittings with projected Hartree-Fock on challenging cases; (3) The development of a multi-component symmetry projected approach; and (4) the evaluation of excited states on extremely difficult proof-of-principle systems like C_2 .

Electronic Structure Theories of Singlet Fission and Multiple Exciton Generation

Institution: Northwestern University
Point of Contact: Toru Shiozaki
Email: shiozaki@northwestern.edu
Principal Investigator: Toru Shiozaki
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: Research was supported with prior fiscal year funding. (2014)

PROGRAM SCOPE

The objective of this project is to develop novel multireference electronic structure theory to understand the mechanism of the singlet fission processes in solar energy conversion. Singlet fission is a molecular analogue of multiple exciton generation, in which a single photon is converted to two charge carriers. Since the final state is a two-exciton state, standard time-dependent density functional theories cannot be applied, which warrants theory development. In this project, we develop a new theory based on the so-called active space decomposition ansatz, and obtain mechanistic insights into the processes. This research would help rationally design such materials. In addition, developed programs will be interfaced to an open-source BAGEL package, which is publicly available to end users.

FY 2014 HIGHLIGHTS

We have developed a method, in which large active space wave functions are decomposed into a linear combination of products of fragment active space wave functions. Our method is not only a clever way of performing active space computation of unprecedented size, which is necessary for accurate description of excitonic processes, but also a novel way to map chemical systems to tensor networks that have been developed in condensed matter physics. The extensions of the ASD method to restricted active space (RAS) wave functions were performed in this research. In addition, we have established a methodology with which we construct accurate few-state diabatic model Hamiltonians from our ASD method. The model Hamiltonians are the basis of dynamics simulations using a quantum-master-equation formalism. We have implemented the method into an efficient, parallel program that scales well at least up to 512 CPU cores. The program has been openly distributed in the BAGEL package. The above methods have been applied to singlet fission processes in pentacene and tetracene crystals to derive the diabatic model Hamiltonians. We have demonstrated that the coupling between the initial states and charge-transfer intermediate states are strong (~ 100 meV), and that the direct coupling between the initial and final two-exciton states is less than 1 meV in both cases, supporting a mechanism mediated by the charge-transfer states. We have also validated the use of diabatic states in the mechanistic studies of singlet fission.

Plasmon Enhanced Photovoltaics: Modeling Energy and Charge Transfer in Solar Nanoassemblies

Institution: Baylor University
Point of Contact: Kevin Shuford

Email: Kevin_Shuford@baylor.edu
Principal Investigator: Kevin Shuford
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: Research was supported with prior fiscal year funding. (2014)

PROGRAM SCOPE

The overarching goal of the project is to better understand how energy and charge move through assemblies of nanomaterials such as wide bandgap semiconductors, strongly absorbing dye molecules, and plasmonic nanoparticles. The former two are highly relevant for current photovoltaic devices and the latter are known to have unique optical properties resulting from surface plasmon excitations. We want to determine if the highly tunable plasmon modes supported by the metal particle – and the sizeable electromagnetic fields generated upon exciting them – can be utilized to enhance the chemical and physical processes associated with photovoltaic devices. Energy and charge transfer in multicomponent nanoassemblies are being investigated using a variety of modeling and simulation techniques, including classical electrodynamics, density functional theory, and ab-initio molecular dynamics. We are also developing a hybrid method that describes both the electromagnetic and chemical processes that occur when molecules are in close proximity to metal surfaces.

FY 2014 HIGHLIGHTS

We have demonstrated that plasmonic components can efficiently direct incident electromagnetic energy into thin semiconductor layers. Light absorption in a plasmonic grating nanosurface can be calculated by means of a simple, analytical model based on a transmission line equivalent circuit. We have shown the utility of the circuit theory for understanding how the peaks in the absorption coefficient are related to the resonances of the equivalent transmission model and how this can help in designing more efficient structures. We have also investigated a two-dimensional corrugated plasmonic nanosurface for robust light trapping. The two-dimensional configuration is more efficient than its one-dimensional counterpart in terms of the short circuit photocurrent density. We have extended these studies to treat the interactions between a molecule and a metal nanoparticle. We find that the molecular absorption and emission processes are drastically altered by the presence of a metal nanoparticle and the degree of inter-nanoparticle coupling. The latter is important because plasmon fields become extremely large in nanoparticle junctions. When a molecule is placed within the gap of a strongly coupled nanoparticle dimer, the radiative decay rate is enhanced notably more than the non-radiative channels for the dimer compared to the single nanoparticle. The result is a suppression of quenching in the dimer case until the molecule is in very close proximity to the metal surface (~2 nm); single nanoparticles quench the emission readily for a metal/molecule distance inside of 15 nm.

Quantum Chemistry of Radicals and Reactive Intermediates

Institution: Texas-Austin, University of
Point of Contact: John Stanton
Email: jfstanton@mail.utexas.edu
Principal Investigator: John Stanton
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$183,106 (2014)

PROGRAM SCOPE

My research group works in the area of theoretical chemical physics, especially on the thermodynamic properties, spectra, and reactions of organic radicals and other transient intermediates. In addition, we are active developers of software for both computational electronic structure and what might be termed computational spectroscopy. Our quantum chemistry research follows a number of paths, including first-principles calculations of bond energies and other thermochemical information (as well as development of methodology for such calculations), methods for the simulation and analysis of molecular spectroscopy, especially those relevant to experiments that can be used to glean thermochemical information, and the development of *ab initio* methods needed for the accurate treatment of transient organic molecules.

FY 2014 HIGHLIGHTS

- We have carried out a kinetic analysis of the ozonolysis reaction that will soon be submitted for publication.
- We have implemented a very efficient version of the so-called CCSDTQ and CCSDT(Q) methods.
- We have made a systematic study of basis set effects on the harmonic frequencies and transition mode frequency for transition states.

Variational Transition State Theory

Institution: Minnesota, University of
Point of Contact: Donald Truhlar
Email: truhlar@umn.edu
Principal Investigator: Donald Truhlar
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$143,000 (2014)

PROGRAM SCOPE

This project involves the development of variational transition state theory (VTST) including optimized multidimensional tunneling (OMT) contributions and the application of this theory to gas-phase reactions with a special emphasis on developing reaction rate theory in directions that are important for applications to combustion. The further development of VTST/OMT as a useful tool for combustion kinetics also involves (i) developing and applying new methods of electronic structure calculations for the input potential energy surface, which is typically an implicit surface ("direct dynamics") defined by a level of electronic structure theory, (ii) methods to interface reaction-path and reaction-swath dynamics calculations with electronic structure theory, and (iii) methods to treat vibrational anharmonicity and vibration-rotation coupling. The project also involves the development and implementation of practical techniques and software for applying the theory to various classes of reactions and transition states and applications to specific reactions, with special emphasis on combustion reactions and reactions that provide good test cases for methods needed to study combustion reactions. The direct dynamics approach to gas-phase reactions in this project involves electronic structure calculations of potential energy surfaces and the use of these surfaces to calculate generalized free energies of activation and multidimensional tunneling probabilities. A key emphasis is the interface of electronic structure calculations with dynamics algorithms as achieved in the POLYRATE computer program and its various RATE interfaces to electronic structure packages.

FY 2014 HIGHLIGHTS

We made progress in the several areas, including: (i) the development of a method for adding tunneling to classical trajectory calculations, (ii) the development of a new method for obtaining reactive force fields from electronic structure calculations, (iii) the prediction of experimentally unavailable product branching ratios for biofuel combustion, and (iv) the development of an improved method for Feynman path integral calculations of anharmonic partition functions, free energies, enthalpies, entropies, and heat capacities. Next I single out one of these areas for a more detailed summary: Isobutanol is a prototype biofuel, and sorting out the mechanism of its combustion is an important objective where theoretical modeling can provide information that is unavailable and not easily obtained by experiment. In the work we carried out, the rate constants and branching ratios for the hydrogen abstraction reactions from isobutanol by hydroxyl radical were calculated using multi-path variational transition-state theory with small-curvature tunneling. We used hybrid degeneracy-corrected vibrational perturbation theory to show that it is critical to consider the anharmonicity difference of high-frequency modes between reactants and transition states. We showed that to obtain accurate rate constants, we must apply different scaling factors to the calculated harmonic vibrational frequencies at the reactants and at the transition states. The factors determining the reaction rate constants have been analyzed in detail, including variational effects, tunneling contributions, the effect of multiple reaction paths on transmission coefficients, and anharmonicities of low- and high-frequency vibrational modes. The analysis quantified the uncertainties in the rate calculations. A key result of the work is a prediction for the site dependence of hydrogen abstraction from isobutanol by hydroxyl radical.

Quantum Chemistry via Walks in Determinant Space

Institution:	Cornell University
Point of Contact:	Cyrus Umrigar
Email:	CyrusUmrigar@cornell.edu
Principal Investigator:	Cyrus Umrigar
Sr. Investigator(s):	
Students:	4 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding:	Research was supported with prior fiscal year funding. (2014)

PROGRAM SCOPE

The main purpose of this Collaborative Research Team (CRT) is to improve upon the recently developed initiator full-configuration interaction quantum Monte Carlo (i-FCIQMC) method, with the goal of developing a highly accurate method for treating difficult chemical systems of interest to the DOE. Another goal is to have cross-fertilization of ideas between i-FCIQMC and phaseless Auxiliary Field quantum Monte Carlo (AFQMC), developed by the Zhang-Krakauer group, since both methods employ walks in a space of determinants.

FY 2014 HIGHLIGHTS

We have implemented non-abelian symmetries for the Hubbard model in our recently developed semistochastic quantum Monte Carlo (SQMC). Inclusion of the symmetries greatly reduces the size of the walker population needed and thereby the efficiency of the method. We have demonstrated the efficacy of using projected Hartree-Fock (PHF) wave functions as the trial wave function in constrained path Monte Carlo calculations. The PHF approach gives a hierarchy of wavefunctions of increasing quality -- the more symmetries that are broken and restored in a self-consistent variation-after-

projection approach the higher the quality of the wavefunction. In tests on the 2-D Hubbard model, the PHF wave functions gave highly accurate results (as benchmarked by constraint-release). One of the key advantages of the PHF wave functions is that their computational cost, unlike a multiconfiguration self-consistent field (MCSCF) wave function, scales polynomially with system size. In collaboration with Garnet Chan's group at Princeton, George Booth at Cambridge, and Takeshi Yanai in Japan we have implemented an F12 method to enhance the convergence of energies and other properties to the infinite basis limit.

Theoretical Studies of the Reactions, and the Spectroscopy of Radical Species Relevant to Combustion Reactions and Diagnostics

Institution: Johns Hopkins University
Point of Contact: David Yarkony
Email: yarkony@jhu.edu
Principal Investigator: David Yarkony
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

My research deals with nonadiabatic chemistry a ubiquitous area of chemical physics in which molecular motion transitions radiationlessly between coupled potential energy surfaces thereby interconverting distinct forms of chemical energy. Nonadiabatic processes may be initiated by the absorption of a photon and consequently are relevant to vision, photosynthesis, solar energy storage and combustion relevant processes including nonadiabatic electron detachment and photoionization, and molecular photodissociation, with the later two processes being the focus of our DoE funded research. A principal goal of our research, is to bring state of the art electronic structure methods to bare on nonadiabatic dynamics simulations. Currently the preponderance of nonadiabatic reactive dynamics is carried out using on-the-fly or direct dynamics, in which the electronic structure data is determined as required by a call to the electronic structure program. While easy to implement and use, this approach suffers from two limitations (i) the determination of the electronic structure data is slow so to obtain reasonable turnaround times low-level (low accuracy) electronic structure methods are used, and (ii) the electronic structure data suffers from discontinuities as a result of the requisite changes in the active space as distinct channels are explored. Our fit coupled surfaces approach avoids these issues. It is based on high-level (high accuracy) multireference configuration interaction single and double excitation wave functions and it is least squares based so it has the ability to smooth out the discontinuities in the electronic structure data. Since the electronic structure data is represented by a diabatic Hamiltonian H_d whose blocks are described by polynomial forms, the time to determine the electronic structure data at a single point is on the order of tens of milliseconds, compared to minutes or even hours in direct dynamics. The challenge is to construct H_d .

FY 2014 HIGHLIGHTS

In our DoE funded research we have focused on applications of the fitting algorithm. Our recent construction of an H_d for the multichannel, multistate, nonadiabatic photodissociation of hydroxymethyl, studied experimentally by Reisler (USC), has demonstrated the potential of this approach. A manuscript is being prepared, which describes the representation, in the full nine dimensional internal coordinates, of 3 potential energy surfaces coupled by conical intersections and

producing 3 distinct dissociation channels, $\text{CH}_2\text{O}+\text{H}$, cis- and trans- $\text{HCOH}+\text{H}$. This high quality representation which is based on 67 million configuration state functions (CSFs), and made possible by a grant of computer time from NERSC, is unique in this field. A second paper describing the use of this Hd to simulate the production of the dominant $\text{CH}_2\text{O} +\text{H}$ channel is also being prepared. In this later study a statistically significant simulation is achieved using 10,000 surface hopping trajectories for each laser energy. Using on-the-fly techniques only ~ 100 such trajectories, using much less sophisticated wave functions, would be possible. In a second tour de force calculation we are constructing an Hd to describe the photodissociation of phenol, $\text{C}_6\text{H}_5\text{OH}+\text{h}\nu \rightarrow \text{C}_6\text{H}_5\text{O}+\text{H}$, from its excited S_1 and S_2 states. This work which is nearing completion, uses 4 diabatic states, based on ~ 100 million CSFs, and is performed in the full 33 dimensional internal coordinate space. It too is made possible by a grant of computer time from NERSC. As part of an ongoing study of the spectra of cyclo-alkoxy radicals, which complements the experimental work of Miller(OSU) we have reported a study of the ground state of cyclopentoxy. We have shown that, contrary to all previous calculations, the ground electronic state is correctly described as the component of a two state pseudo Jahn-Teller system.

EARLY CAREER: Accurate *Ab-initio* Methods for Correlated Surface Problems

Institution: Michigan, University of
Point of Contact: Dominika Zgid
Email: zgid@umich.edu
Principal Investigator: Dominika Zgid

Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Transition metal surfaces are widely used in heterogeneous catalysis; however, modeling of catalytic processes on such surfaces remains very challenging due to the difficulty in describing accurately the electronic correlation in the d-orbitals of the transition metals for bulk problems containing thousands of atoms. The objective of this project is to develop new theoretical techniques to address the challenge of correlated surfaces and to properly describe different correlations present between the localized, strongly correlated d-orbitals and the delocalized, weakly correlated s- and p-orbitals in a systematically improvable, ab-initio manner. In this project, methods from both condensed matter physics and quantum chemistry will be employed to build a computationally feasible embedding approach that tackles the size of the problem. This newly developed approach will be used to study the complex interactions between molecule and surface, to model directly measurable experimental quantities such as the photoelectron spectra and to enable a systematic search for new classes of catalytic materials.

FY 2014 HIGHLIGHTS

We have developed three new methods during the first year of support.

1. Iterative GF2 (Green's function second order) scheme (J. Chem. Phys. 140, 241101 (2014))
2. A method for parametrizing model Hamiltonians used in Green's function's method (J. Chem. Phys. 141, 194105 (2014))
3. Self-energy embedding method that is the one of the most efficient schemes for combining GF2 and the self-energy coming from ED method (arXiv:1410.5118, Phys. Rev. B to be published)

The PI has given 8 talks acknowledging DOE support.

Two supported graduate students won poster awards (Yao Li Physical Chemistry Division in Indianapolis, 2013, Alexei Kananenka during Midwestern Meeting of Theoretical Chemistry, Northwestern 2014).

Density Functional Based Software for the X-ray Based Spectra

Institution: Texas-El Paso, University of
Point of Contact: Rajendra Zope
Email: rzope@utep.edu
Principal Investigator: Rajendra Zope
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$99,687 (2014)

PROGRAM SCOPE

The X-ray based core-hole spectroscopy (XPS, XAS (EXAFS and NEXAFS), XES) are important techniques in materials characterization. Through X-ray induced hole creation and decay process, a variety of information about the system such as the chemical state, nature of chemical bonding, local geometric structure etc. can be obtained using these techniques. The project concerns development of a suite of software at various levels of sophistication to perform calculations of core-hole excitation spectra using the first principles methods such as density functional theory. This includes development of robust suite of Perl/Python scripts to perform calculations on core-hole excitations of large systems on computers with large number of processors in parallel. Another software development component is Graphical user interface development for visualization, for setting up the inputs for calculations using pull up and pop-up menus, and for execution and analysis of calculated spectra. The GUI development is aimed at bringing the core-hole calculations to the level of use-friendliness so that it could also be used for classroom teaching of core-hole spectroscopy and molecular physics. Apart from software development, recently developed perturbative delta SCF method for charge transfer excitations will be adapted and further refined for the core-hole excitation. A few other developments such as implementation of simple self-interaction schemes for core-electron binding energies will be implemented and tested.

FY 2014 HIGHLIGHTS

The following developments were carried out: i) The GUI development was extended to allow plotting of generated spectra and molecular orbitals, ii) a number of widely used Gaussian basis sets were included so that users can now specify the name of the basis set, iii) the part of the code which calculates the intensities of transition is parallelized. The parallelization of the code that calculates intensities was tested on a light harvesting β -Carotene-Porphyrin- C_{60} triad, which due to its large size, creates a bottle neck in the serial calculation of joint density of states, as originally only the master node performed required calculation of transition dipoles. This test was at our university's research cloud using 84 processors. We obtained reduction in time from 12,721 to 956 secs. The scaling tests were also performed subsequently and the code was found to scale fairly well up to 300 processors. The GUI allows plotting of calculated spectra. A tutorial screencast of how to use GUI for setting up calculations and post processing the outputs is made available in YouTube. As performance test of the overall development of the code, we have studied the dielectric properties of endohedral fullerenes and carbon onions. The site specific partitioning of polarizabilities indicates that the polarizability of the endohedral fullerene is essentially due to the outer fullerene cage and has insignificant contribution from the encapsulated unit. Thus outer fullerene cages effectively shield the encapsulated clusters and behave like Faraday cages. The application of the site specific polarizabilities to $C_{60}@C_{240}$ and $C_{60}@C_{180}$ onions

shows that the encapsulation of C_{60} in C_{240} and C_{180} fullerenes reduces its polarizability by 75% and 83%, respectively. The differences in the polarizability of C_{60} in two onions are a result of differences in the bonding (intershell electron transfer), fullerene shell relaxations, and intershell separations.

DOE National Laboratories

Chemical Physics - Base Program

Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$485,000 (2014)

PROGRAM SCOPE

The primary focus of the theoretical Chemical Physics program at Ames Laboratory is the development and extensive application of methods that enable the study of condensed-phase and surface reaction phenomena, especially heterogeneous catalysis. The program supports an integrated effort including both electronic structure theory and non-equilibrium statistical mechanical and multiscale modeling. Also of interest are solvent effects, mechanisms of homogeneous catalysis in organometallic chemistry, and excited states in large molecular systems. Electronic structure theory efforts combine development of fundamental theory, expanding the capability for accurate treatment of large systems of interest to U.S. Department of Energy, Basic Energy Sciences, with optimal strategies for computational implementation within GAMESS. Theory development includes fragment molecular orbital and effective fragment potential approaches with applications to liquid-solid interfaces, and embedding methods for solid surfaces. A newer focus is on excited states and non-adiabatic dynamics with applications to photocatalysis. Statistical mechanical and multiscale modeling studies focus on catalytic reaction-diffusion phenomena often incorporating input from electronic structure analyses. A core focus is the predictive molecular-level modeling of chemisorption and heterogeneous catalysis on metal surfaces, including fundamental studies of catalytic poisoning transitions. We also implement heterogeneous multiscale modeling for spatiotemporal behavior on extended surfaces, and analyze fluctuation-mediated behavior in nanoscale catalyst systems. Other major efforts include modeling of the interplay between restricted transport and catalytic reaction in functionalized mesoporous materials, and modeling of reaction processes on non-conducting surfaces. There are extensive collaborations with the Ames Laboratory program "Homogeneous and Interfacial Catalysis in 3D Controlled Environments".

FY 2014 HIGHLIGHTS

We detailed the inhibited molecular passing processes in narrow pores; the passing propensity strongly impacts reaction yield for catalytically functionalized nanoporous materials. We modeled the effects of multifunctionalization of these materials to enhance reaction yield. We developed a general, but realistic and predictive molecular-level stochastic model for CO-oxidation on metal(100) surfaces for Pd, Rh, Pt, and Ir. Density functional theory and Kinetic Monte Carlo simulations led to insight into local-environment dependence of the sticking probability for dissociative adsorption of oxygen on metal(100)

surfaces, noting that this process is a critical step in catalytic oxidation reactions. With the catalysis program, a new mixed oxazoline-carbene borate Zn compound was found to provide isolable monomeric Zn alkylperoxide. We showed that there is a significant distortion of the Zn methyl group from the pseudo tetrahedral position as a result of subtle electronic rather than steric effects. Full, highly accurate potential energy curves were calculated for the 4 lowest lying singlet states of the CEEIS method for electron correlation recovery. Excellent agreement was found with all known vibrational-rotational spectral data and dissociation energies. A quantitative analysis of H^{2+} , H_2 , B_2 , C_2 , N_2 , O_2 , F_2 has shown that the intra-atomic contraction of atomic valence shells occurs because it enhances the inter-atomic delocalization and, thereby, lowers the kinetic energy. This result confirms that covalent bonds are created by the drive of electron waves to lower their kinetic energy by expansion. The dynamics package NEWTON-X and the occupation restricted multiple active space method in GAMESS were interfaced for nonadiabatic and adiabatic on-the-fly dynamics simulations. Single excitations between the orbital subspaces qualitatively recovered the state populations. Orbital integrity issues were shown to be more prevalent than previously thought.

Theoretical and Computational Tools for Modeling of Energy Relevant Catalysis on Multiple Scales

Institution: Ames Laboratory
Point of Contact: Cynthia Jenks
Email: cjenks@ameslab.gov
Principal Investigator: Mark Gordon
Sr. Investigator(s): James Evans; Ames Laboratory
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$122,000 (2014)

PROGRAM SCOPE

This theory and computation program develops new strategies for and integrated combinations of electronic structure analysis and statistical mechanical, coarse-grained, and multi-scale modeling approaches to treat energy-relevant heterogeneous catalytic systems. Currently, there is a lack of effective molecular-level modeling for overall catalytic reaction processes and a critical need to incorporate high-level energetics for predictivity. Essential to these efforts is development of novel new approaches in not only theoretical chemistry and materials science (BES), but also computational science and applied mathematics (ASCR). Applications motivating the work include analysis of catalysis in mesoporous oxides and catalysis on metal and oxide surfaces.

FY 2014 HIGHLIGHTS

We have developed an efficient Kinetic Monte Carlo simulation algorithm for general, realistic molecular-level multi-site stochastic lattice-gas modeling of catalytic CO-oxidation on unreconstructed metal(100) surfaces. In addition, we established analytic theories to describe: (i) multi-stability as well as bistability in CO-oxidation kinetics; (ii) nucleation-mediated CO-poisoning kinetics, i.e., nucleation of "droplets" the CO-poisoned-phase embedded in a metastable reactive phase. We also have developed an analytic statistical mechanical description of the local-environment dependence of the sticking probability for dissociative adsorption of oxygen on metal(100) surfaces. We implemented strongly-damped Langevin dynamics (including rotational diffusion), and also adaptive-mesh finite-element-method analysis of the equivalent Fokker-Planck equations, describing of inhibited molecular passing processes in narrow pores; the associated passing propensity strongly impacts reaction yield for catalytically functionalized nanoporous materials. We have developed the theory for the fully analytic

gradient for density functional theory (DFT) based on the fragment molecular orbital (FMO) method. This is very important for future applications of FMO/DFT to heterogeneous catalysis. Furthermore, we have demonstrated the theory for the combination of nonlinear spectroscopic techniques with the EFP method to study the effects of solvent on nonlinear optics.

Simulating the Generation, Evolution and Fate of Electronic Excitations in Molecular and Nanoscale Materials with First Principles Methods

Funding: \$756,000 (2014)

PROGRAM SCOPE

There are strong existing limitations on calculations of bound excited states in large molecules, and for resonance states in any polyatomic molecule. These limitations partly reflect deficiencies of existing software and algorithms. But more fundamentally they also reflect limitations of existing methods and models, particularly for resonances, or where multiple electrons are excited, or strong electron correlations are in play. The overall goal of this proposal is to make meaningful progress by coupling new and improved models for bound and metastable excited states from physical scientists with advances on underlying methodological challenges in applied mathematics, and practical realization via high performance computing. This will be achieved by developing new and reduced scaling methods for bound excited states in large molecules, and adapting modern electronic structure methods to treat resonance states using a rigorous approach based on complex scaling. Object-oriented tensor libraries will be used to implement these methods, and as a platform for introducing compact decompositions to increase efficiency. Linear algebra developments center on the eigensolvers needed for excited states, and a strong coupling to leadership class computing is built into the work plan.

FY 2014 HIGHLIGHTS

For strongly correlated bound states, the formulation of spin-flipping methods was improved in two significant ways. First, second order perturbative corrections were developed that replace variational evaluation of excitations external to the active space with large speedups. Second, a novel variational spin-flip procedure that uses configuration-specific non-orthogonal orbitals to remove the need for external excitations was developed. For unbound states, the first implementation of the method of complex basis functions into a modern electronic structure program was achieved (for the static exchange model), and demonstrated on polyatomic molecules of up to a dozen atoms. Progress was made in the formulation and implementation of a fully grid-based Hartree-Fock program. To treat the tensors that arise in electronic structure theory, a variety of developments in a tensor library were

completed. These developments increase numerical performance, give demonstrably improved parallel scaling on shared memory architectures, and lay the ground for more effectively using distributed memory massively parallel computing resources. Improvements in solvers for the non-Hermitian complex eigenvalue problem, which is central to treating resonances by the complex basis function method, were also achieved.

Theoretical/Computational Studies of the Fundamentals of One Component and Alloy Based Nanocatalysis Relevant to Alternative Sources of Energy

Institution: Argonne National Laboratory
Point of Contact: Emilio Bunel
Email: ebunel@anl.gov
Principal Investigator: Julius Jellinek
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$169,000 (2014)

PROGRAM SCOPE

This project constitutes a program of theoretical/computational studies that aim at advancing our fundamental understanding of one-component and alloy metal based nanocatalysis relevant to alternative sources of energy. The emphasis is on unraveling and characterizing the separate and combined roles of the structural and electronic features of metal nanocatalysts and the key mechanisms that underlie their activity and selectivity. These are investigated as a function of the catalyst particles size and composition, both elemental and percentile. Among the primary targets are catalysts and reactions for efficient conversion of hydrocarbons into alternative sources of energy. The main computational tools here are those of density functional theory. The work is carried out in close contact with the related experimental work at Argonne and elsewhere. Our emphasis is on fundamental scientific issues, which in addition to those mentioned above also include the important in the context of catalysis aspect of thermal stability and thermally induced structural and phase transformations of alloy nanoparticles. This aspect of the studies involves methodological developments and is carried out using molecular dynamics techniques in combination with semiempirical potentials.

FY 2014 HIGHLIGHTS

We performed detailed computational studies of catalytic reforming reactions of glycerol, $C_3O_3H_8$, and its derivatives, which are relevant to conversion of biomass into liquid fuels and other chemicals. As a prototypical case, we considered the $C_3O_3H_7$ derivative, which is a precursor of hydroxyacetone, $C_3O_2H_6$, identified as the most abundant intermediate in initial stages of glycerol reforming. We obtained and characterized the various possible adsorption conformations of 8 forms of $C_3O_3H_7$ on pure Pt_7 and mixed Pt_5Mo_2 and Pt_3Mo_4 nanocatalysts. The two energetically most preferred adsorption complexes for each nanocatalyst were then used as reactant states, and for each reactant the full minimum energy paths for all possible abstractions of an H atom, an OH group, or an O atom, as appropriate, were mapped out. For each path, the barrier height and the reaction exothermicity were quantified and the reaction mechanism was characterized. We have found that multiple paths can be energetically competitive and that some reactions that involve O-H bond scission in $C_3O_3H_7$ proceed via an accompanying H transfer within the molecule. Analysis of the nanocatalyst composition effects on activity and selectivity revealed that the presence of Mo leads to reduction in barrier heights for the dehydrogenation and dehydroxylation reactions. This reduction is larger for dehydroxylation, and for both reactions the

degree of reduction increases with the Mo concentration. Other aspects of the performed studies include exploration and characterization of the interactions of H₂, both molecular and dissociative, with Pd_n, n=2-4, 7 and 13, nanocatalysts as a function of the catalyst size and the degree of hydrogen coverage up to and including the saturation limit (relevant for direct synthesis of H₂O₂ from H₂ and O₂), and application of a new dynamical descriptor – the time-dependent mixing coefficient - for a refined analysis of temperature-induced structural changes in alloy nanoparticles.

An Expert *Ab Initio* Transition-State-Theory-Based Master Equation Code

Institution: Argonne National Laboratory
Point of Contact: Emilio Bunel
Email: ebunel@anl.gov
Principal Investigator: Stephen Klippenstein
Sr. Investigator(s): Ahren Jasper; Sandia National Laboratories-Livermore
Judit Zador; Sandia National Laboratories-Livermore
James Miller; Argonne National Laboratory
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$147,000 (2014)

PROGRAM SCOPE

The goal of this project is to develop expert codes for accurately predicting the kinetics of gas phase chemical reactions. The *ab initio* transition state theory based master equation (AITSTME) approach provides the basic framework for this effort. The code development effort is designed to facilitate all aspects of the implementation of the AITSTME approach while also increasing its utility through further advances in its theoretical underpinnings. A successful code package will be widely used in the modeling of key reactions in combustion chemistry, atmospheric chemistry, astrophysics, and chemical vapor deposition, for example.

FY 2014 HIGHLIGHTS

Our new general-purpose AITSTME software package, which is termed PAPER (Predictive Automated Phenomenological Elementary Rates), implements a new formulation of the master equation for complex-forming chemical reactions with multiple wells and multiple bimolecular products. The PAPER code, which is now finding widespread use within our team and in external research efforts, incorporates a variety of advances beyond other existing codes, including automated merging of species as their equilibration rates exceed collisional stabilization rates, threaded parallelization of the key diagonalization step, and a procedure for properly modeling the separation into thermal and direct kinetics for hot initial distributions. These advances allow for improved accuracy in the predictions while also greatly reducing the effort involved in making the predictions. In exploratory work, we have developed a method for making accurate *a priori* predictions of the pressure dependence of the kinetics. This work required the solution of a two-dimensional master equation (2DME) in energy E and angular momentum J, as well as accurate calculations of collision induced E and J transfer rates. New methods for characterizing details of the collisional transfer function that are not typically considered (J-dependence, E/J coupling, etc.) were developed and implemented in the molecular dynamics code DiNT, while a new two-dimensional master equation code was developed. In other work, DiNT was further improved with a new method for predicting spin-forbidden kinetics and with options for computing exact classical diffusion coefficients. A particularly useful approximation for estimating Lennard Jones

parameters was interfaced with our universal PESs and incorporated into a stand-alone code called OneDMin.

Next Generation First Principles Molecular Dynamics

Institution: Los Alamos National Laboratory
Point of Contact: David Morris
Email: demorris@lanl.gov
Principal Investigator: Anders Niklasson
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

Molecular dynamics (MD) simulation is one of the most general and widely used methods for obtaining a broad variety of properties in computational chemistry, materials science and molecular biology, such as phase transitions, molecular structures, and chemical reactions. Most MD simulations depend on a parametrization of a simplified classical model of the atomic interaction potential. These simulations are often not very reliable because of limited transferability between the unknown systems of interest and the original set of parameterized structures. First principles MD derived from self-consistent field (SCF) theory such as density functional theory (DFT) offers a more rigorous and reliable alternative. DFT based MD simulations within the Born-Oppenheimer (BO) approximation of uncoupled electronic and nuclear motion is regarded as one of the most reliable standards for atomistic simulations. Unfortunately, first principles BOMD is often limited by some fundamental shortcomings, such as a very high computational cost or unbalanced phase-space trajectories, numerical instabilities and a systematic long-term energy drift. These problems are often either accepted as an unavoidable limitation or simply ignored, for example, by using thermostats that cover up an unphysical underlying dynamics. The overreaching goal of this proposal is to go beyond conventional BOMD and create a framework for a new generation of first principles MD schemes that overcome previous shortcomings and limitations. This will open the door to reliable and highly efficient atomistic simulations of large complex systems that radically extends current capabilities.

FY 2014 HIGHLIGHTS

- 1) "Extended Lagrangian Born-Oppenheimer molecular dynamics in the limit of vanishing self-consistent field optimization", P. Souvatzis and A.M.N. Niklasson, *J. Chem. Phys.* 139, 214102 (2013)
- 2) "First principles molecular dynamics without self-consistent field optimization", P. Souvatzis and A.M.N. Niklasson, *J. Chem. Phys.* 140, 044117 (2014)
- 3) "Generalized extended Lagrangian Born-Oppenheimer molecular dynamics", A.M.N. Niklasson and M.J. Cawkwell, *J. Chem. Phys.* 141, 164123 (2014).

The first two publications presents the first demonstrations of first principles based extended Lagrangian BOMD using a single diagonalization and Hamiltonian construction per time step, yielding trajectories that are practically indistinguishable from "exact" BOMD. The demonstrations of these fast "0-SCF" simulations were performed at the theory level of Hartree-Fock (1) and DFT including hybrid functionals (2). This new capability allows accurate first principles BO MD simulations at a fraction of the cost of regular simulations. The third publication presents a generalized framework for a new generation extended Lagrangian BOMD that allows stable integration in the limit of vanishing SCF optimization for a

broader class of materials. The framework has some remarkable features, apart from a more rigorous derivation. Geometric integration schemes, like the velocity Verlet algorithm, can be understood from a backward analysis. Instead of an approximate integration, a geometric integration allows an exact integration of an underlying approximate shadow dynamics. In the same way, the generalized framework allows an exact integration with exact forces that are calculated in a single step (instead of using multiple SCF iterations) for an underlying approximate shadow Hamiltonian. We have developed the concept of a shadow Hamiltonian also for SCF theory. This approach opens the door to new applications, including fast MD formulations for orbital-free DFT and polarizable force fields.

Discontinuous Methods for Massively Parallel QMD: Li-ion Interface Dynamics from First Principles

Funding: \$361,000 (2014)

Jointly funded by the Chemical Sciences, Geosciences, & Biosciences Division and Materials Sciences and Engineering Division

PROGRAM SCOPE

We develop and employ for the first time new Discontinuous Galerkin (DG) and Pole Expansion/Selected Inversion (PEXSI) electronic structure methods to accomplish quantum molecular dynamics (QMD) on an unprecedented scale; and apply the new methodologies to address fundamental questions in energy storage: the formation and evolution of the solid-electrolyte interphase (SEI) layer in Lithium-ion cells. We employ state-of-the-art massively parallel planewave codes in the initial phase of the work while the new DG and PEXSI methodologies are developed and verified. We then apply the new methodologies to much larger systems, up to 10,000 atoms, in order to reach for the first time sufficient system complexity to effectively model complete liquid-on-anode configurations. The remarkable properties of the new methodology are made possible by releasing the constraint of continuity through the DG formulation of the Kohn-Sham equations. By virtue of these properties, our initial parallel implementation has accomplished *ab initio* calculations with over 4,000 atoms with planewave accuracy. Initial DG QMD simulations show excellent energy conservation, with energy drift < 2 meV/atom/ps. To reach the largest system sizes, we develop and employ the new PEXSI methodology, eliminating the need for diagonalization while retaining strict systematic improvability and applicability to both metals and insulators. In partnership with the SciDAC FASTMath Institute, we have completed MPI parallelization of the PEXSI code, testing on a wide range of systems, documentation, and release (<http://www.pexsi.org>). The resulting code can scale to over 100,000 processors and has now been applied to systems containing over 45,000 atoms. Current work focuses on the combination of DG and PEXSI methodologies to reach the length and time scales necessary to model mixed-phase anode-electrolyte configurations to begin to understand for the first time the chemistry and dynamics at this critical interface.

FY 2014 HIGHLIGHTS

We accomplished all FY14 project milestones and commenced work on FY15 milestones. Four journal articles were published and five more submitted. We carried out an extensive series of QMD simulations of ethylene carbonate (EC), ethyl methyl carbonate (EMC), and EC/EMC mixture solvents with LiPF₆ salt, as widely used in practice. We found that Li prefers tetrahedral coordination in all electrolytes considered, consistent with experiment for EC, and providing a prediction for EMC and EC/EMC mixture. Most significantly, we found a key correlation of solvation and mobility in all electrolytes considered: the stronger the solvation, the less the mobility. This finding has the potential to significantly impact the engineering and improvement of Li-ion battery electrolytes going forward, and with that, battery systems as a whole. Regarding the new Discontinuous Galerkin (DG) computational methodology being developed to reach the needed length and time scales to model full anode-electrolyte systems, we made a number of advances. We implemented independent grids for density and wavefunctions, yielding accurate forces for all atomic species, soft and hard, metals and nonmetals alike. We implemented molecular dynamics, obtaining excellent energy conservation. We implemented MPI parallelization of local Kohn-Sham solves to form DG basis in each element, yielding a 70-fold speedup. Regarding the new Pole Expansion and Selected Inversion (PEXSI) methodology being developed to eliminate the need for diagonalization altogether, we parallelized, tested, documented, and released a full production code (<http://www.pexsi.org>). The new MPI code scales to over 100,000 CPUs. The new PEXSI code has been incorporated into the widely used SIESTA electronic structure code, yielding a factor of 18 speedup. Finally, we implemented the new PEXSI methodology with the DG basis to reach the largest length and time scales needed to model full anode-electrolyte configurations.

PROGRAM SCOPE

We seek a fundamental understanding of important processes such as solvation, transport, and reaction in complex condensed-phase and interfacial environments. This research provides a basis for the development of new and improved energy technologies and the control of environmental impacts of energy use. We have focused on processes in aqueous solutions, interfacial water, ionic liquids, and molecular frameworks. We systematically connect processes in simpler to increasingly more complex systems and advance fundamental understanding of molecular systems through the development of molecular modeling methods. This includes the construction of models of molecular interaction based on empirical forms as well as explicit electronic structure. We combine this development with appropriate statistical and dynamical sampling techniques to elucidate fundamental properties and

behavior of well-characterized systems for benchmarking by experimental measurement. With an established knowledge of fundamental processes, we better understand the ability to control and design processes in more complex systems where complexity is due to heterogeneity in space or time scales.

FY 2014 HIGHLIGHTS

The group has made significant steps towards an improved understanding and characterization of the solvation of ions by developing and combining models of molecular interaction, electronic structure and statistical mechanics. These approaches have been benchmarked by experimental measurement using X-ray absorption, optical vibrational and photoelectron spectroscopies. We have examined the consequences of empirical models on the dynamics of the ion-pairing process. To this end, sound theoretical protocol is used to not only compute rates of ion pairing but also determine the important and measurable excess molar volumes. These studies provide the development of stringent tests for the accuracy of pair potentials to be used in complex processes such as nucleation. We are developing a molecular understanding of the non-linearity that give rise to solvation. Our research will go beyond the phenomenology of the Born model to theoretically account for the explicit short-range response giving rise to free energies of solvation. An exciting consequence of this research is that it will, in general, be model dependent and will take full advantage of our current research on connecting molecular detail to the measured hydration structure using the molecular dynamics – extended X-ray absorption fine structure (MD-EXAFS) approach. We are developing a framework of universal potential energy functions to describe intermolecular interactions from the very weak to the very strong. In addition, we are modeling the electronic states of multivalent metals and their variation with the degree of aqueous solvation. We have combined theoretical and experimental photoelectron spectroscopy characterizations of solvated clusters, confirming the importance of local solvent structure in regulating solute specific effects.

Pressure Dependence of Combustion Reactions: Quantum Inelastic Dynamics on Automatically Generated Potential Energy Surfaces

Institution: Argonne National Laboratory
Point of Contact: Emilio Bunel
Email: ebunel@anl.gov
Principal Investigator: Albert Wagner
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$422,000 (2014)

PROGRAM SCOPE

This project studies the pressure-dependence of combustion reactions, in part by developing and using high quality potential energy surfaces (PES). This project has evolved in two directions. The first is classical molecular dynamics studies of excited molecules in a buffer gas at pressures high enough so that isolated binary collisions are unusual. This requires explicit simulation of both the molecule and the buffer gas. At pressures relevant to advanced internal combustion engines, energy relaxation rates can no longer be directly proportional to pressure and the mechanisms that lead to this are a focus of the study. The second and unexpected direction that arose out of working with high quality potential energy surfaces is the development of second order vibrational perturbation theory (VPT2) to derive tunneling probabilities. I have modified semiclassical tunneling methods that use VPT2 results, thereby enabling their calculation of deep tunneling. Such methods may offer a fast alternative to reaction path following

tunneling methods because VPT2 calculations are readily parallelized but most methods to characterize reaction paths are sequential in character. This project involves collaborations with others in BES in PES development and use and with the Thompson group (U. Missouri) in molecular dynamics studies.

FY 2014 HIGHLIGHTS

1. An energy relaxation study of excited CH_3NO_2 in an Ar bath gas by classical molecular dynamics techniques was carried out over a pressure range of 10 to 400 atm. At all pressures a Lendvay-Schatz fit accurately represented the relaxation rate in terms of an initial rate k_i and an "m" parameter describing the curvature on a semi-log plot of energy versus time. k_i is not directly proportional to pressure for pressures beyond ~ 100 atm. A combinatorial model was developed to account at higher pressures for the molecule undergoing multiple simultaneous Ar collisions and this model could be adjusted to fit the k_i pressure dependence. That fit suggested that N multiple collisions are not as efficient as N single collisions, resulting in a changing pressure dependence. A paper describing this has just been published in FY15.
2. An improved semiclassical tunneling theory based on second order vibrational perturbation theory was published at the beginning of FY14 and tested on multiple potentials of HOCO in a second paper in FY14. The tests show good comparisons with tunneling probabilities from reaction path following methods and, with the best of four potential energy surfaces, good comparisons with experiment.

Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$136,000 (2014)

PROGRAM SCOPE

Transition metal ion-molecular complexes are studied in the gas phase to investigate the fundamental interactions in catalysis, metal-ligand bonding and metal ion solvation. Cation-molecular complexes of the form $M_x^{n+}(L)_y$, where M= transition metals (Fe, Co, Ni, Cu, etc.) in singly or multiply charged states, and L= small molecules such as CO, CO₂, O₂, H₂O or benzene, are produced in a molecular beam by pulsed laser vaporization of solid metal targets. Complexes containing a specific number of metal atoms and ligands are cooled by a supersonic expansion, size-selected in a reflectron time-of-flight mass spectrometer, and studied with infrared laser photodissociation spectroscopy. The resulting vibrational spectra reveal the shifts that occur for ligand/adsorbate vibrations upon binding to metal, how this varies with the number of ligands, the geometric and electronic structures of complexes, the number of ligand/solvent molecules in the full coordination sphere around the metal, and the possible occurrence of ligand reactions mediated by the metal center. New experiments employ photofragment imaging technology to further investigate low frequency vibrations and metal-molecular bond energies. The experimental work is elucidated and complemented by density functional theory computations. The increased understanding of fundamental metal interactions impacts diverse areas such as heterogeneous and homogeneous catalysis, solar energy generation, hydrogen storage, CO₂ sequestration, and nuclear waste management.

FY 2014 HIGHLIGHTS

Ongoing experiments have employed infrared laser photodissociation methods to measure infrared spectroscopy of metal ion-water and metal ion-benzene complexes. Computational chemistry was employed to predict structures, electronic states and vibrational spectra for these systems. In a major new direction, a modified mass spectrometer system was constructed and implemented for photofragment imaging of the decomposition products resulting when metal ion complexes dissociate. The new instrument produces cold ions, selects them by mass, and dissociates them on electronic or vibrational resonances. Velocity map imaging and slice imaging methods provide high resolution images, yielding new and improved thermochemistry for a variety of metal ion-molecule complexes.

Confinement, Interfaces, and Ions: Dynamics and Interactions in Water, Proton Transfer, and Room Temperature Ionic Liquid Systems

Institution: Stanford University
Point of Contact: Michael Fayer

Email: fayer@stanford.edu
Principal Investigator: Michael Fayer
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$270,000 (2014)

PROGRAM SCOPE

A variety of topics are being addressed that have a common theme, that is, the relationship between dynamics, structure, and interactions in systems that are structurally heterogeneous on mesoscopic distance scales. The studies are addressing a variety of chemical and materials systems. Room temperature ionic liquids (RTIL) are organized into ionic and organic regions. Water is found in nanoconfined materials such as polyelectrolyte fuel cell membranes, which have nanoscopic channels that contain water and conduct protons, liquids in porous SiO₂ and porous SiO₂ particles functionalized with a heterogeneous photocatalyst, water in reverse micelles, and proton transfer in nanoconfined systems, particularly fuel cell membranes and reverse micelles. Porous SiO₂ functionalized with a homogeneous catalyst to form a heterogeneous catalyst have dynamics dictated by the proximity of the surface and interactions with nanoconfined solvents. RTILs, which are becoming important in batteries and other applications, segregate into ionic and organic regions on nanometer length scales. Water occurs in many nanoconfined systems, where its properties differ greatly from bulk water. Mesoscopically structured systems are being studied with ultrafast 2D IR vibrational echo methods. 2D IR is akin to 2D NMR but it operates on times scales that are ten orders of magnitude faster than NMR. 2D IR experiments make it possible to observe dynamics of complex molecular systems on the time scales of the fundamentally important events. IR polarization selective pump-probe experiments are being used to measure molecular orientational relaxation and vibrational lifetimes, which provide a detailed view of the relationships between structure and dynamics. Optical heterodyne detected optical Kerr effect experiments and fast fluorescence experiments are also important techniques being used in the study dynamics and structure in the mesoscopically structured systems.

FY 2014 HIGHLIGHTS

Ultrafast 2D IR vibrational echo experiments have been applied to the study of room temperature ionic liquids to understand the dynamics and nature of water and small alcohols, i. e., methanol and ethanol solutes, in the RTILs. IR pump-probe experiments were also used to measure orientational relaxation. The dynamics observed with 2D IR slow only slightly as the solute gets larger although the orientational relaxation time slows a good deal as the solute size increases. In addition, 2D IR experiments have been used to study the dynamical interactions of dihydrogen bonded ions with water. In particular, borohydride dihydrogen bonded to water was examined both from the perspective of water bound to borohydride using the dihydrogen bonded hydroxyl stretch as the vibrational probe, and from the system “inside” the anion using the B-H stretch of borohydride as the probe. In addition, IR pump-probe orientational relaxation measurements were made on this system. The remarkable results show that the hydrogen bond dynamics in concentrated NaBH₄ systems are virtually identical to those of pure water, in contrast to other concentrated salt solution. It is proposed that the limited affect of borohydride on water dynamics occurs because borohydride provides a tetrahedral hydrogen bonding arrangement. Proton transport in water, ionic and non-ionic reverse micelles, and several fuel cell polyelectrolyte membranes were investigated. Proton transport is studied by measuring the fast fluorescence from a photoacid placed in each type of system. A new theory that properly extracts the proton transfer dynamics from the time dependent fluorescence spectroscopy of the protonated and

deprotonated emission band of the photoacid was developed. Proton transfer in the nanoconfined water in ionic and neutral reverse micelles are fundamentally different. Differences in proton transfer in fuel cell membranes made by different companies are also beginning to be observed.

EARLY CAREER: Probing Chromophore Energetics and Couplings for Singlet Fission in Solar Cell Applications

Institution: Wisconsin-Madison, University of
Point of Contact: Etienne Garand
Email: egarand@chem.wisc.edu
Principal Investigator: Etienne Garand
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$141,000 (2014)

PROGRAM SCOPE

The goal of this project is to provide a molecular-level understanding of processes that can improve efficiencies of alternative sources of energy, such as dye-sensitized solar cells. In particular, the mechanisms and molecular requirements for efficient exciton multiplication through singlet fission are explored using high-resolution anion photoelectron (PE) spectroscopy. The experiments are capable of observing directly the singlet, triplet, and charge transfer states involved in singlet fission and determining precisely their energetics, vibrational structures and couplings. More specific aims are (1) to probe the evolution of the electronic structure as a function of cluster size in order to understand singlet fission in crystals, (2) to explore the relationship between the nature of linkers and the electronic structure in covalently-bonded chromophore dimers, and (3) to highlight the differences, including exciton delocalization and the effects of solvent interactions, between the crystalline species and the isolated covalently-bonded dimers. The electronic states of organic chromophore clusters and covalently-bonded dimers will be probed via high-resolution photoelectron spectroscopy (SEVI) of mass-selected radical anion precursors. Specifically, starting with the radical anion with a doublet ground state, all the low-lying singlet and triplet states of the neutral molecule that involve removal of a single electron can be accessed in the one-photon experiment. Therefore, with the exception of the doubly excited state, all the electronic states relevant to singlet fission will be accessible. Using anions also provide the added advantage of mass selection, which is crucial for studying the behavior of singlet fission as a function of cluster size.

FY 2014 HIGHLIGHTS

Since the beginning of this program in July 2013, we have started to design and build the cryogenic SEVI setup. Currently, the electrospray source, the ion guides, the main quadrupole ion trap, and the time-of-flight mass spectrometer has been built, and the assembly process is almost complete. At the same time, simulations and designing of the VMI stage is being carried out to achieve optimal signal-to-noise ratio and energy resolution. Conventional VMI setup has two main issues that are amplified when the method is applied to low energy electrons. Namely, spherical aberration causes electrons with different kinetic energies to have different focal points, and electrons ejected from VMI electrodes can cause significant background noise in the image. The latter becomes particularly overwhelming when the photon energy exceeds the work function of the electrode, which is often a necessity when probing excited electronic states. A new multiple-electrode VMI is being designed that should simultaneously alleviate both problems, giving the SEVI apparatus a wider applicability. We also began investigating the

formation of the polyacene radical anion directly from electrospray ionization using a separate already operational cryogenic ion vibrational spectrometer. Two different approaches are being tested. In one method, a strong reducing agent is added to the polyacene solution, where a faint color change can be observed indicating the polyacene has been reduced. Electrospray of the reduced solution has yielded radical anion signals, however source conditions need to be optimized for signal stability. The other method utilizes electrochemistry to controllably reduce the polyacene species, many of which has known redox potentials.

PROGRAM SCOPE

This SISGR program utilizes recently developed instrumentation including integrated ultra-high vacuum tip-enhanced Raman spectroscopy/scanning tunneling microscopy (UHV-TERS/STM) and surface-enhanced femtosecond stimulated Raman scattering (SE-FSRS) to advance the spatial and temporal resolution of chemical imaging for the study of photoinduced dynamics of molecules on plasmonically active surfaces. For example, UHV-TERS/STM at liquid helium temperatures achieves unprecedentedly high spectral resolution, which allows the conformation of adsorbates to be deduced with respect to surface features such as atomic step edges. The UHV environment also minimizes adsorbate degradation at high laser intensities, thus enabling TERS to be performed with ultrafast excitation. A wide range of materials and adsorbates are being studied including chemically functionalized graphene, two-dimensional silicon, and organic donor-acceptor molecular heterostructures. An accompanying theory program includes modeling of charge and energy transfer processes using constrained density functional theory, thereby providing a detailed description of excited state dynamics. Overall, this SISGR program directly addresses the DOE BESAC Grand Challenges by realizing fundamental advances such as: (a) Characterization of chemical reactions with unprecedented spatial and temporal resolution; (b) Improved understanding of optical interactions with nanoscale materials; (c) Development of new optically active materials; (d) Establishment of a powerful platform for studying photochemistry on atomically engineered surfaces. Technologically, these fundamental developments impact efforts to extract useful energy from solar radiation including: (a) Photovoltaic devices; (b) Artificial photosynthesis; (c) Photocatalytic materials.

FY 2014 HIGHLIGHTS

Over the past year, significant experimental and theoretical progress has been made on multiple topics including ultrafast UHV-TERS/STM and chemically modified graphene and silicon on plasmonic substrates:

- (1) Ultrafast UHV-TERS/STM: The SISGR team reported the first UHV-TERS data with liquid helium cooling of the sample, from which the adsorbate-substrate interactions of the rhodamine

6G/Ag(111) system were quantified. In particular, the spectra exhibited significant line narrowing up to the instrument-limited response along with new vibrational characteristics of rhodamine 6G that were identified through theoretical analysis. Temporally resolved TERS was also advanced by incorporating picosecond pulses into the UHV-STM for pulsed-excitation UHV-TERS. UHV-TERS spectra of rhodamine 6G on Ag(111) were gathered using picosecond irradiation and, importantly, these experimental results show that the UHV environment mitigates signal decay.

- (2) Chemically Modified Graphene and Silicon on Plasmonic Substrates: The SISGR team achieved the first growth of graphene on Ag(111). Since traditional chemical vapor deposition techniques that are typically utilized for graphene growth do not work on Ag substrates, an alternative method was developed based on direct deposition of elemental carbon. In an effort to diversify the range of surface chemistries on plasmonically active substrates, the SISGR team also completed an extensive study that follows the evolution of silicon deposition on Ag(111) from multiple surface alloy phases to the precipitation of two-dimensional sheets of crystalline silicon. This silicon growth method is compatible with graphene growth on silver, which facilitates the synthesis of both lateral and vertical graphene-silicon heterostructures. These substrates allow direct interrogation of the interaction of adsorbates with two contrasting surfaces: highly reactive silicon and relatively inert graphene.

Spectroscopic Imaging of Molecular Functions at Surfaces

Institution: California-Irvine, University of
Point of Contact: Wilson Ho

Principal Investigator: Wilson Ho
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$501,000 (2014-2016)

PROGRAM SCOPE

The functions of a molecule depend on its composition, structure, and environment. The composition is determined by identifying the atoms in the molecule. The arrangement of the atoms gives its structure. The changes that the molecule undergoes are in response to its environment, such as temperature, light, charge, and other chemical species. The proposed research seeks an understanding of molecular functions by relating them to the composition, structure, and environment with low temperature scanning tunneling microscopes (STM). Recent advances with the STM in real-space imaging of molecular structure by resolving each atom and bond in a molecule, combined with electronic and vibrational spectroscopies and manipulation, provide renewed opportunities to understand molecular functions at the single molecule level. The relationships between structure and bonding are central for understanding chemistry in the proposed study. The proposed research focuses on four key problems in chemistry: 1. the nature of hydrogen bonding, 2. the mechanisms of tautomerism, 3. molecular responses to environmental changes, and 4. the nature of the chemical bond and interactions. In addition to obtaining fundamental understanding and control of interfacial chemistry, knowledge gained from these experiments provide the scientific basis for technologies, such as heterogeneous catalysis, organic solar cells, environmental remediation, water management, alternative energy, and green chemistry.

FY 2014 HIGHLIGHTS

A new and generally applicable technique based on the scanning tunneling microscope (STM) explains the origin of the ball-and-stick representation of molecules and relates structure to function. Images of chemical bonds by the inelastic tunneling probe (itProbe) reveal molecular structure and multi-centered hydrogen bonding. A tip terminated with a single carbon monoxide (CO) molecule was scanned over a single cobalt-phthalocyanine (CoPc) molecule adsorbed on Ag(110) surface at 600 mK while monitoring the hindered translational vibration of the CO by inelastic electron tunneling spectroscopy (IETS). The variations in the vibrational intensity in the scan provide the contrast in the CoPc skeletal structure due to the CO molecule sensing the repulsive potential of CoPc. The energy, intensity, and line shape of the CO vibration are sensitive to the skeletal structure in the molecule [cobalt phthalocyanine (CoPc): 57 atoms, 68 bonds, and 4 lone pairs] and its surrounding. The CO vibration senses the skeletal structure differently than elsewhere, and is detected by STM-IETS at 600 mK. The itProbe is expected to be generally applicable to other molecules. In addition to providing an understanding of the scientific basis for the ball-and-stick model, itProbe is used to obtain new insights into intramolecular and extramolecular hydrogen bonding. Specifically, hydrogen atoms can be shared among a larger number of centers to form three-center two-hydrogen intramolecular hydrogen bonds within a CoPc molecule, five-center four-hydrogen intermolecular hydrogen bonds between two CoPc molecules, and three-center one-hydrogen bonds with the substrate. The structural images reveal intra- and extramolecular multicenter bonds involving hydrogen. Direct visualization of the bifurcated hydrogen bonding provides an understanding into the relation of structure and function in self-assembly, biological molecules, and chemistry.

Theory of the Reaction Dynamics of Small Molecules on Metal Surfaces

PROGRAM SCOPE

Our objective is to develop realistic theoretical models for molecule-metal interactions important in catalysis and other surface processes. Recent efforts have focused on the dissociative chemisorption of methane on metal surfaces, the rate-limiting step in the chief industrial process for production of H₂. Initial studies of methane dissociation on Ni(111) and Ni(100) used DFT to compute barrier heights and explore the potential energy surface for this reaction, with an emphasis on how it changes due to lattice motion. We found that when the Ni atom over which the molecule dissociates vibrates in and out of the plane of the surface, the barrier to dissociation changes. Quantum scattering calculations showed that this leads to a strong increase in reactivity with temperature. Subsequent studies on Pt(111), Pt(100) and Pt(110)-(1x2) found similar behavior. We have developed sudden models that accurately add the effects of thermal lattice motion to static-lattice calculations. We have explored the dynamics of methane dissociation using a formulation based on the Reaction Path Hamiltonian. We first locate the reaction (minimum energy) path for dissociation, and perform a normal mode analysis at several points along this path. This generates a full-dimensional description that includes all 15 degrees of freedom of the methane. Time-dependent quantum dynamics based on this Hamiltonian were used to examine

methane dissociation on Ni(100), Ni(111), and the highly-corrugated Pt(110)-(1x2). Agreement with experiment was good with respect to the magnitude of the reactivity and its variation with translational energy and the vibrational state of the methane. More importantly, the ability to examine the flow of energy between the various molecular and lattice degrees of freedom during the reaction has allowed us to learn much about the reaction dynamics, and mode-selective chemistry in particular.

FY 2014 HIGHLIGHTS

We explored the dissociative adsorption of methane on Ni(100) and Ni(111) using a classical form of the Reaction Path Hamiltonian. This allowed us to test approximations used in our quantum model, and to examine the limitations of classical methods. Our quantum perturbative assumption was shown to be highly accurate, and we found that the large amount of zero point vibrational energy in the molecule led to errors in the reaction probability for ground state molecules at low translational energies. Working with the Kroes group (Leiden) we used *ab initio* molecular dynamics to study methane dissociation on Pt(111) and Ni(111). In this classical approach forces are computed “on the fly”, via DFT. The surfaces were modeled with large dynamical slabs, and energies and temperatures were chosen to avoid errors due to the use of classical mechanics. As part of a 4-way interaction, experiments were performed at these same energies and temperatures by the Utz (Tufts) and Beck (EPFL) groups. One goal was to test the accuracy of different density functionals and van der Waals treatments, and develop more accurate functionals. Another was to better understand the dynamics of these reactions. We found that our sudden treatment of molecular translation parallel to the surface was very reasonable, but that the rotational dynamics were closer to sudden than adiabatic. Using what we learned in these studies, we significantly improved the treatment of molecular rotation in our quantum model, and significantly expanded our vibrational basis set. In a new and more detailed study of methane chemisorption on Ni(111) we found excellent agreement with some new data from the Utz lab, and were able to explain why the temperature dependence of the reaction differed so dramatically above and below an energy threshold. Most recently we have begun to examine mode-specific and bond-selective chemistry in the reactions of CHD₃ and CH₂D₂ on Ni(111).

Probing Catalytic Activity in Defect Sites in Transition Metal Oxides and Sulfides Using Cluster Models: A Combined Experimental and Theoretical Approach

Institution: Indiana University
Point of Contact: Caroline Jarrold
Email: cjarrold@indiana.edu
Principal Investigator: Caroline Jarrold
Sr. Investigator(s): Krishnan Raghavachari; Indiana University
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

Our research program combines experimental and computational methods to study well-defined cluster models of heterogeneous catalytic materials. The focus has been transition metal oxide and sulfide clusters in non-traditional oxidation states (surface defect models) and their chemical and physical interactions with water, with the goal of modelling and understanding the role of various processes involved in H₂ production from photocatalytic decomposition of water using Group 6 (Mo and W) oxides and sulfides. The experiments and calculations are designed to probe fundamental, cluster-substrate molecular-scale interactions that are governed by charge state, peculiar oxidation states, and unique

physical structures. The general strategy of our studies is as follows: (1) Determine how the molecular and electronic structures of transition metal suboxide and subsulfide clusters evolve as a function of oxidation state by reconciling anion photoelectron spectra of the bare clusters with high-level DFT calculations. Anions are of particular interest because of the propensity of metal oxide and sulfides to accumulate electrons in applied systems. (2) Measure and analyze the kinetics of cluster reactions with water. (3) Dissect possible reaction mechanisms computationally to determine whether catalytically relevant interactions are involved. (4) Verify the computational studies by anion photoelectron spectroscopic investigation of observed reactive intermediates. (5) Probe the effect of local electronic excitation on bare clusters and cluster complexes, to evaluate photocatalytic processes. The overarching goal of this project is to identify particular defect structures that balance structural stability with electronic activity, both of which are necessary for a site to be simultaneously robust and catalytically active, and to find trends and patterns in activity that can lead to improvement of existing systems, or the discovery of new systems.

FY 2014 HIGHLIGHTS

We have a series of successful computational and experimental studies on tungsten and molybdenum oxides and sulfides, along with their interactions with water, that have led to six publications in fiscal year 2014, with several additional manuscripts in preparation. We have completed a series of experimental reactivity studies and computational studies on mechanisms and energies for the $M_xO_y + H_2O$ ($M = Mo, W; x = 2, 3; y < 3x$) reactions from which we have probed the interplay between electrostatic interactions, oxygen vacancies, M-O bond energies, and subtle differences in barrier heights on cluster-water interactions. Of note is the importance of strong dipole-dipole interactions, which are more important than charge-dipole interactions in initiating water decomposition. From past studies, proton mobility featured prominently in the decomposition mechanism. We have subsequently completed several cluster-alcohol reactivity studies to evaluate this finding. Metal sulfide clusters proffer different mechanisms for water decomposition with H_2 production relative to their oxide analogs. Specifically, dithiol complexes can lead to H_2 evolution. Additionally, calculations mixed metal sulfide clusters predict higher chemical activity toward water decomposition. Finally, we have initiated temperature-dependence studies on cluster-water reactions, and have measured size- and composition-dependent anti-Arrhenius behavior that can be correlated with low-barrier interactions between the clusters and water, along with entropic factors.

Critical Evaluation of Theoretical Models for Aqueous Chemistry and CO_2 Activation in the Temperature-Controlled Cluster

Institution: Yale University
Point of Contact: Mark Johnson
Email: mark.johnson@yale.edu
Principal Investigator: Mark Johnson
Sr. Investigator(s): Gary Weddle; Fairfield University
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$120,000 (2014)

PROGRAM SCOPE

Our program exploits strongly coupled experimental (Johnson at Yale) and theoretical (Jordan at Pittsburgh) studies of size-selected clusters as a medium with which to unravel molecular level pictures of key transient species in condensed phase and interfacial chemistry that are relevant to radiation

damaged systems as well as to catalytic activation of carbon dioxide for conversion into transportable fuels. Much of this work involves trapping labile free radicals created using negatively charged, gas phase molecular clusters as powerful reducing agents. On the experimental side, this is carried out using custom built apparatus, under DOE support, of cryogenic ion trapping methods interfaced with ambient ionization sources that allow direct access to species with very low vapor pressure and that indeed sometimes only exist when surrounded by solvent. Our current focus is on the elementary processes underlying the elementary steps by which proton-coupled electron transfer through water networks mediates electron capture onto secondary molecular electron scavengers. Part of this effort necessarily involves understanding the speciation of an excess proton in restricted hydration environments. Our approach is to unravel how an excess proton reports on the nature of its local environment through its vibrational signature in the infrared region of the spectrum. Here the coupling between theory and experiment has been crucial and effective, as these signatures are often quite complex, requiring the introduction of new theoretical methods to explain their quantum mechanical origins. An emerging direction for our work involves understanding the molecular-level interactions between components in room temperature ionic liquids (ILs), as these media are increasingly used for “green chemistry” and as solvents for carrying electrochemical conversion of carbon dioxide.

FY 2014 HIGHLIGHTS

The major advance in this fiscal year has been a breakthrough regarding the identification of the spectral signature of an excess proton trapped in a three-dimensional, cage-like water cluster. Although the nature proton accommodation by smaller water networks ($n < 11$) is now well established from our work a decade ago, the extension of those measurements to sufficiently large clusters to accurately mimic bulk behavior has proven to be remarkably difficult. It was therefore a major advance in the spring of 2014, when we succeeded in obtaining a D_2 predissociation spectrum of the $n=21$ “magic number” cluster, and analyzing the structural implications of it with anharmonic calculations of the vibrational spectra predicted for various possible cluster geometries. The first paper describing these results was published in *Science* in 2014, and was highlighted in *Chemistry World* (<http://www.rsc.org/chemistryworld/2014/05/water-cluster-structure-proton-acid>) and *Yale News* (<http://news.yale.edu/2014/06/05/case-closed-where-missing-proton-goes>). We immediately followed this paper with a second Communication in the *Journal of Chemical Physics* where we minimized the extent of the structural distortion introduced by the relatively strongly bound D_2 molecule in the first measurement by replacing it with an extremely weakly bound helium atom. A third paper was also submitted to *Proceedings of the National Academy of Sciences* reporting the identification of the cage structure type by assigning particular features in the OH stretching region to specific hydrogen bonding sites in the network. A second major advance in this fiscal year has been our definitive study quantifying the role of hydrogen bonding in ionic liquids based on the commonly used imidazolium cation.

Critical Evaluation of Theoretical Models for Aqueous Chemistry and CO_2 Activation in the Temperature-Controlled Cluster Regime

Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$115,000 (2014)

PROGRAM SCOPE

Our program exploits strongly coupled experimental (Johnson at Yale) and theoretical (Jordan at Pittsburgh) studies of size-selected clusters as a medium with which to unravel molecular level pictures of key transient species in condensed phase and interfacial chemistry that are relevant to radiation damaged systems as well as to catalytic activation of carbon dioxide for conversion into transportable fuels. Much of this work involves trapping labile free radicals created using negatively charged, gas phase molecular clusters as powerful reducing agents. On the experimental side, this is carried out using custom built apparatus, under DOE support, of cryogenic ion trapping methods interfaced with ambient ionization sources that allow direct access to species with very low vapor pressure and that indeed sometimes only exist when surrounded by solvent. Our current focus is on the elementary processes underlying the elementary steps by which proton-coupled electron transfer through water networks mediates electron capture onto secondary molecular electron scavengers. Part of this effort necessarily involves understanding the speciation of an excess proton in restricted hydration environments. Our approach is to unravel how an excess proton reports on the nature of its local environment through its vibrational signature in the infrared region of the spectrum. Here the coupling between theory and experiment has been crucial and effective, as these signatures are often quite complex, requiring the introduction of new theoretical methods to explain their quantum mechanical origins. An emerging direction for our work involves understanding the molecular-level interactions between components in room temperature ionic liquids (ILs), as these media are increasingly used for “green chemistry” and as solvents for carrying electrochemical conversion of carbon dioxide.

FY 2014 HIGHLIGHTS

Much of our early effort has been directed at understanding how the shape of the water network controls the excess electron binding properties. During the present grant period, we have completed a long-standing goal of experimentally isolating the spectral contributions of water molecules in individual network sites to the broad vibrational envelope, and established bounds on the barriers separating the different isomers by measuring the energy dependences of their photochemical interconversions. Midway through this period, we began expanding the scope of our work beyond water to explore the excess electron-driven proton transfer event at the heart of free radical formation in radiation-induced DNA damage. Most recently, we exploited the methodologies we have developed over several years of DOE support to initiate a series of studies aimed at understanding the molecular level processes underlying reductive CO₂ activation in the development of solar fuels. After a brief review of these advances, we outline exciting opportunities both in the basic science of aqueous chemistry and in molecular level aspects of CO₂ activation in ionic liquids.

Probing Ultrafast Electron (De)localization Dynamics in Mixed Valence Complexes Using Femtosecond X-ray Spectroscopy

Institution: Washington, University of
Point of Contact: Munira Khalil
Email: mkhalil@uw.edu
Principal Investigator: Munira Khalil
Sr. Investigator(s): Niranjan Govind; Pacific Northwest National Laboratory
Robert Schoenlein; Lawrence Berkeley National Laboratory
Shaul Mukamel; California-Irvine, University of
Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$700,000 (2014)

PROGRAM SCOPE

The goal of this recently funded project (started on 9/1/2014) is to directly measure photoinduced electron delocalization/localization dynamics on a sub-50 fs timescale at the atomistic level in a series of solvated transition metal mixed valence complexes. The experiments will utilize the femtosecond X-ray pulses at LCLS (XPP/SXR instruments) to perform femtosecond X-ray absorption, emission and resonant inelastic X-ray scattering (RIXS) spectroscopies following photoexcitation of the sample. This study will aim to understand valence electron motion following metal-to-metal charge transfer (MMCT) excitation in mixed valence complexes. In the chosen complexes, the communication between the two metal atoms is varied by changing the identity and oxidation state of the metal atom and varying the ligand shell surrounding the metal atom. The chosen complexes provide a rich molecular playground to study the effects of electronic coupling, delocalization and electron-nuclear coupling between two transition metals connected with a cyanide bridge. The ultrafast X-ray experiments will be performed by the Khalil and Schoenlein group members and will allow for an unprecedented view of the motion of the valence electrons between the metal centers and subsequent electronic and structural relaxation following MMCT. The success of the experiments will depend on the ability to interpret the core-level spectra of the photo-excited states of electron-rich transition metal molecular systems in solution. The experiments will be combined with theoretical X-ray spectroscopic and ultrafast electronic dynamics simulations performed by the Govind and Mukamel group members. The results will provide a molecular-level understanding of “the extent of electron delocalization” during a photoinduced chemical reaction, which remains a fundamental question in the field of mixed valence chemistry and crucial to designing mixed valency in supramolecular complexes and in molecular electronics.

FY 2014 HIGHLIGHTS

The project was started on September 1, 2014. Given the start date, there are no significant accomplishments to report in the fiscal year 2014.

Single-Molecule Interfacial Electron Transfer

Institution: Bowling Green State University
Point of Contact: H. Peter Lu
Email: hplu@bgsu.edu
Principal Investigator: H. Peter Lu
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$338,000 (2014)

PROGRAM SCOPE

Our research at the Photochemical Sciences Center and Department of Chemistry, Bowling Green State University, is focused on the use of single-molecule high spatial and temporal resolved techniques to study molecular dynamics in condensed phase and at interfaces, especially, the complex reaction dynamics associated with electron and energy transfer rate processes. The complexity and inhomogeneity of the interfacial ET dynamics often present a major challenge for a molecular level comprehension of the intrinsically complex systems, which calls for both higher spatial and temporal resolutions at ultimate single-molecule and single-particle sensitivities. Combined single-molecule spectroscopy and electrochemical atomic force microscopy approaches are unique for heterogeneous and complex interfacial electron transfer systems because the static and dynamic inhomogeneities can

be identified and characterized by studying one molecule at a specific nanoscale surface site at a time. The goal of our project is to integrate and apply these spectroscopic imaging and topographic scanning techniques to measure the energy flow and electron flow between molecules and substrate surfaces as a function of surface site geometry and molecular structure. We have been primarily focusing on studying interfacial electron transfer under ambient condition and electrolyte solution involving both single crystal and colloidal TiO₂ and related substrates. The resulting molecular level understanding of the fundamental interfacial electron transfer processes will be important for developing efficient light harvesting systems and broadly applicable to problems in fundamental chemistry and physics.

FY 2014 HIGHLIGHTS

We have made significant advancement on deciphering the underlying mechanism of the complex and inhomogeneous interfacial electron transfer dynamics in dye-sensitized TiO₂ nanoparticle systems that strongly involves with and regulated by molecule-surface interactions. We have studied interfacial electron transfer on TiO₂ nanoparticle surfaces by using ultrafast single-molecule spectroscopy and electrochemical AFM metal tip scanning microscopy, focusing on understanding the interfacial electron transfer dynamics at specific nanoscale electron transfer sites with high-spatially and temporally resolved topographic-and-spectroscopic characterization at individual molecule basis, characterizing single-molecule rate processes, reaction driving force, and molecule-substrate electronic coupling. One of the most significant characteristics of our new approach is that we are able to interrogate the complex interfacial electron transfer dynamics by actively pin-point energetic manipulation of the surface interaction and electronic couplings, beyond the conventional excitation and observation.

Dynamics Studies of Photo- and Electron-Induced Reactions on Nanostructured Surfaces

Institution: Columbia University
Point of Contact: Richard Osgood
Email: osgood@columbia.edu
Principal Investigator: Richard Osgood
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$369,000 (2014-2016)

PROGRAM SCOPE

Photoexcitation has been of continuing interest for its importance in several methods of solar-energy conversion, in photocatalytic destruction of environmental pollutants, and in a variety of applications of nanotechnology. The goal of our current research project is to examine the photon-, electron- and hole-initiated reaction mechanisms, half-collision dynamics, and other nonequilibrium dynamics effects, occurring with excitation of adsorbates on well-characterized metal-oxide and nanocrystal surfaces. We have developed new synthesis methods for uncapped titanium oxide nanocrystals on an inert substrate with specific crystallographic orientation and controlled size distribution in a UHV STM instrument. These nanocrystals are used to evaluate nano-size effects in TiO₂ photochemistry through comparison with photochemistry on single-crystal surfaces. We use an *in situ* monochromated UV lamp to initiate photoreactions on studied surfaces or the tunneling current from the tip of our STM to excite adsorbate molecules at specific surface sites. The resulting chemistry and surface dynamics is investigated via comparison of atomic-resolution STM images of the surfaces before and after the application of excitations as well as via analysis of thermal desorption products. Additional research tools are time-of-

flight detection, standard UHV probes, XPS, and molecular computational tools, some of which are available to us through collaboration with BNL.

FY 2014 HIGHLIGHTS

Understanding the behavior of photo-generated electrical charges at the interface of the semiconductor is crucial for renewable solar-energy technologies such as photocatalysis and photovoltaics. We have explored the charge-induced phenomena on TiO₂ on a single-molecule scale using Scanning Tunneling Microscopy (STM) and temperature-programmed desorption (TPD) as a primary research tools. We have studied both single-crystal rutile(110) surface and arrays of TiO₂ nanocrystals prepared *in situ* on an Au(111) surface. Photo-induced desorption of tri-methyl acetic acid (TMAA) molecules adsorbed on TiO₂ surfaces has been selected as a model photocatalytic reaction. By using monochromated light from an Hg-Xe lamp to drive the photoreaction we demonstrated a strong dependence of the reaction rates on both the wavelength of the incident light and the state of the surface. Specifically, we have found that TMAA photodesorption rates from as-prepared rutile(110) surface for 300 nm UV light are almost 3 orders of magnitude higher than for 365 nm, in spite of the fact that photon energies for both wavelengths are well within the bandgap of titania. The difference in the photo-yields is partially explained by the different absorption depths for these two wavelengths but also by the fact that the reduced rutile(110) has a surface charge barrier that prevents the photo-generated holes with insufficient energies to interact with the adsorbed TMAA molecules. The existence of such charge barrier was demonstrated through measurements of changes in TMAA photo-desorption efficiency resulting from TiO₂ surface treatment with H₂O and O₂ prior to TMAA adsorption. Another important experimental finding was the demonstration of photocatalytic activity of Au(111)-supported TiO₂ nanocrystals for TMAA photo-desorption. The calculated efficiency of the photoreaction driven by 300 nm UV light on TiO₂ nanocrystals was comparable to that on single-crystal rutile(110) surface.

Studies of Surface Adsorbate Electronic Structure and Femtochemistry at the Fundamental Length and Time Scales

Institution:	Pittsburgh, University of
Point of Contact:	Hrvoje Petek

Funding:	\$259,000 (2014)

PROGRAM SCOPE

Our research focuses on the electronic structure and dynamics of solids, surfaces, and molecule-covered surfaces. We are interested in the surface electronic excitation and the subsequent dynamics leading to charge transfer or photochemistry. The correct description of surface electronic structure, photoexcitation, interfacial charge transfer, energy and momentum relaxation of carriers, and femtochemistry are essential for the intellectual framework for applications of photoinduced phenomena at interfaces, such as the photovoltaic and photocatalytic solar energy conversion. The research is conducted on two main themes. We are investigating the electronic structure of molecules on surfaces using low-temperature STM and electronic structure theory. In particular, we are interested in the superatom states of hollow molecules such as fullerenes and aromatic molecules. The superatom

states are interesting because they form nearly free electron bands holding the promise of metal-like charge transport in molecular systems. Furthermore, we are studying the interaction of metal-organic chains and CO₂ molecules. The capture and chemisorption of CO₂ molecules will enable molecule resolved studies of CO₂ reduction by tunneling electrons and photo excitation. The other topic concerns the fundamental electron dynamics in solid state materials and surfaces. To this end, we are studying multiphoton photoemission processes on noble metal surfaces in order to understand their phase and energy relaxation processes, as well as correlated electron, hole, phonon, etc. dynamics. Time resolved photoemission studies are extended to alkali atom and CO₂ modified noble metal surfaces with the goal of understanding their electronic structure, photo excitation processes and femtochemistry.

FY 2014 HIGHLIGHTS

We have discovered evidence for transient excitonic states in metals by multi-dimensional multi-photon photoemission spectroscopy. Such states have been predicted theoretically, but due to their short (sub-femtosecond) lifetimes, they have not been observed. In the case of Ag(111) surface, we discovered that the excitonic state formed by promotion of electron from the Shockley surface state lives for >10 fs due to inefficient screening of the Coulomb interaction. We furthermore studied the multiphoton photoemission processes on Au and Cu surfaces. In the case of these noble metals, we find evidence of photoemission, which is driven by local fields associated with the d- to sp-band transitions. In other research, we studied the electronic level alignment of the LUMO state of C₆F₆ molecule on several Cu and Au surfaces. We developed a simple theory that predicts the unoccupied state alignment based on the properties of the isolated molecule, the surface, and their main mode of interaction. The LUMO of C₆F₆ is a superatom state, which hybridizes into a nearly free electron band in molecule aggregates. We studied other superatom systems by electronic structure theory to explore the possibility of electron transport through nonnuclear media. Finally, we have described the self-catalyzed capture of CO₂ molecules by metal-organic chains on Au surfaces. Chains formed by phenylene-diisocyanide and Au atoms respond to the presence of CO₂ molecules by undergoing nanometer scale motion. Multiple chains coalesce around CO₂ molecules to capture them in single molecule wide ranks. The chemisorption of CO₂ molecules seeds the condensation of other CO₂ molecules in single molecule thick islands up to full monolayer coverage. Such condensation allows us to image CO₂ molecules by STM in the chemisorbed and physisorbed states. This system, therefore, provides a platform for studying CO₂ reduction at the single molecule scale.

EARLY CAREER: Ultrafast Electron Transport Across Nanogaps in Nanowire Circuits

Institution:	California-Irvine, University of
Point of Contact:	Eric Potma
Email:	epotma@uci.edu
Principal Investigator:	Eric Potma
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$150,000 (2014)

PROGRAM SCOPE

In this Program we aim for a closer look at electron transfer through single molecules. To achieve this, we use ultrafast laser pulses to time stamp an electron tunneling event in a molecule that is connected between two metallic electrodes, while reading out the electron current. A key aspect of this project is the use of metallic substrates with plasmonic activity to efficiently manipulate the tunneling probability.

In the first phase of this program we developed highly sensitive tools for the ultrafast optical manipulation of tethered molecules through the evanescent surface field of plasmonic substrates. In the second phase of the program, we used these tools for exercising control over the electron tunneling probability. We have shown that electron currents across engineered nanogaps can be generated with plasmonic excitations, both in the tunneling regime and in the field emission regime.

FY 2014 HIGHLIGHTS

The highlights acquired during the period under review are as follows:

1. We have provided a firm experimental demonstration of light-controlled electron current across nanometer-sized junctions. We have shown that light-induced electron tunneling can be accomplished in nm-sized junctions in a controllable fashion. Importantly, the electron currents are stable and reproducible at ambient temperatures and pressures.
2. We have elucidated the mechanism of photo-induced electron currents across nm junctions. Electron tunneling typically occurs only in sub-nm junctions. For much larger junctions, the mechanism of field emission is prevalent. In nm-sized junctions, however, an intermediate regime exists where a transition from tunneling to field emission can be observed. We have characterized the mechanism of electron transport in this regime, and found that electron transfer is mediated both by direct tunneling through field-induced barrier lowering as well as by field emission.

A Single-Molecule Approach for Understanding and Utilizing Surface and Subsurface Absorption to Control Chemical Reactivity and Selectivity

Institution: Tufts University
Point of Contact: Charles Sykes
Email: charles.sykes@tufts.edu
Principal Investigator: Charles Sykes
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$668,170 (2014-2016)

PROGRAM SCOPE

Heterogeneously catalyzed reactions are among the most scientifically intriguing and technologically important chemical conversions and play a major role in the energy, petrochemical, pharmaceutical and food industries. While the reaction pathways themselves are often highly complex, basic steps can frequently dictate important parameters like activity and selectivity. Rational design of the next generation of effective catalysts requires detailed knowledge of the molecular-level phenomena that control activity and selectivity. However, the atomic-scale structure of the active sites in industrial catalysts is hard, if not impossible, to characterize by conventional methods. We have adopted an approach using high-resolution scanning tunneling microscopy coupled with temperature programmed reaction measurements and surface spectroscopies to interrogate this chemistry. These methods offer the opportunity to study the atomic-scale composition and structure of active sites and relate this information to their ability to activate, spillover and react industrially relevant small molecules. We use these guiding principles to examine catalytic metal alloys from a new perspective and discover new processes. Specifically, we are interested in how the reactivity of a catalytically active metal is altered when it is atomically dispersed in a more inert host metal and how important reaction steps can be further tuned as a function of ensemble size, from the single atom up. Such an approach offers a means

to temper and control the reactivity of very active elements and provides fundamental design rules for cost-effective catalysts that utilize very small amounts of the precious metal.

FY 2014 HIGHLIGHTS

Co-Cu nanoparticles have recently been explored for Fischer-Tropsch synthesis (FTS) as a way to combine the long chain selectivity of Co with Cu's activity for alcohol formation in order to synthesize oxygenated transportation fuels. Depending on particle size, hydrogen dissociation can be a rate determining step in cobalt-catalyzed FTS. To understand the fundamentals of uptake and release of hydrogen from the Co/Cu bimetallic system, we prepared well-defined Co nanoparticles on Cu(111). By exploring H₂ uptake on a model catalytic system composed on Co nanoparticles deposited on Cu(111), we were able to characterize the spillover of H atoms from energetically preferred Co sites to a Cu support at catalytically relevant surface coverages of H. We show that this spillover to Cu, as well as the formation of a high-density H-(1x1) phase on Co, is facilitated by Co-Cu interface sites and that desorption from these sites occurs at a temperature that is lower than either the Cu or Co surfaces alone. Given this new low temperature pathway for H₂ uptake and release from Co-Cu interfaces, these results have ramifications for Co FTS catalysts, as it was recently demonstrated that H₂ dissociation is an important step in the rate of FTS on small Co nanoparticles. Additionally, H spillover from Co (where carbon monoxide prefers to adsorb) could limit the interface between H and CO during FTS, which could pose kinetic limitations on their reaction. This effect could be even more pronounced for the bimetallic Co-Cu catalysts currently being explored for FTS, given that segregation of the two metals has been observed in multiple systems and that CO dissociation is known to occur only on Co sites, whereas our data indicate facile spillover of H atoms to Cu sites.

Solvation Dynamics in Nanoconfined and Interfacial Liquids

Institution: Kansas, University of
Point of Contact: Ward Thompson
Email: wthompson@ku.edu
Principal Investigator: Ward Thompson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$99,997 (2014)

PROGRAM SCOPE

There is significant interest in nanostructured materials that can confine liquids in nanoscale pores. This is due to both the appearance of new fundamental phenomena in these systems and their wide range of potential applications, including catalysis, sensing, separations, electrochemistry, and optical materials. However, the design principles are still lacking for the development of such mesoporous (2 nm < diameter < 50 nm) materials for practical applications that take advantage of their large surface area-to-volume ratio and their high degree of tunability through pore size, shape, roughness, and chemical functionality. At the same time, this gap points to the need to improve our fundamental understanding of how complex liquid dynamics can arise from nanoscale confinement and vary strongly with the confining environment properties. In this work we are addressing some of the outstanding questions regarding nanoconfined liquid dynamics and the implications for chemical reactions by using solvation dynamics as a basis. Solvation dynamics is closely related to the reaction coordinate for charge transfer reactions such as electron or proton transfer reactions and is often dramatically affected by nanoconfinement. We are examining three key issues: 1) Solvation dynamics at silica interfaces, 2)

Origins of non-Gaussian statistics, and 3) Reorientational and hydrogen-bond dynamics of bulk and confined liquids.

FY 2014 HIGHLIGHTS

In the past year, we have used theory and simulation to advance understanding of nanoconfined liquid and hydrogen-bonding dynamics. We have worked to extend our understanding of solvation dynamics at liquid/oxide interfaces, using silica surfaces as the model. We have completed replica exchange molecular dynamics simulations of the dye molecule C153 dissolved in ethanol confined within 2.4 nm silica pores. Both ground- and excited-state C153 were simulated in hydrophilic and hydrophobic pores. Our results demonstrate that the C153 position distribution depends on its charge distribution. Moreover, the positions are determined by a subtle mixture of effects including hydrogen-bonding (H-bonding), solvent layering, and entropy. These results have implications for numerous applications as chemical processes involving charge distribution changes are ubiquitous. In collaboration with Damien Laage (Ecole Normale Supérieure, Paris), we have continued our examination of bulk and confined H-bonding liquids. First, we showed that the observed non-exponential decay for confined water reorientation that arises from individual H-bond acceptors on the pore surface each having their own timescale for exchange of H-bonding partners. The timescale for each acceptor is determined primarily by two entropic effects associated with the restrictions imposed by the pore surface on the H-bonding network. Second, we have examined the diffusion of water in nanoscale silica pores, focusing on the anisotropy and mechanism of diffusion and the role of surface heterogeneity. Third, we have simulated the linear and nonlinear infrared spectra of nanoconfined water to elucidate the information contained in different possible approaches for probing the water structure and dynamics. Fourth, we continued our work on the OH reorientation in alcohols. We have investigated how the arrangement of the same total steric bulk affects OH reorientation by looking at the four isomers of butanol.

EARLY CAREER: Imaging Interfacial Electric Fields on Ultrafast Timescales

Institution: Massachusetts Institute of Technology
Point of Contact: William Tisdale
Email: tisdale@mit.edu
Principal Investigator: William Tisdale
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$411,000 (2014)

PROGRAM SCOPE

The objective of this research is to explore a novel methodology for visualization of ultrafast electronic processes at interfaces. The method, which is based on optical stimulation, builds upon previous success using spontaneous surface nonlinear optical probes to track the temporal evolution of interfacial electric fields resulting from charge separation across an interface. A goal is to speed signal acquisition by up to seven orders of magnitude so that laser scanning ultrafast microscopy becomes feasible. The ultimate aim is to generate movies of interfacial electronic phenomena occurring on femtosecond timescales and submicron length scales, thereby informing our understanding of disorder, heterogeneity, and morphology, and how these factors affect ensemble behavior in photovoltaic, electrochemical, and optoelectronic systems.

FY 2014 HIGHLIGHTS

In the first year of funding for this project, we successfully completed proof-of-principle demonstrations of stimulated second harmonic generation, achieving signal enhancement factors greater than 10,000. A manuscript detailing these achievements has been submitted for review, and technical improvements are under development. Additionally, we made notable progress in the synthesis of semiconductor nanocrystals, achieving unprecedented monodispersity in ensembles of PbS colloidal quantum dots (Weidman *et al.*, ACS Nano 2014), which are used in solar cells, photodetectors, and infrared imaging. Finally, supplemental funding from the CPIMS program was used to purchase a new state-of-the-art ultrafast laser system, which was installed in December, 2014. This new instrument will enable high repetition rate, multi-color pump-probe experiments with sub-20 fs time resolution.

Structural Dynamics in Complex Liquids Studied with Multidimensional Vibrational Spectroscopy

Institution: Chicago, University of
Point of Contact: Andrei Tokmakoff
Email: tokmakoff@uchicago.edu
Principal Investigator: Andrei Tokmakoff
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$271,000 (2014)

PROGRAM SCOPE

The physical properties of water and aqueous solutions are linked to the development of new sustainable energy sources. Energy conversion, storage, and transduction processes, particularly those that occur in biology and soft matter, use water for storing and moving charge. Water's physical and chemical properties depend on the ability of water molecules to participate in up to four hydrogen bonds, and the rapid fluctuations and ultrafast energy dissipation of its hydrogen-bonded networks. Our goal is a fundamental description of the properties of water at a molecular level, and how it participates in proton transport in aqueous media. Our work over the past year can be divided into four areas: (1) the generation of short pulses of broadband infrared light (BBIR) and use in two-dimensional spectroscopy (2DIR); (2) the investigation of intra- and intermolecular coupling in the vibrational relaxation process in H₂O; and (3) the study of aqueous hydroxide and strong acids to describe the interaction of the ion and water and explore the dynamics of proton transfer in water; and (4) the coupled motion of water and its hydrogen-bonding solutes. All of the experimental studies of water and aqueous solutions that we have completed in the past year have been enabled by our development of a new ultrafast infrared light source for unprecedented access to the study of dynamical intermolecular interactions. Our newest spectrometer, built since moving to the University of Chicago last year, uses a laser plasma source to generate coherent pulses of broadband infrared light shorter than 70 fs and have a spectrum spanning the entire mid-IR, from 3800 cm⁻¹ to <1000 cm⁻¹. This source is integrated as a probe pulse in ultrafast pump-probe and 2DIR experiments. Our development of this spectrometer continues and future plans involve amplification of this source to use for excitation and detection in 2DIR experiments.

FY 2014 HIGHLIGHTS

The large bandwidth of our BBIR probe pulse has helped us study the broad absorption features in neat H₂O. The most striking feature we observed in the broadband 2DIR and transient absorption spectra of

H₂O is the broad excited state absorption between the $v=1$ and $v=2$ states of the OH stretch, which is over 1000 cm⁻¹ broad and relaxes with a 275 fs time constant. Ongoing work is aimed at theoretically modeling the collective vibrational dynamics of H₂O. Focusing on our long-term objective to characterize the structure and transport of excess protons in water, we have performed BB 2DIR spectroscopy of aqueous strong acids. Like hydroxide solutions, excess protons in water give rise to a continuum absorption in the mid-IR that is largely featureless and spans over 2000 cm⁻¹. 2DIR spectroscopy reveals that the entire continuum responds immediately upon exciting OH stretching vibrations and continuum relaxation occurs on sub-100 fs timescales. Our ongoing work is aimed at studying spectral regions associated with Eigen complexes, improving vibrational assignments to features within the continuum, and using excitation and probing throughout the IR to follow the ultrafast exchange of proton structures. Finally, to understand the 2D IR spectroscopic signatures of a model hydrogen-bonding interaction, we performed BB 2DIR experiments to watch the correlated vibrational motion of the hydrogen bond donor and acceptor. We used dimers of N-methylacetamide, in which the N-H group donates a hydrogen bond to the C=O group of another molecule. We identified a series of crosspeaks that arise solely from the intermolecular interaction, and demonstrated that the N-H C=O and C-N bonds on both partners move synchronously as a result of the hydrogen bond. These results are being extended to water-solute systems, where the water forms a hydrogen bond with the solute.

The Role of Electronic Excitations on Chemical Reaction Dynamics at Metal, Semiconductor, and Nanoparticle Surfaces

Institution: Yale University
Point of Contact: John Tully
Email: john.tully@yale.edu
Principal Investigator: John Tully
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Achieving enhanced control of the rates and molecular pathways of chemical reactions at the surfaces of metals, semiconductors and nanoparticles will have impact in many fields of science and engineering, including heterogeneous catalysis, photocatalysis, materials processing, corrosion, solar energy conversion and nanoscience. However, our current atomic-level understanding of chemical reactions at surfaces is incomplete and flawed. Conventional theories of chemical dynamics are based on the Born-Oppenheimer separation of electronic and nuclear motion. Even when describing dynamics at metal surfaces where it has long been recognized that the Born-Oppenheimer approximation is not valid, the conventional approach is still used, perhaps patched up by introducing friction to account for electron-hole pair excitations or curve crossings to account for electron transfer. There is growing experimental evidence that this is not adequate. We are examining the influence of electronic transitions on chemical reaction dynamics at metal and semiconductor surfaces. Our program includes the development of new theoretical and computational methods for nonadiabatic dynamics at surfaces, as well as the application of these methods to specific chemical systems of experimental attention. Our objective is not only to advance our ability to simulate experiments quantitatively, but also to construct the theoretical framework for understanding the underlying factors that govern molecular motion at surfaces and to aid in the conception of new experiments that most directly probe the critical issues.

FY 2014 HIGHLIGHTS

Two major highlights emerged from our laboratory in Fiscal Year 2014. First, we have completed a thorough testing of our Independent Electron Surface Hopping theory on NO scattering from Au(111) in which the N–O stretching coordinate is treated by quantum mechanics. This is the first attempt of which we are aware to combine quantum mechanical electronic and vibrational transitions on an equal footing by surface hopping. The calculations are computationally feasible, and the classical and quantum results for state-to-state vibrational excitation of scattering of NO ($v=0$) are in surprisingly good accord with each other and with experiment. Second, we have developed a theoretical model that convincingly explains some remarkable recent measurements by Guo and Yan (Yale University) of the thermal rate of isomerization of the 11-cis retinyl chromophore in the visual pigment rhodopsin: at temperatures between 52.0 and 64.6°C, the measured rate constants fit well to an Arrhenius straight line with, however, an unexpectedly large activation energy of 114 ± 8 kcal/mol and an unprecedentedly large prefactor of 1072 ± 5 s⁻¹, about 45 orders of magnitude larger than any previously reported prefactor for a unimolecular reaction! A key factor of the model is the lowering of the reaction barrier when the protein is melted compared to when the chromophore is more constrained in the rigid folded state. If the initial state is ordered and the transition state is partially or completely melted, there will be huge increases in both the enthalpy and entropy of activation, as observed. This behavior may well prove to be quite general, not only in biological reactions, but also in condensed phase and surface reactions carried out at temperatures and pressures close to 2D or 3D phase transitions. (Collaborative: Experiments by Ying and Guo, theory by Tully).

Room Temperature Single-Molecule Detection and Imaging by Stimulated Raman Scattering Microscopy

Institution: Harvard University
Point of Contact: Xiaoliang Xie
Email: xie@chemistry.harvard.edu
Principal Investigator: Xiaoliang Xie
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The objective of this proposal is to achieve Raman-based single-molecule detection using near-resonant stimulated Raman scattering (SRS) microscopy. SRS microscopy was a new optical technique that was developed in our lab a few years ago for imaging heterogeneous samples based on their intrinsic vibrational contrasts, which provides much higher molecular specificity than absorption and fluorescence. It has improved the imaging speed over traditional confocal Raman imaging by a few orders of magnitude. However, the sensitivity limit of SRS microscopy is still confined to the millimolar range, similar to confocal Raman. We propose to capitalize on our state-of-the-art SRS microscopy and develop near-resonance enhanced SRS for sensitivity enhancement with the ultimate goal of achieving single molecule detection.

FY 2014 HIGHLIGHTS

In the last funding period, we have achieved a SRS detection sensitivity limit of 100nM for beta-carotene, a factor of ten away from single molecule detection. This is done through the use of near-resonant SRS by pumping at 532nm. The bottleneck of further improvement in sensitivity is

photodamage: the beta-carotene molecule is destroyed before enough photons can be collected. To overcome this problem, we designed a new molecule based on the principle of triplet state quenching that is recently employed to improve the photostability of fluorophores. We have successfully synthesized a beta-carotene molecule covalently conjugated to a triplet state quencher molecule cyclooctatetraene. However, compared with beta-carotene, the synthesized molecule does not show improved photostability when excited with 532nm and 578nm picosecond lasers. We are still investigating the possible origin of photodamage and developing alternative routes to stabilize the carotenoid molecule under near-resonant excitation. A major development that results from this process is our development of frequency-modulation SRS imaging technique. Although SRS imaging has a major advantage compared to CARS in that it automatically removes non-resonant background, it is still susceptible to cross-phase modulation (XPM) induced background when the SRS signal is extremely weak. XPM-induced background is mostly independent of the pump and probe wavelengths, and therefore can be removed by subtracting on-resonance and off-resonance SRS signal. We termed this technique frequency-modulation SRS. Based on a previously demonstrated femtosecond spectral focusing SRS technique, we have successfully demonstrated frequency-modulation SRS by rapidly switching the time delay between the pump and probe pulses at 20 MHz. Because in spectral focusing SRS, the probed Raman frequency depends linear on the time delay, XPM-induced background is effectively removed in real-time by up to 10 fold.

DOE National Laboratories

Molecular Environmental Sciences (MES) Beamline

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Musahid Ahmed
Sr. Investigator(s): David Shuh; Lawrence Berkeley National Laboratory
Hendrik Bluhm; Lawrence Berkeley National Laboratory
Mary Gilles; Lawrence Berkeley National Laboratory
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$873,000 (2014)

PROGRAM SCOPE

The LBNL Chemical Sciences Division (CSD) Molecular Environmental Sciences (MES) Beamline at the Advanced Light Source (ALS) is a leading national resource in the field of soft X-ray synchrotron radiation research. It supports multidisciplinary, state-of-the-art spatially-resolved, molecular-level spectroscopic investigations of the chemistry and physics at complex interfaces under increasingly real environments by utilizing revolutionary new, best-in class experimental resources for staff and users. The MES Beamline and staff carry out and make possible unique, forefront molecular-level research in catalysis, nanoscience, contemporary surface science, f-element chemistry, aerosol science, environmental science, and atomic, molecular, and optical science that contribute knowledge necessary for the U.S. DOE to successfully address its energy mission. The MES program develops and implements innovative, world-leading scanning transmission X-ray microscope (STXM) and ambient pressure photoelectron spectroscopy (APPES) instrumentation. Research at the MES Beamline and by staff are providing some of the first significant molecular-level understandings of important chemical and physical processes taking place at interfaces under real or more realistic conditions than ever before possible for scientific disciplines directly-related to energy. The scientific programs of the MES Beamline are synergistic with

those of international, national, and local beamline facilities including the LBNL CSD Chemical Dynamics Beamline Facility at the ALS.

FY 2014 HIGHLIGHTS

The interaction of carbon monoxide with surfaces and interfaces (metal, metal alloy and 2D film interface) was mapped out from pristine ultra-high vacuum to ambient conditions with X-ray photoelectron spectroscopy. New evidence for 5f covalency in actinocenes was determined from Carbon K-Edge X-Ray Absorption spectroscopy when combined with electronic structure theory. A novel experimental platform was implemented which allowed for *In Situ* Soft X-Ray Absorption Spectroscopy of Flames. Absorbance images for methane, carbon monoxide and carbon dioxide were measured at the carbon K edge by raster scanning a flame burner across the X-Ray beam. The surface active species in substituted Lanthanum Iron Perovskite-Oxide Electrocatalysts were observed in an *In-Operando* system. The interfacial photoelectrochemical dynamics in dye sensitized solar cells were captured with picosecond time-Resolved X-Ray photoelectron spectroscopy by combining ambient pressure photoemission spectroscopy with tunable X-Ray radiation and a high repetition rate laser synchronized to the Advanced Light Source. Novel developments in instrumentation and computer algorithms led to chemical composition mapping with nanometer resolution by Soft X-Ray Microscopy. Selective Gas Adsorption in the presence of water on hybrid nanoporous films was measured via ambient pressure photoemission spectroscopy. Spectrochemical imaging of aerosol aging and brown carbon chromophores was performed with scanning X-Ray transmission microscopy.

Kinetics of Charge Transfer in a Heterogeneous Catalyst-Reactant System

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Tanja Cuk
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$320,000 (2014)

PROGRAM SCOPE

One of the greatest challenges in the design of efficient and selective catalysis technologies is the limited fundamental understanding of how interfacial properties at solid state/reactant interfaces guide catalytic reactions. What is needed is to directly follow the trajectory of how charge carriers in solid state catalysts initiate interfacial charge capture by reactant molecules, from the creation of the charge carrier in the bulk, to its accumulation at the interface, and to the moment at which a reactant molecule transforms and, in the process, consumes the charge carrier. This proposal will use optical and infrared pump-probe spectroscopy, inclusive of second harmonic generation, transient diffraction gratings, and sum frequency generation to investigate the kinetics of charge transfer at a catalyst/reactant interface. The charges will be injected into the catalyst via an embedded photovoltaic or Schottky junction and the reactant environment will be controlled in a vacuum chamber. Oxidative reactions are chosen since they are strongly endoergic and often the limiting factor in full integrated artificial photosynthetic systems. Methanol oxidation and water oxidation will be explored on three different types of oxides (n-type TiO₂, p-type Co₃O₄, and RuO₂). Ferrocene oxidation will be used as a model one electron transfer reaction.

FY 2014 HIGHLIGHTS

New transient reflectance results on n-SrTiO₃ in an in-situ electrochemical cell reveal a marked change in kinetics as a function of voltage applied on the electrochemical cell. In a recently published manuscript, we ascribe the potential dependent hole kinetics to mapping out the activation barrier of the initial hole transfer of the water oxidation reaction, [h⁺] + [OH⁻] to form [OH], where OH is a neutral, OH radical. In particular, we quantify how much a change in the potential of interfacial holes reduces the activation barrier. We also find the kinetics of charge transfer at the equilibrium thermodynamic potential of the reaction. The values are within expectations for a simple, one hole transfer reaction, as can be determined by electrochemistry for such reactions using steady state current flow. Steady state current, however, cannot follow multi-component reactions accurately and without extensive modeling. The new finding here is that we have been able to both separately follow and quantify a single hole transfer step from a multi hole transfer reaction using transient spectroscopy. The physical picture is that we have quantified the initial step to transferring a hole over from a delocalized valence band edge of O 2p orbitals in the solid state catalyst into a molecular oxygen bond at the interface.

Ultrafast Molecular Scale Chemical Imaging

PROGRAM SCOPE

Photophysical processes at the heart of photovoltaic, photocatalytic and photosynthetic processes in molecular-scale complexes hinge on structure-property relationships that are enshrined at the atomic scale, far beyond the spatial resolution of optical spectroscopies alone. The goal of this project is to develop and exploit an advanced experimental approach that integrates ultra-high vacuum (UHV) scanning tunneling microscopy and spectroscopy (STM/STS) and single particle laser spectroscopy in order to explore the photophysics of single molecules or molecular systems with atomic-scale spatial resolution and ultrafast time scales. The overarching scientific goal of this work is to experimentally decipher the correlation between the photophysical functioning of a molecular system and its detailed conformation and local environment; this would provide a critical touchstone for connecting with theory to develop a fundamental understanding of these processes. We are targeting transport and photophysical processes in (i) self-assembled small molecule acceptor-donor complexes, (ii) covalently-bonded acceptor-donor molecules, and (iii) bio-inspired photosynthetic molecular systems deposited and probed on UHV clean surfaces. In addition to metal substrates, we are also exploring 2D materials (e.g. graphene) as a substrate to provide a weakly-interacting surface in order to minimize perturbations to the electronic and optical properties of the molecular systems. After developing an understanding of morphology and electronic structure of the molecular systems on these surfaces with UHV STM, we will explore photoexcitation and photo-induced charge separation in these well-characterized systems using single particle laser excitation and spectroscopy techniques.

FY 2014 HIGHLIGHTS

We have been building on recent successes in our project involving the investigation of self-assembled chiral donor-acceptor heterojunctions on Cu(111), the demonstration of the weak coupling of donor and acceptor molecules to a graphene substrate, and the growth of graphene on Ag(111). Laser excitation and spectroscopy of these systems requires custom UHV STM instrumentation developed in house; we have recently improved the energy resolution and stability for these measurements with the demonstration of our homebuilt low temperature (4K) UHV STM with integrated optical microscopy and spectroscopy access. In order to limit the mobility of molecules on graphene systems, we have developed a method in which molecules are deposited onto a pre-formed network of surface supported graphene nanoribbons. We used this method to localize metalized porphyrin molecules, TBrPP-Co, on nanoribbons of various widths. This enabled us to spectroscopically study the molecules, where a feature characteristic of the magnetic 'Kondo' interaction was observed. These results are the first indication of a hetero-molecular Kondo interaction through any graphene system. Beyond graphene (2D carbon), we have been exploring other 2D materials to serve as substrates for our experiments and ultimately as platforms for molecular electronics, opto-electronics, and photovoltaics. The ability to reduce silicon to a single atomically thin layer ("silicene") has received considerable attention. However, its realization remains elusive. Despite previous reports of the growth and observation of "silicene" on an Ag(111) surface by several research groups, we have demonstrated that the observed structure was most likely a previously known Ag surface reconstruction forming on bulk silicon precipitation. This result underscores the challenges associated with understanding structure at the atomic scale and its critical role in understanding behavior and developing applications.

PROGRAM SCOPE

The Condensed Phase Chemical Physics Program supports the mission of the DOE Office of Basic Energy Sciences to foster and support fundamental research in the natural sciences to provide a basis for new and improved energy technologies (e.g., catalysis and energy conversion) and for understanding and mitigating the environmental impacts of energy use. This research provides a foundation for understanding fundamental interactions of atoms, molecules, and ions with materials and with photons and electrons in their chemical environment. Research underpins the fundamental knowledge of chemical transport and reactivity in the condensed phase. It also addresses fundamental uncertainties in thermal and non-thermal (i.e., radiation) chemistry, interfacial molecular and ionic transport (key to subsurface contaminant transport and to separations processes) and other processes in complex

systems related to energy use, environmental remediation, and waste management. Our research focuses on structures and processes of molecular and nanoscale systems in complex environments such as condensed phases and interfaces. Experimental and theoretical models are used to better understand natural systems and guide the development of new materials and approaches for clean and efficient energy use. Another central feature is the development of new experimental methods with broad applications to research in the natural sciences.

FY 2014 HIGHLIGHTS

Research highlights in FY 2014 include (1) the investigation of the competitive displacement kinetics between H₂O and CO₂ on model oxide (TiO₂ (110)) and natural mineral (Mg₂SiO₄(011), forsterite) surfaces using temperature desorption and molecular beam techniques; (2) the demonstration of depth dependent radiation chemistry in electron-irradiated H₂O/CO/H₂O ices where it was discovered that the product distribution is dependent on the position of the CO layer in the H₂O ice film; (3) the report that the Cl⁻-H₃O⁺ contact ion pair persists throughout a broad concentration range and that characterizing distinct populations of these ion pairs gives rise to a novel molecular level description of how to view the reaction network for acid dissociation and how it relates to our fundamental picture of acid–base equilibria; (4) the publication of a high resolution negative ion photoelectron spectrum of a model green fluorescent protein, GFP, chromophore anion, that produced experimental adiabatic and vertical detachment energies with sufficient accuracy and resolution to provide much needed robust benchmarks for future theoretical investigations; (5) the demonstration of how the efficiency of coupling light waves into isolated plasmonic holes can be tuned by varying hole diameter and how efficient optical coupling and nanohole assemblies can be used to rationally control plasmon propagation and interferometric plasmonic lensing.

Surface Chemical Dynamics

Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$1,070,000 (2014)

PROGRAM SCOPE

This program focuses on fundamental investigations of the dynamics, energetics and morphology-dependence of thermal and photoinduced reactions on planar and nanostructured surfaces that play key roles in energy-related catalysis and photocatalysis. Laser pump-probe methods are used to investigate the dynamics of interfacial charge and energy transfer that lead to adsorbate reaction on metal and metal oxide surfaces. State- and energy-resolved measurements of the gas-phase products are used to infer the dynamics of product formation and desorption. Time-resolved correlation techniques follow surface reactions in real time and are used to infer the dynamics of adsorbate–substrate energy transfer. Measurement of the interfacial electronic structure is used to investigate the impact of adsorbate-surface and cluster-support interactions on the activity of thermal and photoinduced reactions. Capabilities to synthesize and investigate the surface chemical dynamics of arrays of supported metal nanoparticles (NPs) on oxide surfaces include the deposition of size-selected

gas-phase clusters as well as solution-phase synthesis and deposition of narrow-size-distribution nanometer-scale particles.

FY 2014 HIGHLIGHTS

- We are using nanoparticle (NP) arrays to investigate the size-dependence of the surface reaction dynamics in ultrafast time-resolved studies. Recent advances in our diblock-copolymer inverse-micelle-based synthesis of palladium nanoparticle arrays on titanium dioxide have provided good size control in the few-nm size range. We are now able to tune the mean particle size between 3 and 8 nm, while maintaining an interparticle distance of approximately 35 nm.
- We have extended earlier surface dynamics investigations on single crystal Pd(111). We recently observed a dramatic coverage dependence in the photoinduced desorption cross section for CO from Pd(111) that correlates with population of atop binding sites. We also found that the presence of O⁻ atoms further enhances this cross section. Understanding binding-site and lateral-interaction effects is crucial to the interpretation of NP measurements.
- Velocity map imaging (VMI) in conjunction with a novel 4D fast camera (x, y, time, intensity) have been used for the first time to discriminate between primary and secondary products from surface photoreactions. Initial experiments concerned the fate of ethyl radicals resulting from the UV photooxidation of 2-butanone on TiO₂(110), which previous studies suggest undergo secondary reactions to form ethane and ethylene. The VMI images, however, prove that all the observed product ions originate from the nascent ethyl radical. This proof-of-principle experiment demonstrates the utility of coupling VMI and 4D imaging for unraveling the product distributions from photoreactions at surfaces.
- Two-photon photoemission has been used to probe the interfacial electronic structure of a wide range of metal oxide nanoclusters (M_xO_y; M = W, Mo, Ti, Nb) supported on Cu(111) and Cu₂O/Cu(111) surfaces.

Condensed Phase and Interfacial Molecular Science

Funding: \$1,193,000 (2014)

PROGRAM SCOPE

Condensed Phase and Interfacial Molecular Science (CPIMS) research seeks a molecular-level understanding of chemical, physical, and electron-driven processes in aqueous media and at interfaces, as these underlie contemporary directions in energy production and storage, and their environmental consequences. Studies of model condensed-phase systems target first-principles understanding of molecular reactivity and dynamical processes in solution and at interfaces by confronting the transition from molecular-scale chemistry to collective phenomena in complex systems. Novel theory and

experiments address the details of solvation (particularly hydration) and interfacial properties and dynamics of a variety of energy related phenomena, such as the selective surface adsorption of ions and the development of models to describe molecular details of evaporation (currently one of the principal uncertainties in modeling the long-term effects of fossil fuel by products) and free radical reactions of hydrocarbons at aqueous interfaces. New models are developed for examining spatial distributions of ions and complex organic molecules near interfaces and the nature of molecular vibrations in nonuniform liquid systems. Complementary theory and experiments address charge transport at complex interfaces and the effects of phase transitions on charge transport, with the goal of advancing battery, fuel cell, and solar fuel production technology.

FY 2014 HIGHLIGHTS

Recent advances in understanding liquid interfacial dynamics include a general and efficient procedure for identifying instantaneous interfaces from molecular coordinates and a generalization of umbrella sampling methods for collecting statistics on rare but important density fluctuations. These methods have identified important mechanistic pathways in water evaporation, the structure and dynamics of water at metal and hydrophobic interfaces. New theoretical descriptions have been developed of selective ion adsorption at the air-water interface through the construction of an analytically tractable microscopic model for ion solvation, yielding further insights into the molecular underpinnings of anion adsorption selectivity at the liquid interface. The dissolution of carbon dioxide in water and the ensuing hydrolysis reactions are of profound importance for understanding the behavior and control of carbon in the terrestrial environment. New experiments at the Advanced Light Source measured the first X-ray absorption spectra of aqueous carbonates, including the short-lived carbonic acid species itself. Measured and calculated spectra are in excellent agreement and reveal that each carbonate species exhibits similar, but distinct, spectral features which are interpreted in terms of the relative C-O bond strengths, molecular configuration, and hydration strength. Recent progress has been made understanding the excess electron dynamics in ultrathin layers of NaCl on Ag(100); a model system for a wide range of technologically relevant devices. It was observed that the free electrons excited into the image potential states localize on the ultrafast time scale due to trapping at neutral defect states existing at the NaCl/vacuum interface. These observed trap states could have a potential impact on electron transport in systems where ultrathin layers of insulating layers are used, and have a subsequent impact on device efficiency.

EARLY CAREER: Free Radical Reactions Hydrocarbon at Aqueous Interfaces

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Kevin Wilson
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Chemical reactions of hydrocarbon radicals occurring at water and electrolyte interfaces govern a wide array of environmentally and technologically important processes in electrochemistry, catalysis, aerosol aging, cloud chemistry, lipid peroxidation, and corrosion. Predictions of interfacial reactivity based solely upon chemical structure (e.g. the number and kind of molecular reactive sites in an isolated gas phase

molecule) are often inaccurate by many orders of magnitude, since interfacial molecular orientation and solvent structure all play significant and complex roles in controlling the activation energy of a surface reaction. This proposed research program will combine state-of-the-art ambient pressure droplet train X-ray photoelectron spectroscopy with novel surface sensitive mass spectrometry to reveal how chemical structure, thermodynamic phase, interfacial thickness and solvent structure govern molecular weight growth and degradation of hydrocarbons at water and electrolyte interfaces. This work supports key missions of the DOE Basic Energy Sciences program to better assess, mitigate and control the environmental impacts of energy use by providing innovative approaches for obtaining a first principles understanding of surface chemistry of aqueous interfaces.

FY 2014 HIGHLIGHTS

Sensitive measurements of the droplet size were conducted, at a relative humidity (~99.9%) just below saturation, on submicron particles containing an ammonium sulfate core and an organic layer of a model compound of varying thickness. The 12 model organic compounds are a series of di-carboxylic acids (C_3 to C_{10}), cis-pinonic, oleic, lauric, and myristic acids, which represent a broad range in solubility from miscible (malonic acid) to insoluble. The growth in droplet size with increasing organic fraction cannot be explained by assuming the organic material is dissolved in the bulk droplet. Instead, the wet droplet diameters exhibit a complex and non-linear dependence on organic volume fraction, leading to droplet growth that is in some cases smaller and in others larger than that predicted by bulk solubility alone. A model based on the two-dimensional van der Waals equation of state is used to explain the complex droplet growth with organic aerosol fraction and dry diameter. The model suggests that mono- and di-carboxylic acids with limited water solubility partition to the droplet interface and reduce surface tension only after a two dimensional (2D) condensed monolayer is formed. There is a clear alternation in the threshold for droplet growth observed for odd and even carbon numbered diacids, explained in the model by differences in the excluded molecular areas of even and odd diacids. These differences are consistent with the odd diacids being arranged at the droplet interface in end-to-end configurations with only one acid group in contact with the aqueous phase; in contrast to even carbon numbered diacids forming folded films with both acids groups in contact with the bulk phase. These results reveal a new and complex relationship between the composition of an organic particle and its water uptake, suggesting that organic surface films might strongly influence the multiphase surface chemistry of organic particles as well as cloud droplet formation.

Theoretical Investigation of Kinetic Processes in Small Radicals

Institution: Maryland, University of
Point of Contact: Millard Alexander
Email: mha@umd.edu
Principal Investigator: Millard Alexander
Sr. Investigator(s): Paul Dagdigian; Johns Hopkins University
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$155,811 (2014)

PROGRAM SCOPE

Our group studies inelastic and reactive collisions of small molecules, focusing on radicals important in combustion environments. Our goal is the better understanding of kinetic processes that may be difficult to access experimentally. An essential component is the accurate determination of potential energy surfaces (PESs). After fitting the *ab initio* points to obtain global PESs, we treat the dynamics using time-independent (close-coupling) methods. A focus of recent work in our program has been the study of energy transfer collisions (rotationally, vibrationally, and/or electronically inelastic) of small hydrocarbon radicals (CH_2 and CH_3). Our calculations have been compared with experimental measurements of rate constants (CH_2) and differential cross sections (CH_3). We have also initiated the calculation of accurate transport properties for collision systems involving a free radical, concentrating on collision pairs relevant to species in a $\text{H}_2/\text{O}_2/\text{He}$ flame. We are presently using these accurate transport properties in 1-dimensional flame simulations.

FY 2014 HIGHLIGHTS

We have extended study of collisional relaxation of methylene (CH_2) to the vibrational relaxation of the bending mode of $\text{CH}_2(\text{X})$ in collisions with He. A characteristic of A to X collision-induced internal conversion (CIIC), of methylene is the dominant role of weak coupling between perturbed pairs of rotational levels. We have computed CIIC rate constants with a model involving coherent mixing of the scattering T-matrix elements associated with collisional transitions within the unmixed X and a states. We have used these rate constants to simulate the relaxation of $\text{CH}_2(\text{X},a)$ in collisions with He. The group of Orr-Ewing (Bristol, UK) has measured differential cross sections for scattering of CD_3 with He, H_2 , Ar, and N_2 . We have employed PES's determined by our group for the first 3 collision partners to compute differential cross sections. We find excellent agreement between the measurements and our calculations. We find that the dynamics of collision of the symmetric top CD_3 is richer than that of a diatomic. Chemical kinetic models require knowledge of not only the rate constants of all the relevant species, but also transport properties for an accurate description of the species concentrations, as well as for the calculation of flame. We have been computing accurate transport properties for a series of collision systems involving a free radical. In current work, we computed transport properties for collision pairs relevant to species in species in a $\text{H}_2/\text{O}_2/\text{He}$ flame, with the use of *ab initio* PES's. We have carried 1-dimensional flame simulations of a freely propagating $\text{H}_2/\text{O}_2/\text{He}$ flame with two sets of transport properties. The first set employed transport properties obtained with the conventional method of parameterized LJ 12-6 potentials, while in the second set transport properties for the above collision

pairs were substituted. A modest increase in laminar flame speeds, comparable to differences for various chemistry models, was found for both flames.

Predictive Large-Eddy Simulation of Supercritical pressure Reactive Flows in the Cold-Ignition Regime

Institution: California Institute of Technology
Point of Contact: Josette Bellan
Email: Josette.Bellan@jpl.nasa.gov
Principal Investigator: Josette Bellan
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$405,000 (2014-2017)

PROGRAM SCOPE

We address issues highlighted in the Basic Energy Needs for Clean and Efficient Combustion of 21st Century Transportation Fuels (DOE BES, 2006) under the topic of Combustion under Extreme Pressure. Specifically: (1) “the most basic concepts of thermal autoignition” are “based on experience and theory at near atmospheric pressures” and that “as pressure increases significantly..., many of these conceptual pictures begin to change or disappear” (2) “A better description of the coupling and interaction of high pressure flow and molecular transport processes with chemistry is also necessary”, (3) “Ignition and flame propagation of alternative and renewable fuels, as well as of the changing feed stocks of conventional fossil-based fuels, are very likely to be much different at very high pressures than under the more familiar, lower pressure conditions of current engines.” (4) “Under such conditions distinctions between gas and liquid phases become moot, new equations of state must be used...”, (5) There must be “a re-examination of the basic assumptions that govern the physics and chemistry related to combustion; and the need for this type of re-examination increases as the combustion pressure increases.” Under “Multiscale Modeling” it is stated “The combination of unexplored thermodynamic environments and new physical and chemical fuel properties results in complex interactions among multiphase (according to the above, the multiphase distinction becomes moot with increasing pressure) fluid dynamics, thermodynamic properties, heat transfer, and chemical kinetics that are not understood even at a fundamental level.” The objective of this study is the investigation of the coupling among thermodynamics, transport properties, intrinsic kinetics and turbulence under the high-pressure and the relatively (with respect to combustion) low-temperature conditions of the auto-ignition regime, with particular emphasis on the manifestation of this coupling on the effective kinetic rate.

FY 2014 HIGHLIGHTS

To accomplish the goals we have created a database of several Direct Numerical Simulations of a reactive temporal mixing layer created between two counter-flow streams: air mixed with traces of water and carbon dioxide in the upper stream at 1000 K temperature and n-heptane with traces of water and carbon dioxide in the lower stream at 600 K temperature. The water and carbon dioxide mimic exhaust gas recirculation. The initial Reynolds number, the free-stream pressure (60 – 80 bar) and the amounts of water and carbon dioxide were varied among simulations. This database is currently being thoroughly analyzed to understand the peculiarities of the turbulent reaction at high pressure. The analysis conducted so far has revealed that (1) the reaction zone is a combination of a diffusion flame flanked by two premixed flames, (2) due to occurring uphill diffusion of water and carbon dioxide at the high pressures under consideration, exhaust gas recirculation has the advantage of increasing turbulence through the formation of high species-density-gradient regions which act akin to a mesh in

the flow, and (3) the highest dissipation is that due to the reaction, but viscous, species-mass and heat dissipation may be active at other locations, meaning that all these various contributions to the dissipation should be modeled in Large Eddy Simulation.

EARLY CAREER: Towards Predictive Simulations of Soot Formation: From Surrogate to Turbulence

Institution: California Institute of Technology
Point of Contact: Guillaume Blanquart
Email: g.blanquart@caltech.edu
Principal Investigator: Guillaume Blanquart
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$159,733 (2014)

PROGRAM SCOPE

The combustion of hydrocarbon fuels, including kerosene, gasoline, and diesel, leads to the formation of soot particles which are known to be the source of several health problems and environmental issues. The objective of the proposed work is to fill the gap in the present understanding and modeling of soot formation both in laminar and turbulent flames. This effort spans all critical length scales from the molecular level to large scale turbulent transport. The objectives are three fold: 1) develop the first combined chemical and soot model validated for all relevant components usually found in real fuel surrogates; 2) develop a framework able to explain the complete evolution of soot particles from cluster of PAHs to oxidation of large fractal aggregates; 3) understand and model the interplay between unsteady chemistry, differential diffusion, and turbulent transport. While this project focuses on numerical simulations, the objective is also to develop a true synergy between experiments and computations through collaborations with experimental groups for each topic.

FY 2014 HIGHLIGHTS

In the past year, we applied our latest developments in the simulations of multiple laminar premixed flames, laminar co-flow diffusion flames, and turbulent jet diffusion flames. Central to this effort, Large Eddy Simulations (LES) have been performed on an ethylene/air piloted turbulent non-premixed sooting jet flame to quantify the importance of aromatic chemistry-turbulence interactions. Aromatic species are of primary importance since their concentrations control directly the soot nucleation rates. The proposed simulation framework relies on four major components: a gas-phase chemistry model, a turbulence closure model, a PAH relaxation model, and finally a soot model. The results, in excellent agreement with experimental data from Sandia National Laboratory, highlight the greater importance of unsteady aromatic-chemistry over the most commonly assumed soot-turbulence interactions. Consistently with our results in the laminar premixed and diffusion flames, these turbulent flame results also emphasize the need for a more fundamental understanding of the growth of aromatic molecules and their nucleation into soot particles. Work has also been done on these last two aspects. For instance, we showed that excited states of PAH molecules might play a critical role in the rate and reversibility of the soot inception process. The year 2014 culminated with the second International Sooting Flames (ISF) workshop where our work was showcased.

Dynamics of Product Branching in Elementary Combustion Reactions - OH + Alkenes and Nitrogen

Institution: Chicago, University of
Point of Contact: Laurie Butler
Email: L-Butler@uchicago.edu
Principal Investigator: Laurie Butler
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$163,000 (2014)

PROGRAM SCOPE

Radical intermediates play a key role in combustion. The addition of a radical such as OH to an unsaturated hydrocarbon generates a transient, highly vibrationally excited, radical intermediate along the bimolecular reaction coordinate. Our experiments directly investigate the dynamics of the product channels that arise from such radical intermediates. The experiments developed in my group generate a particular isomeric form of an unstable radical intermediate and study the branching between the ensuing product channels of the energized radical as a function of its internal rotational and vibrational energy under collision-less conditions. The experiments use a combination of: 1) measurement of product velocity and angular distributions in a crossed laser-molecular beam apparatus, with electron bombardment detection in my lab in Chicago or 2) with tunable vacuum ultraviolet photoionization at Taiwan's National Synchrotron Radiation Research Center (NSRRC), and 3) velocity map imaging using state-selective REMPI ionization, single photon ionization, and now tunable vacuum ultraviolet photoionization of radical intermediates and reaction products.

FY 2014 HIGHLIGHTS

This year we finished and published our experiments on two radical intermediates in the reaction of OH + propene, the 1-hydroxy-2-propyl radical produced when the OH adds to an end carbon and the 2-hydroxy-1-propyl radical from addition at the center carbon. Using a combination of velocity map imaging and photofragment translational spectroscopy, we detected several products from the unimolecular dissociation of the radical intermediates, including OH + propene, methyl + acetaldehyde, and ethyl + formaldehyde. Using a velocity map imaging apparatus, we produced the radical intermediates photolytically from brominated precursors, which allowed us to determine the internal energy distribution of the radical intermediate from the speed distribution of the recoiling bromine atoms. Resolving the velocity distribution of $\text{Br}(^2P_{1/2})$ and $\text{Br}(^2P_{3/2})$ separately allows us to determine the total (vibrational + rotational) internal energy distribution in the nascent radicals. By modeling the amount of rotational energy imparted to the radicals upon dissociation of the halogenated precursors, we determine the vibrational energy distribution of the nascent radicals. With this model, we predict the percentage of radicals having vibrational energy above and below the lowest dissociation barrier, that to OH + propene; it accurately predicts the measured velocity distribution of stable radicals. We also use the angular momenta of the unstable radicals to estimate the energy partitioned to relative kinetic energy when they dissociate to OH + propene radicals. The results develop insight on product channel branching in reactions that proceed via an addition/elimination mechanism and provide a key benchmark for emerging electronic structure and dynamics calculations on polyatomic reactions that proceed through unstable radical intermediates.

Institution: California-San Diego, University of
Point of Contact: Robert Continetti
Email: rcontinetti@ucsd.edu
Principal Investigator: Robert Continetti
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$350,000 (2014-2016)

PROGRAM SCOPE

This research program focuses on studies of the energetics and reaction dynamics of transient neutral molecules and collision complexes relevant to combustion phenomena. The general goal is to carry out benchmark-quality measurements of radicals and neutral reaction systems including oxygenated radicals and hydroxyl radical reactions. Measurements of energetics, including bond dissociation energies, tunneling dissociation rates and product branching ratios for oxygenated radicals and hydroxyl radical reactions have been a central focus of recent work. An important element of this program has included close collaboration with theoretical groups to test *ab initio* potential energy surfaces and quantum dynamics calculations that will be required for first-principles understanding of more complex chemical systems. The experiments use photodetachment of precursor molecular and cluster anions to prepare energy-selected reactive intermediates, and then directly measure the stability and dissociation dynamics of energy-selected reactive intermediates. These experiments combine photoelectron spectroscopy with photofragment translational spectroscopy in the unique technique called photoelectron-photofragment coincidence (PPC) spectroscopy for studying dissociative photodetachment (DPD) processes. The PPC technique now makes use of an electrostatic ion beam trap (EIBT), permitting the storage of molecular anions for many seconds and also opening the door to preparation of vibrationally excited anions for studying new aspects of chemical reactivity. A next generation improvement of this apparatus involving a new ion source, and a cryogenic octupole accumulator trap to improve preparation of larger molecular systems with very low internal temperatures is in progress, and will allow studies of larger species relevant to biofuel combustion under well-defined conditions.

FY 2014 HIGHLIGHTS

The fluorine-water system was studied using the DPD of the fluoride-water anion. In collaboration with Hua Guo (New Mexico), the results were compared to full dimensional quantum dynamics calculations on *ab initio* potential energy surfaces (PESs). The comparison between theory and experiment for this system was impressive and was reported in Science. This included observation of stable and metastable complexes, the latter being Feshbach resonances supported by the open HF(ν) + OH product channels. The quantitative differences between theory and experiment indicate that the ground and excited state *ab initio* potential energy surfaces require further examination. Efficient infrared (IR) vibrational excitation of anions prior to injection into the EIBT was also demonstrated by recording an action spectrum of the autodetaching vibrational states of NO⁻. Data was then obtained examining the effect of excitation of the proton transfer vibration in (F-H-OH)⁻. Clear evidence for partitioning of vibrational energy to product translation was observed consistent with addition of the vibrational energy from the IR photon. Studies of the OH + CO reaction included experiments on the stability and dissociation dynamics of the formyloxyl radical that yielded product bending vibration resolved data for the carbon dioxide product. In collaboration with Al Wagner (Argonne) and others, the model previously introduced for tunneling dissociation of HOCO to H + carbon dioxide was tested using different *ab initio* PESs. The

model was found to provide a useful measure of the properties of the PES in the tunneling region. In a separate publication a detailed examination of the implications of the PPC experiments on the dynamics for dissociation into the OH + CO entrance channel was reported, showing that a more detailed theoretical examination of the cis – trans isomerization of HOCO and how that couples to the OH + CO entrance channel is needed.

Vibrational Dynamics and Dissociation of Ground-and Excited-State Clusters

Institution: Wisconsin-Madison, University of
Point of Contact: Fleming Crim
Email: fcrim@chem.wisc.edu
Principal Investigator: Fleming Crim
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

Many excited-state processes involve the intersection of two electronic states along one or more coordinates, and the resulting interaction often creates a conical intersection between the two states. These structures are both intriguing and significant because the evolution of molecules through conical intersections determines the disposal of energy into dissociation fragments and the branching between different reaction pathways. This project studies the photodissociation of molecules that contain conical intersections to learn about the influence of vibrational excitation on their dissociation pathways. Our candidate molecules also form complexes with species such as CO, CO₂, C₂H₂, H₂O, and NH₃ that offer a range of bond strengths and geometries. The experiments use infrared excitation to prepare vibrationally excited molecules and complexes in combination with resonance enhanced multiphoton ionization and ion imaging detection to monitor the decomposition products. In the vibrationally mediated photodissociation experiments, a pulse of ultraviolet light, coming after the vibrational excitation pulse and before the detection pulse, transfers the vibrationally excited molecule to an electronically excited state where it dissociates. In many cases, it is possible to resolve quantum states of the detected product and infer the state of the unobserved product. Thus, the experiments discover the influence of vibrational excitation and complexation, individually and in combination, on the excited-state decomposition dynamics and pathways in a variety of molecules. It is even possible that the combination of electronic and vibrational excitation will initiate new reactions within the complexes. The experiments can identify dissociation pathways, discover the factors that control the course of decompositions, and test theoretical models of the dissociation of energized molecules.

FY 2014 HIGHLIGHTS

One of our primary accomplishments in 2014 was the study of the vibrational predissociation dynamics of the hydrogen-bonded 3-aminophenol-ammonia cluster (3-AP-NH₃) in the OH stretching and NH stretching regions. The vibrational energy is sufficient to dissociate the cluster into its constituent 3-AP and NH₃ monomers, and we detect the 3-AP fragments via (1+1) resonance-enhanced multiphoton ionization (REMPI). The distribution of vibrational-state population of the 3-AP fragment suggests the presence of two distinct dissociation pathways. The first dissociation channel produces a broad, unstructured predissociation feature in the REMPI-action spectrum after excitation of any of the O-H or N-H stretching vibrations, suggesting a nearly statistical dissociation pathway with strong coupling of the vibrations in the cluster during the predissociation. The second dissociation channel produces sharp

features on top of the broad predissociation features, but only following excitation of the OH stretch or the symmetric NH₃ stretch in the cluster. This striking mode-specificity is consistent with strong coupling of these two modes to the dissociation coordinate (the O-H...N bond). The measurements show that vibrational excitation is driving the isomerization of the trans-isomer to the cis-isomer in the course of the dissociation of the cluster.

Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The aim of this research program is to better understand the mechanisms and product energy disposal in elementary bimolecular reactions fundamental to combustion chemistry. Using the crossed molecular beams method, the angular and velocity distributions of neutral products from single reactive collisions are measured using VUV laser ionization methods.

FY 2014 HIGHLIGHTS

During this funding period, we have further developed vacuum ultraviolet (VUV) generation by four-wave mixing of collimated (i.e., unfocussed) nanosecond laser pulses. Using our rotatable source crossed beams apparatus, we employ universal pulsed photoionization detection, typically using 0.1 mJ pulses at 9.9 eV (125 nm). We have recently studied the reactions of phenyl radicals with propene, trans 2-butene, and molecular oxygen. We have developed a technique for producing radiation extending into the extreme ultraviolet (XUV; $\lambda < 110$ nm) with higher conversion efficiencies than previously reported. Our method involves noncollinear phasematching of focused lasers in laser vaporized mercury (Hg) at room temperature. This approach easily facilitates windowless operation. Furthermore, using noncollinear phasematching, the short wavelength radiation is spatially isolated from the residual UV and visible beams without need for lossy optical elements such as windows, lenses, and gratings. Our approach using "soft" single photon pulsed ionization allows product molecules to drift to a triply differentially pumped detector before ionization, spreading out due to their velocities. This method is well suited for experiments using pulsed radical sources. In contrast to ion imaging or Rydberg tagging, where VUV is introduced into the high-pressure molecular beam crossing region, no interference from photodissociation or ion-molecule reactions is observed. As illustrated in our studies of phenyl radical reactions, the high ionization efficiency and low background leads to quite high signal to noise ratios. However, the need to scan the laser delay to measure product TOF distributions represents the key remaining limitation. To address this, we have initiated the development of a new detection method employing coaxial universal photoionization of products from crossed beam reactions within an ion guide. This method promises to dramatically improve detection sensitivity.

EARLY CAREER: Vibrational Spectroscopy of Transient Combustion Intermediates Trapped in Helium Nanodroplets

Institution: Georgia, University of
Point of Contact: Gary Douberly
Email: douberly@uga.edu
Principal Investigator: Gary Douberly
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of this research is to isolate and stabilize transient intermediates and products of prototype combustion reactions. This will be accomplished by Helium nanodroplet isolation (HENDI) spectroscopy, a novel technique where liquid helium nanodroplets freeze out high energy metastable configurations of a reacting system, permitting infrared spectroscopic characterizations of products and intermediates that result from hydrocarbon radical reactions with molecular oxygen and other small molecules relevant to combustion environments. The majority of these transient species have never been directly observed in traditional spectroscopy experiments. HENDI spectroscopy will be used to carry out the first direct observation of the elusive hydroperoxyalkyl radical (QOOH) and its oxygen adducts (O_2QOOH), important in the low-temperature hydrocarbon oxidation chemistry associated with homogeneous charge compression ignition (HCCI) engines. HENDI will also be used to probe the outcome of the self-reactions of resonantly stabilized free radicals, which are important in the earliest stages of soot formation. Thus, these studies may lead to an improved understanding of the detailed mechanisms of hydrocarbon combustion, resulting in more accurate predictive combustion models. Furthermore, mid-infrared spectral signatures of important combustion intermediates will be obtained to develop laser diagnostic tools for modern chemical kinetics studies.

FY 2014 HIGHLIGHTS

We spectroscopically probed the outcome of the reaction between the propargyl radical (C_3H_3) and O_2 within He droplets. A pick-up technique was employed where He droplets doped with a propargyl radical (generated by pyrolysis of 1-butyne-4-nitrite) were sequentially doped with an O_2 molecule. The reaction carried out at 0.4 K resulted exclusively in the formation of the acetylenic-trans-propargyl peroxy radical ($HC\equiv C-CH_2-OO\bullet$). This work helped to elucidate the shape of the entrance channel on the potential energy surface, as it was unclear whether or not there exists a small barrier to formation of the peroxy species. The rapid cooling afforded by the He droplets motivates the conclusion that if a barrier does indeed exist, it is too small to kinetically stabilize a van der Waals complex between C_3H_3 and O_2 . MRCI computations carried out in collaboration with Stephen Klippenstein and co-workers indicate that the reaction is barrierless, similar to alkyl + O_2 reactions. High resolution infrared spectra were obtained for the allyl radical (C_3H_5) and the products of the He-mediated reaction between allyl and O_2 . In the IR spectrum of He-solvated allyl, we observed rovibrational bands near the reported band origins in previous high resolution gas-phase studies. In addition to the fundamental CH stretching modes, four other bands were assigned to the allyl radical using a consistent set of rotational constants. Indeed, it was observed in the gas-phase studies that the CH stretch bands are heavily perturbed, but no explanation was given as to the nature of the perturbations. The lower temperature of the He droplets greatly decreases the number of populated rovibrational levels, and aided by anharmonic frequency computations and the resolved rotational substructure, we assigned the ν_1 (a_1), ν_3 (a_1), ν_{13} (b_2) fundamentals and the $\nu_{14}/(\nu_{15}+2\nu_{11})$ (b_2) and $\nu_2/(\nu_4+2\nu_{11})$ (a_1) Fermi dyads, in addition to an unassigned resonant resonant polyad near the ν_1 mode.

Spectroscopic and Dynamical Studies of Highly Energized Small Polyatomic Molecules

Institution: Massachusetts Institute of Technology
Point of Contact: Robert Field
Email: rwfield@mit.edu
Principal Investigator: Robert Field
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Tunable laser and Chirped Pulse millimeter-Wave spectroscopies are used to examine the structure and dynamics of highly energized, small polyatomic, combustion relevant molecules. Dynamical processes include unimolecular isomerization, photofragmentation, pyrolysis, predissociation, and Intramolecular Vibrational Redistribution. Particular emphasis is placed on mechanistic models of dynamics rather than merely numerical or statistical descriptions.

FY 2014 HIGHLIGHTS

The 2014 highlights of the DOE-supported research include:

1. Discovery and exploitation of the spectroscopic signature of the vibrational states proximal to an isomerization barrier. This signature is a dip in the vibrational level spacing. Examples include the S_1 electronic states of acetylene and HCN.
2. Calculation of full dimensional Franck-Condon factors for an electronic transition between bent and linear geometry electronic states. A new propensity rule is discovered for the Franck-Condon brightness of transitions, which simplifies the assignment of S_1 - S_0 transitions in acetylene.
3. Level-specific predissociation rates are discovered in the S_1 state of acetylene by comparing the intensity of fluorescence from intact HCCH to that of the H atom photofragment. This discovery was facilitated by the use of H atom 3d-2p H laser induced fluorescence.
4. IR-UV double resonance studies of the C-state of SO_2 provide detailed energy level structure that permits a vibronic coupling explanation for the apparent asymmetric equilibrium structure of the C-state.
5. Chirped Pulse millimeter-Wave spectroscopy has been used to document the mechanisms of pyrolysis reactions.

Spectroscopy and Kinetics of Combustion Gases at High Temperatures

Institution: Stanford University
Point of Contact: Ronald Hanson
Email: rkhanson@stanford.edu
Principal Investigator: Ronald Hanson
Sr. Investigator(s): Craig Bowman; Stanford University
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

This program involves two complementary activities: (1) development and application of cw laser absorption methods for the measurement of concentration time-histories and fundamental spectroscopic parameters for species of interest in combustion chemistry; and (2) shock tube studies of reaction kinetics relevant to combustion mechanisms. These activities are focused on the study of small ketones and aldehydes (e.g. acetaldehyde, propanal, and 2-butanone) and their reactions. A deeper understanding of and strong constraints on the pyrolysis and oxidation kinetics of ketones and aldehydes is possible if the time-histories of individual species can be measured during chemical reactions. In addition to the diagnostics we currently have in this area, two other species are being investigated in the spectroscopic portion of the research: CO (whose sensitive detection is now possible because of the availability of QC lasers in the IR near 4600 nm) and CH₂O (which can be measured using ring-dye laser absorption in the UV near 305 nm or using DFG lasers in the IR near 3500 nm). Accurate modeling of oxygenate kinetics requires accurate knowledge of key radical reaction rates. However, the values of many key reaction rate constants used in current oxygenate mechanisms are based on theoretical estimates only and this can greatly degrade the confidence in these models. The kinetics portion of this program is focused on the measurement of reaction rates of selected oxygenate species with OH. This combination of spectroscopic and kinetics studies should provide a strong, and needed, database toward the development and refinement of oxygenate fuel models. It should also provide a better understanding of the combustion chemistry of individual ketone and aldehyde species, whose health and pollution roles in engine emissions are of increasing interest.

FY 2014 HIGHLIGHTS

A direct measurement for the rate constant of the acetone dissociation reaction, $\text{CH}_3\text{COCH}_3 = \text{CH}_3\text{CO} + \text{CH}_3$, was conducted behind reflected shock wave, utilizing a sub-ppm sensitivity CO diagnostic achieved by cavity-enhanced absorption spectroscopy (CEAS). By investigating the clean pyrolysis of less than 20ppm acetone in argon, the current experiment eliminated the influence from secondary reactions and temperature change. For the first time, the acetone dissociation rate constant was directly measured over 5.5 orders of magnitude with high degree of accuracy. This result was seen to agree with most previous studies, and has bridged the gap between their temperatures and pressures conditions. The current work also served as an example demonstration of the potential of using the CEAS technique in shock tube kinetics studies. The rate constant of the H-abstraction reaction of formaldehyde by hydrogen atoms (H), $\text{CH}_2\text{O} + \text{H} = \text{H}_2 + \text{HCO}$, has been studied behind reflected shock waves using a sensitive mid-IR laser absorption diagnostic for CO, over temperatures of 1304 - 2006 K and at pressures near 1 atm. C₂H₅I was used as an H-atom precursor and 1,3,5-trioxane as the CH₂O precursor, to generate a well-controlled CH₂O/H reacting system. By designing the experiments to maintain relatively constant H-atom concentrations, the current study significantly boosted the measurement sensitivity of the target reaction and suppressed the influences of interfering reactions. A transition-state-theory (TST) calculation, using the CCSD(T)-F12/VTZ-F12 level of theory, is in good agreement with the shock tube measurement and extended the temperature range of the current study to 200 - 3000 K.

Kinetics and Product Channel Studies in Combustion Chemistry

Institution: North Dakota State University
Point of Contact: John Hershberger
Email: john.hershberger@ndsu.edu
Principal Investigator: John Hershberger
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$233,000 (2014-2016)

PROGRAM SCOPE

This project involves the use of high resolution infrared laser spectroscopy to probe the products of chemical reactions and photochemistry relevant to the combustion chemistry of nitrogen-containing compounds. Emphasis is placed on obtaining reliable quantitative information on product yields, especially in reactions that have more than one possible product channel. When appropriate, we also perform *ab initio* calculations of the potential energy surfaces of some of these reactions.

FY 2014 HIGHLIGHTS

Work during fiscal year 2014 has concentrated on experimental work on the photochemistry of fulminic acid (HCNO). Fulminic acid is an intermediate in acetylene combustion, and is the less stable isomer of isocyanic acid (HNCO). Kinetics of HCNO reactions have been studied in our laboratory for the past decade, but only recently have we investigated the photolysis channels. Initial work used 248 nm photolysis wavelength, and more recent work has used 193 nm. We find a rich photochemistry with this molecule, with five measurable photochemical product channels. Although all channels are active at both photolysis wavelengths, there are significant differences in the product yields.

Probing the Reaction Dynamics of Hydrogen-Deficient Hydrocarbon Molecules and Radical Intermediates via Crossed Molecular Beams

Institution: Hawaii, University of
Point of Contact: Ralf Kaiser
Email: ralfk@hawaii.edu
Principal Investigator: Ralf Kaiser
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$171,000 (2014)

PROGRAM SCOPE

The objectives of this project are to understand the formation mechanisms of bicyclic and tricyclic polycyclic aromatic hydrocarbons (PAHs) in combustion processes of hydrocarbon-based fuel. The formation and growth mechanisms of PAHs is an unsolved problem in the combustion chemistry community. To achieve these objectives, we will experimentally explore the energetics, chemical dynamics, potential energy surfaces (PESs), and reactions of key representatives of resonantly stabilized free radicals (RSFRs) and of aromatic radicals (ARs) with hydrocarbon molecules utilizing the crossed molecular beam approach. Our studies focus on four key systems: First, we untangle the collision energy dependent reaction dynamics of RSFRs [propargyl (H_2CCCH ; C_3H_3), cyclopentadienyl ($\text{c-C}_5\text{H}_5$), benzyl ($\text{C}_6\text{H}_5\text{CH}_2$; C_7H_7) and tolyl ($\text{C}_6\text{H}_5\text{CH}_3$; C_7H_7) with benzene (C_6H_6), vinylacetylene (C_4H_4), and acetylene (C_2H_2), respectively. These experiments access the C_9H_9 PES and investigate the formation of the bicyclic indene molecule (C_9H_8). Second, we aim to unravel the reaction dynamics of the key RSFR 1,2,3-butatrien-1-yl (H_2CCCCH ; $\text{i-C}_4\text{H}_3$) with benzene (C_6H_6) accessing the C_{10}H_9 PES. This study probes the formation of the bicyclic naphthalene molecule (C_{10}H_8). Third, we will expose the reaction dynamics of key ARs [1- and 2-naphthyl (C_{10}H_7)] with vinylacetylene (C_4H_4) accessing the $\text{C}_{14}\text{H}_{11}$ PES. These studies investigate the synthesis of the tricyclic anthracene/phenanthrene molecules ($\text{C}_{14}\text{H}_{10}$). Finally, we reveal the reaction dynamics of key ARs with hydrocarbon molecules, i.e. 1- and 2-naphthyl (C_{10}H_7) with methylacetylene/allene (C_3H_4) and of 2- and 7-indenyl (C_9H_7) with vinylacetylene (C_4H_4) accessing various

parts of the C₁₃H₁₁ PES. These studies investigate the formation of the tricyclic fluorene/¹H-benz[f]indene/¹H-benz[e]indene, as well as of 1H-phenalene (C₁₃H₁₀). The results of the scattering experiments are combined with *ab initio* calculations (Alexander Mebel) and with flame modeling.

FY 2014 HIGHLIGHTS

The objectives of this project were to understand the formation mechanisms of bi- and tricyclic polycyclic aromatic hydrocarbons (PAHs) in combustion processes of hydrocarbon-based fuel utilizing cross beam method: First, resonantly stabilized free radicals (RSFRs) C₅H₅ isomers 1- and 3-vinylpropargyl, C₆H₅ isomers other than phenyl and non-cyclic C₇H₇ isomers were observed in the reactions of dicarbon (C₂) with propene C₃H₆, C₄H₆ isomers (1-butyne, 2-butyne and 1,2-butadiene), and 1,3-pentadiene, respectively. Second, monocyclic aromatic and their radicals (ARs), the benzyl radical (C₇H₇) and toluene (C₇H₈) were formed by reactions of dicarbon C₂ and methylidene (C₂H) with isoprene (C₅H₈), respectively. Third, reactions of the phenyl radical with 1,2-butadiene (C₄H₆), 1,3-pentadiene and isoprene (C₅H₈) and phenylacetylene (C₈H₆) formed 2-phenyl-1,3-butadiene, PAHs 2- and 1-methyl-1,4-dihydronaphthalene and a range of substituted biphenyls. Fourth, reactions of para-tolyl with allene and methylacetylene (C₃H₄), vinylacetylene (C₄H₄), 1,3-butadiene (C₄H₆), 1,2-butadiene (C₄H₆) and isoprene, formed 5- and 6-methylindene (C₁₀H₁₀), 2-methylnaphthalene (C₁₁H₁₀), 6-methyl-1,4-dihydronaphthalene (C₁₁H₁₂), tolyl-1,3-butadiene (C₁₁H₁₂) and dimethyldihydronaphthalenes (C₁₂H₁₃), respectively. Finally, several investigations were conducted using a pyrolysis nozzle at the Advance Light Source, Berkeley. The phenyl radical reaction with 1,3-butadiene formed a range of C₉H₈ isomers with indene being insignificant. The phenyl reaction with two acetylene molecules formed first phenylacetylene (C₈H₆) then naphthalene (C₁₀H₈) revealing the HACA mechanism. Finally the reaction of phenyl with oxygen at two temperatures was investigated yielding 18 products along with their temperature dependent branching ratios.

Intermolecular Interactions of Hydroxyl Radicals on Reactive Potential Energy Surfaces

Institution: Pennsylvania, University of
Point of Contact: Marsha Lester
Email: milester@sas.upenn.edu
Principal Investigator: Marsha Lester
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$30,000 (2014)

PROGRAM SCOPE

The DOE-BES research program in the Lester laboratory aims to characterize important, yet often elusive, reaction intermediates in combustion chemistry using novel spectroscopic and dynamical methods. A robust, state-selective ionization scheme is being developed for the hydroxyl radical, a key oxidant in combustion, by combining OH A-X excitation with VUV ionization. The research is aimed at understanding the ionization step via autoionizing Rydberg states and utilizing the novel OH detection scheme in various applications. Carbonyl oxides of general form R₁R₂COO, important intermediates in tropospheric hydrocarbon oxidation and some combustion reactions, are also being investigated through their UV spectroscopy and photochemistry. The research is focused on the UV photodissociation dynamics of prototypical carbonyl oxides to O¹D and O³P products in order to determine dissociation energies and dynamical pathways involving multiple potential energy surfaces.

FY 2014 HIGHLIGHTS

This laboratory utilized a new velocity map imaging apparatus to study the UV photodissociation dynamics of the simplest Criegee intermediate CH₂OO. Here, the velocity and angular distributions of O¹D photofragments are characterized following UV excitation of CH₂OO on the B¹A' ← X¹A' transition. An anisotropic angular distribution indicative of prompt dissociation yields the orientation of the transition dipole moment, which reflects the π* ← π character of the electronic transition associated with the COO group. The total kinetic energy release distributions obtained at several photolysis wavelengths provide detail on the internal energy distribution of the formaldehyde cofragments and the dissociation energy of CH₂OO X¹A' to O¹D + H₂CO X¹A₁. A common termination of the total kinetic energy distributions, after accounting for the different excitation energies, gives an upper limit for the CH₂OO X¹A' dissociation energy of D₀ < 54 kcal mol⁻¹, which compares favorably with theoretical predictions including high level multi-reference *ab initio* calculations. A complementary theoretical study utilized wave packet dynamics on the excited B-state to examine the dissociation dynamics of CH₂OO. These calculations indicate that dissociation occurs promptly and primarily along the diabatic B-state potential to O³P + H₂CO a³A' products. A much smaller yield is predicted for the lowest spin-allowed channel to O¹D + H₂CO X¹A' products, which arises from couplings between multiple diabatic states.

Computational Flame Diagnostics for Direct Numerical Simulations with Detailed Chemistry of Transportation Fuels

Institution: Connecticut, University of
Point of Contact: Tianfeng Lu
Email: tlu@enr.uconn.edu
Principal Investigator: Tianfeng Lu
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The goal of the proposed research is to create computational flame diagnostics that are rigorous numerical algorithms to detect critical flame features, such as ignition, extinction, and premixed and non-premixed flamelets, and to understand the underlying physicochemical processes controlling limit flame phenomena, flame stabilization, turbulence-chemistry interactions and pollutant emissions etc. The goal will be accomplished through an integrated effort on mechanism reduction, direct numerical simulations (DNS) of flames at engine conditions, computational diagnostics, and DNS data mining. The computational diagnostics are primarily based on the chemical explosive mode analysis (CEMA) and a recently developed bifurcation analysis using datasets from first-principle simulations of 0-D reactors, laminar flames, and 2-D and 3-D direct numerical simulations (DNS) (collaboration with Dr. J.H. Chen at Sandia). Non-stiff reduced mechanisms for transportation fuels amenable for 3-D DNS are developed through graph-based methods and timescale analyses. DNS for premixed and non-premixed flames at diesel jet and homogeneous charge compression ignition (HCCI) engine conditions using the non-stiff reduced chemistry are performed through a collaborative effort (with J.H. Chen and C.S. Yoo). The flame structures, stabilization mechanisms, local ignition and extinction etc., and the rate controlling chemical processes are unambiguously identified.

FY 2014 HIGHLIGHTS

Reduced mechanisms for a variety of practical engine fuels are developed based on directed relation graph (DRG), analytically solved linearized quasi steady state approximations, and dynamic chemical stiffness removal etc., for dimethyl ether (DME), ethanol-air with NO_x formation, primary reference fuels (PRF), and a ternary biodiesel surrogate. The reduced mechanisms are employed in Sandia's (J.H. Chen) DNS of lifted flames, HCCI and SACI simulations. A reduced mechanism for n-dodecane as diesel surrogate was developed through collaboration with S. Som at Argonne for diesel engine simulations by the engine combustion network (ECN). A dynamic adaptive chemistry (DAC) method is developed to expedite time integration of chemically reacting systems based on DRG. The DAC method is applied in the Strang splitting schemes, and a second order accuracy in time-integration was achieved in simulations of 1-D premixed flames of methane-air. A speedup factor of about 30 is achieved using DAC for HCCI combustion of isooctane-air in a partially stirred reactor, and even larger speedup factors are achieved after combining DAC with in-situ adaptive tabulation (ISAT). A method of bifurcation analysis (BA) is developed based on the description of extinction and ignition states as bifurcation points on the S-curves of steady state combustion. Reactions important to ignition and extinction are systematically identified based on their contributions to the bifurcation states. BA is shown to be overall as effective as the brute-force global sensitivity analysis while featuring significantly higher computational efficiency. Furthermore, DNS data for the ethanol, DME, PRF and biodiesel flames are systematically diagnosed with chemical explosive mode analysis (CEMA) to extract critical flame features, such as premixed flame fronts, local ignition and extinction. Different modes for premixed flame propagation (auto-igniting fronts vs. deflagration waves) are further identified.

Advanced Nonlinear Optical Methods for Quantitative Measurements in Flames

Institution: Purdue University
Point of Contact: Robert Lucht
Email: lucht@purdue.edu
Principal Investigator: Robert Lucht
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Nonlinear optical techniques such as laser-induced polarization spectroscopy (PS), resonant wave mixing (RWM), and electronic-resonance-enhanced (ERE) coherent anti-Stokes Raman scattering (CARS) are techniques that show great promise for sensitive measurements of transient gas-phase species, and diagnostic applications of these techniques are being pursued actively at laboratories throughout the world. The objective of this research program is to develop and test strategies for quantitative concentration and temperature measurements using nonlinear optical techniques in flames and plasmas. We have continued our fundamental theoretical and experimental investigations of these techniques. We have also initiated both theoretical and experimental efforts to investigate the potential of femtosecond (fs) laser systems for sensitive and accurate measurements in gas-phase media. Our initial efforts have been focused on fs CARS, although the systems will be useful for a wide range of future diagnostic techniques involving two-photon transitions.

FY 2014 HIGHLIGHTS

In the last year we have demonstrated the acquisition of single-shot temperature measurements at data rates of 5 kHz in highly turbulent, swirl-stabilized methane-air flames. The fs CARS measurements exhibited high signal-to-noise ratios and temperatures were extracted from nearly every laser shot. Over the past year we have continued our two-color PS measurements. We developed and optimized a new laser system for the two-color PS measurements of nitric oxide featuring two injection-seeded optical parametric generator/pulsed dye amplifier (OPG/PDA) systems, both operating near 452 nm. Collision-induced resonances were clearly observed with this system. We are investigating the physics of both fs CARS and two-color PS by direct numerical integration (DNI) of the time-dependent density matrix equations for the resonant interaction. Significantly fewer restrictive assumptions are required using this DNI approach compared with the assumptions required to obtain analytical solutions. We are concentrating on the accurate simulation of two-photon processes, including Raman transitions, where numerous intermediate electronic levels contribute to the two-photon transition strength. We have made significant progress in the last year on modeling two-color PS of atomic hydrogen, and are obtaining good agreement between experiment and modeling. We have also developed a new technique for simultaneous pure rotational and vibrational CARS, and we have continued to develop and apply this new technique during the past year. This method takes advantage of a two-beam phase-matching scheme for pure rotational CARS.

Detection and Characterization of Free Radicals Relevant to Combustion Processes

Institution: Ohio State University
Point of Contact: Terry Miller
Email: tamiller@chemistry.ohio-state.edu

Principal Investigator: Terry Miller
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Combustion processes have been studied for many years, but the chemistry is very complex and yet to be fully understood. Modern computer codes for its modeling typically employ hundreds of reaction steps with a comparable number of chemical intermediates. The predictions of such models are obviously limited by the dynamical and mechanistic data that are input. Spectroscopic identifications and diagnostics for the chemical intermediates in the reaction mechanisms constitute an important experimental benchmark for the models, as well as providing molecular parameters that are “gold standards” against which quantum chemistry computations of molecular properties may be judged. Our recent work has emphasized the spectroscopy of reactive organic radicals, like peroxides and related molecules, which are known to be key intermediates in combustion reactions as well as being present in atmospheric oxidation of fuels and other organic compounds. We develop the basic spectral information required to produce highly sensitive and selective diagnostics for these reactive intermediates. Moreover the spectroscopic data directly characterizes these species which can be critical for benchmarking *ab initio* computer codes that calculate these quantities, as well as other properties not easily subject to experimental verification.

FY 2014 HIGHLIGHTS

It is well known that larger chain alkanes ($> C_5$ - C_{10}) are important components of gasoline and diesel fuels. Our previous CRDS spectroscopy of combustion intermediates has been limited to the $\tilde{A}-\tilde{X}$ transition of peroxy radicals with ≤ 5 carbon atoms. Recently we have extended our observations to larger chain intermediates, i.e. hexyl, heptyl, octyl, nonyl, and decyl peroxy radicals produced from the C_6 - C_{10} alkanes. In these experiments the peroxy radicals are formed from H atom extraction by Cl atom attack (simulating OH attack in combustion) on the corresponding hydrocarbon followed by reaction with O_2 . It is possible to form multiple isomers of peroxy radicals as there are several unique hydrogen atoms that can be abstracted by the Cl atom. Structural/spectral relationships that have been derived from our earlier data on C_1 - C_5 hydrocarbons, allow assignments of the C_6 - C_{10} peroxy radical spectra which are mostly too large for accurate predictions from electronic structure calculations. Particularly interesting are the spectra of the peroxy radicals resulting from the oxidation of two isomers of octane, n-octane and iso-octane, the latter the standard (100) for the rating of commercial gasolines. We observed that n-octane, like the other larger alkanes studied, produces almost exclusively the sec isomers of the corresponding peroxy radical. On the other hand, in the case of iso-octane only the pri and tert isomers of the corresponding peroxy radicals are observed.

Dynamics of Activated Molecules

Institution: Maryland, University of
Point of Contact: Amy Mullin
Email: mullin@umd.edu
Principal Investigator: Amy Mullin
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 3 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This research program investigates the dynamics of reactive and non-reactive processes of highly excited gas-phase molecules that are involved in combustion chemistry. Elevated temperatures in combustion environments produce vibrationally excited molecules (with $E > 100$ kcal/mol) that have enhanced reaction rates. The means by which molecular energy is available for chemistry is governed by the quantum-mechanical nature of molecular vibrations. Collisional deactivation of highly excited species competes directly with reactive channels and can lower reaction rates if sufficient energy is removed through collisions. In our experiments, highly vibrationally excited molecules are prepared by pulsed UV excitation, followed by rapid radiationless decay. High-resolution transient IR absorption spectroscopy is used to characterize the kinetics of quantum-state resolved energy flow that occurs when highly excited molecules undergo inelastic or reactive collisions. Doppler-broadened IR line profiles of nascent collision products provide a direct measure of how the exchanged energy is partitioned into vibrational, rotational and translational degrees of freedom. The molecular systems under investigation are chosen to reveal how the molecular structure and charge distribution of the high energy molecules and the energy-accepting molecules impact the energy transfer dynamics. These studies yield information about the energy transfer mechanism and the intermolecular potential energy surface that controls the dynamics.

FY 2014 HIGHLIGHTS

The presence of near-resonant vibrational pre-dissociation in collisions of pyrazine(E) with HCl was investigated as the source of an unusual isotope effect in pyrazine/ HCl and DCl collisions. We removed the near-resonant mode by switching to pyrazine-d₄ as an energy donor. The frequency of HCl (2949/cm) is close to pyrazine-h₄ stretch modes (3040-3069/cm) but far from pyrazine-d₄ C-D stretches (2270-2290/cm). We found that J-dependent recoil energies for pyrazine-d₄/HCl collisions are similar to those for pyrazine-h₄, indicating that near-resonant effects are not responsible for the dynamics. Additional evidence that vibrational pre-dissociation is not active comes from similarities in the HCl (v=1) product state distributions for both donors. We conclude that differences in zero-point energies for HCl and DCl collision complexes limit the HCl motion in collisions and reduces the opportunity for multiple encounters during the collisional quenching. A second project explored how methane collisionally quenches pyrazine(E). Methane is the simplest hydrocarbon and is important in combustion. Despite being the simplest hydrocarbon, methane has a complex IR spectrum and our initial task was to sort out the effects of vibration-rotation coupling, centrifugal distortion and nuclear spin statistics on the IR spectrum. Transient measurements showed that methane is scattered in three vibrational states: (0000), (0100) and (0010). No scattering was seen into the higher energy (0001) state. Rotational and translational energy measurements (600 K and 530-780 K for J=2-15, respectively) show that scattering of methane (0000) occurs by impulsive collisions and is the primary pathway quenching pathway (85% of collisions). The (0100) and (0010) product states have cooler rotational (320 K) and translational (380 K) distributions, indicating a long range mechanism. Rate measurements indicate that the (0100) and (0010) states account for 15% of collisions.

Spectroscopy, Kinetics, and Dynamics of Combustion Radicals

PROGRAM SCOPE

This report covers the results from the second year of a three-year program for elucidation of spectroscopy, kinetics and structural dynamics of combustion radicals. Both the dynamics and spectroscopy of jet cooled hydrocarbon transients have been explored, utilizing i) high resolution IR lasers, ii) slit discharge sources for formation of jet cooled radicals, and iii) high sensitivity detection with direct laser absorption methods near the quantum shot noise limit. The advantage of this experimental combination is that such highly reactive radical transients can be made under high pressures/temperatures characteristic of combustion conditions, with the resulting species rapidly cooled to T = 10-15K in the slit supersonic expansion for maximal spectroscopic simplification. Four highlights from work over the last year are summarized below.

FY 2014 HIGHLIGHTS

Hydroxymethyl radical, CH₂OH, plays a critically role as a reactive intermediate in combustion. In addition to fundamental combustion processes, hydroxymethyl radical is an important intermediate for oxidative reactions occurring in the troposphere. For example, atmospheric scrubbing reactions of alkanes, alkenes, and alcohols all involve hydroxymethyl radical as a reactive intermediate.

Hydroxymethyl ($\bullet\text{CH}_2\text{OH}$), is predicted to have a slightly non-planar equilibrium structure with a low barrier across a Cs transition state due to OH internal rotation. This work has profited by the excellent vibrationally tagged double resonance ion depletion (DRID) studies of Reisler and coworkers on $\bullet\text{CH}_2\text{OH}$, which yielded structured rovibrational band contours in the CH and OH stretch regions limited by a 0.4 cm^{-1} laser linewidth. The present studies under sub-Doppler conditions promise to provide over 2 orders of magnitude improvement, which permit complete resolution and analysis of the underlying spectral structure due to end-over-end tumbling, internal OH rotor dynamics as well as coupling with CH/OH vibration modes. We have already made substantial progress, with initial spectral searches for CH_2OH in the symmetric CH_2 stretch region in a methanol doped He/Ne discharge. At sub-Doppler resolution, CH_2OH reveals a surprisingly intense spectrum, with typical S/N of 20:1, and $K_a = 0$ from 0 A-type rotational assignments, which provide first precision molecular constants for this oxyradical species. The transitions are fit to a Watson A-reduced symmetric top Hamiltonian to yield first precision experimental values for the ground state rotational constants as well as improved values for the symmetric stretch rotational constants and vibrational band origin. The results both complement and substantially augment previous spectral efforts as well as offer high resolution predictions for astronomical detection of CH_2OH radical in the mm-wave region.

Determination of Accurate Energetic and Spectroscopic Database for Combustion Radicals and Molecules by High Resolution Photoion-Photoelectron Methods

Institution: California-Davis, University of
Point of Contact: Cheuk-Yiu Ng
Email: cyng@chem.ucdavis.edu
Principal Investigator: Cheuk-Yiu Ng
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$84,000 (2014)

PROGRAM SCOPE

The main goal of this research program is to obtain accurate thermochemical data, such as ionization energies, 0 K dissociative photoionization thresholds, 0 K bond dissociation energies, and 0 K heats of formation for molecular species and their ions of relevance to combustion chemistry. Accurate thermochemical and spectroscopic data for polyatomic molecules, including radical and cationic species, determined in the present study by high-resolution photoionization, photoelectron, and photodissociation methods are also used for benchmarking predictions of state-of-the-art *ab initio* quantum calculations. This effort is aimed to assist the development of the next generation of quantum computation procedures for providing more accurate energetic and structural predictions of neutral and ionic species.

FY 2014 HIGHLIGHTS

We have completed the high-resolution PFI-PE studies of a series of radicals, including propargyl radical (C_3H_3), allyl radical (C_3H_5), and halogen-substituted methyl radicals (CH_2Cl and CH_2Br).

Photoinitiated Reactions of Radicals and Diradicals in Molecular Beams

Institution: Southern California, University of

Point of Contact: Hanna Reisler
Email: reisler@usc.edu
Principal Investigator: Hanna Reisler
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

Open shell species such as radicals and diradicals are central to reactive processes in combustion and environmental chemistry. Our program is concerned with photoinitiated reactions of hydroxyalkyl radicals and carbenes. The goal is to investigate the detailed dynamics of dissociation of free radicals and diradicals in which multiple pathways participate, including molecular rearrangements, and compare them with high-level calculations. Studies include unimolecular reactions on the ground state as well as photodissociation dynamics on excited Rydberg and valence states that involve multiple potential energy surfaces. Reactions are carried out in molecular beams using pulsed laser excitation, and products' quantum states are detected by time-sliced velocity map imaging.

FY 2014 HIGHLIGHTS

Recent experiments on the photodissociation of the hydroxymethyl radical have focused on excited states of the hydroxymethylene product, an elusive intermediate implicated in the unimolecular decomposition of formaldehyde and relevant to combustion processes. By monitoring the velocity and kinetic energy release of H photofragments generated by C-H bond breaking in the radical, we gain information on HCOH(D) products. For example, we have been able to provide new information on the trans- and cis-isomers of HCOH(D) with internal energies ranging from low rovibrational excitations to above their dissociation thresholds to H(D) + H(D)CO. The distinction between the cis and trans isomers becomes clearer when using different H/D isotopologs, which have different vibrational frequencies. The preference for generating the higher-lying cis-HCOH in the photodissociation has been predicted by calculations of the relevant conical intersections that lead to these isomers. We have also determined experimentally for the first time the singlet-triplet gap in HCOH and the energy difference between the triplet states of formaldehyde and hydroxymethylene. This information is derived from time-sliced velocity map imaging experiments, using a new design developed in our lab, which optimizes the velocity resolution in detecting H photofragments. One of the advantages of using the hydroxymethyl radical as a source of hydroxymethylene is that it has continuous absorption over a broad wavelength range, and thus the internal energy of HCOH can be increased progressively by accessing several Rydberg states of the precursor. Current experiments are aimed at developing more efficient sources of hydroxymethylene and its derivatives by using pulsed pyrolysis and photolysis of keto-carboxylic acids such as glyoxylic and pyruvic acids.

Universal and State-Resolved Imaging Studies of Chemical Dynamics

Institution: Wayne State University
Point of Contact: Arthur Suits
Email: asuits@chem.wayne.edu
Principal Investigator: Arthur Suits
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This program is directed to building a fundamental understanding of chemical reaction dynamics with particular emphasis on elementary reactions and mechanisms important in predicting combustion chemistry. This research is conducted using state-of-the-art molecular beam machines and vacuum ultraviolet lasers in conjunction with DC slice ion imaging and other advanced spectroscopic techniques to study frontier areas in photodissociation, unimolecular decomposition, and bimolecular reactions. This program exploits recent advances in high-resolution slice ion imaging, in imaging applications of crossed molecular beam scattering, and in development of new experimental approaches, to extend the range of chemical dynamics studies into frontier areas. A key aspect of this effort is on combining universal probes providing a global perspective with high-resolution state-resolved probes yielding quantum mechanical detail, to develop a molecular-level understanding of chemical phenomena. Two important new experimental avenues are incorporated in the proposed studies. These include the development and application of strong-field ionization as a universal but selective probe of polyatomic reaction products and combustion intermediates, and chirped-pulse mm Wave spectroscopy in pulsed uniform supersonic flows, a powerful new approach that promises both structural and product branching information for unstable reaction intermediates and reaction products. These two novel approaches promise to open new windows into the details of the complex chemistry of combustion systems. The specific objectives of our program remain: to extend the range of powerful dynamics studies to more complex polyatomic systems; to identify novel reaction pathways such as roaming dynamics and characterize them in full detail; to identify transient species in combustion-related reactions; and to benchmark a range of theoretical methods. Our work often involves synergistic collaboration with leading theoreticians.

FY 2014 HIGHLIGHTS

Addition-elimination reactions are textbook reactions familiar to all chemists, where the final products are produced after the formation of a long-lived adduct. These reactions often compete with direct pathways to form the same products, as seen in the gas-phase for reactions of chlorine atoms with unsaturated hydrocarbons. Here, the precise pathway leading to release HCl from the initially-formed adduct was still a mystery. In imaging experiments, the A.G. Suits group studied the scattering distributions when beams of Cl atoms collide with butene molecules, and found both direct and indirect pathways with different energy dependence. They then turned to high-level theoretical calculations from A. M. Mebel to understand the reaction mechanisms. A careful theoretical analysis of the properties of the system revealed that, to decompose, the highly frustrated π adducts must undergo near-dissociation back to the starting reactants before eliminating HCl at the adjacent saturated sites. This is a clear example of roaming radical dynamics, now widely recognized in unimolecular reactions, showing that they play a central role in a broad class of bimolecular reactions as well.

A Novel Multiscale Simulation Strategy for Turbulent Reacting Flows

Institution: Utah, University of
Point of Contact: James Sutherland
Email: james.sutherland@utah.edu
Principal Investigator: James Sutherland
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Turbulent reacting flow remains a grand challenge problem from a modeling and simulation standpoint. Reynolds-Averaged Navier Stokes (RANS) techniques resort to modeling all timescales of the flow, and is not predictive for reacting flows. Large Eddy Simulation (LES) is a technique that resolves the large length/time scales of the flow while modeling unresolved scales, and has gained widespread adoption in the past 20 years. Direct Numerical Simulation (DNS) fully resolves all continuum length and time scales in the flow, but is restricted to simple flows at low Reynolds number due to its tremendous cost. The One-Dimensional Turbulence model provides an alternative to traditional CFD approaches that models the effect of turbulent eddies on the flow field, but in a single spatial dimension. ODT has been shown to capture salient features of a wide range of flow fields, and naturally captures the $-5/3$ energy cascade in isotropic turbulent flows. Additionally, ODT has been shown to capture challenging turbulence-chemistry interactions that govern extinction/reignition. Furthermore, ODT is significantly less expensive than other CFD approaches such as LES and DNS. However, due to its one-dimensional nature, ODT cannot capture multidimensional effects such as recirculation or some mechanisms of flame stabilization such as triple-flames. This project draws on the strength of the ODT model while seeking to overcome its weaknesses by forming a lattice of ODT domains which are fully coupled in their evolution. This provides a simulation approach that resolves the large scales of the flow (integral length and time scales) directly on the lattice while representing the small scales of the flow through each of the ODT lines. We will demonstrate the efficacy of the lattice-ODT approach on canonical flows such as isotropic turbulent decay prior to addressing more complicated turbulent reacting flow problems including lifted partially premixed flames.

FY 2014 HIGHLIGHTS

During FY 2014, we focused on developing the software to implement the modeling framework and scale it to several thousand processors. We employ a hybrid task and data parallelism approach which provides the opportunity for overlapping communication and computation. We considered strong and weak scalability at various lattice spacings, and demonstrated good strong and weak scalability. Because of the unique lattice structure of the approach, data structures and the associated communication patterns specific for this approach had to be developed. In addition to the focus on software design and scalability, we investigated the ability of the new formulation to simulate isotropic turbulence decay. This required significant effort to generate the initial conditions that were appropriate for the lattice, and consumed much more time than we anticipated. However, we are presently running preliminary studies on this. Finally, we have been implementing the required thermochemistry models to allow simulation of reacting flows with detailed kinetic mechanisms, thermodynamics and transport. This is nearly complete as well.

Developing a Predictive Model for the Chemical Composition of Soot Nanoparticles

Institution: Michigan, University of
Point of Contact: Angela Violi
Email: avioli@umich.edu
Principal Investigator: Angela Violi
Sr. Investigator(s): Hope Michelsen; Sandia National Laboratories-Livermore
Nils Hansen; Sandia National Laboratories-Livermore
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Carbonaceous nanoparticles (CNPs) are formed in combustion environments and have significant impacts on society. A significant emission from internal combustion engines, CNPs pose a significant health hazard; CNPs are primarily composed of carcinogenic polycyclic aromatic hydrocarbons (PAHs) and have small size ($\leq 100\text{nm}$) that can increase particle toxicity. In flames, a substantial amount of effort has elucidated the gas-phase chemistry of CNP precursors such as acetylene and benzene, as well as the eventual growth of CNPs into larger soot particles. However, there is still substantial uncertainty concerning particle inception, or the transition from the gas-phase to solid-phase, which is a complex process involving both chemical and physical phenomena. Particle inception or nucleation has a significant impact on the growth of combustion-emitted particles, especially their size distribution and morphology. Moreover, the physiochemical properties of nanoparticles, including size and morphology, greatly influence their toxicology. The aim of this project is to investigate particle inception through the development and application of a novel and detailed theoretical model for CNP growth. The model will be guided and validated with experimental data produced at Sandia National Laboratories and Lawrence Berkeley National Lab. This work will provide novel insight into the size distributions and morphology of chemically grown CNPs in flames, both of which substantially impact physical agglomeration phenomena. The current approach is novel, as it implements a highly flexible algorithm for chemical reactions in significantly greater detail than current models. Moreover, the model considers arbitrary CNP structure rather than, for example, focusing on planar CNP structures. Most importantly, this computational code has been developed to be highly extensible, in order to incorporate physical coalescence of CNPs, as well as to support the implementation of any arbitrary chemistry.

FY 2014 HIGHLIGHTS

We have combined theoretical approaches and experiments to gain new insight into the mechanisms of PAH growth and soot formation. The experimental approach has involved aerosol-mass spectrometry in conjunction with vacuum-ultraviolet photoionization of volatile species vaporizing from particles sampled from simple hydrocarbons, such as C_2H_2 counter-flow diffusion flame at nearly atmospheric pressure (700 Torr). The mass spectra contained a large distribution of peaks, highlighting the importance of small building blocks and showing a variety of chemical species that extended beyond the traditional classification of PAHs based on thermodynamic stability. We developed a new code to describe the chemical growth of PAHs based on stochastic simulations. The code was named SNAPS as it stands for stochastic nanoparticle simulator. The code has been used to interpret the experimental data in order to provide better insight into the chemical composition of species associated with peaks in the measured mass spectra.

Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

Recent research into combustion chemistry has shown that reactions at "low temperatures" (700 – 1100 K) have a dramatic influence on ignition and combustion of fuels in virtually every practical combustion system. A powerful class of laboratory-scale experimental facility that can focus on fuel chemistry in this temperature regime is the rapid compression facility (RCF), which has shown a remarkable ability to examine the details of fuel chemistry in this important regime. Our past studies have advanced our understanding of low temperature chemistry of important fuel compounds and has identified areas of high uncertainty for further research. In particular, we have shown how factors including fuel molecular structure, the presence of unsaturated C=C bonds, and the presence of alkyl ester groups influence fuel auto-ignition and produce variable amounts of negative temperature coefficient behavior of fuel ignition. We have also reported new discoveries of synergistic ignition interactions between alkane and alcohol fuels, with both experimental and kinetic modeling studies of these complex interactions. This project focuses on further clarifying the effects of molecular structure including carbon bond saturation, through low temperature combustion chemistry studies of esters, alkanes, alkenes, and alcohols. Studies of synergistic fuel component interactions are also of interest in this project. Gas-speciation analysis is applied to directly identify decomposition and oxidation pathways and to measure sentinel species for particulate production (e.g. propene).

FY 2014 HIGHLIGHTS

Despite the interest in production and combustion of other alcohols, the dominant alcohol fuel utilized in the U.S. remains ethanol. There have been numerous studies of ethanol combustion behavior and kinetics, and during the past year the University of Michigan rapid compression facility (UM RCF) was used to explore new conditions at higher pressures (~3-10.5 atm) and lower temperatures (less than 1200 K) than previous studies. The results quantify the effects of pressure and temperatures at conditions relevant to modern engines. The effects of bond structure on combustion chemistry remains a topic of considerable interest to quantify fuel reactivity and validate and develop reaction theory. Last year we completed ignition and speciation studies of the three trans hexene isomers: 1-hexene, trans-2-hexene and trans-3-hexene. Ignition delay time data were acquired using the UM RCF over a range of state and mixture conditions for each of these reference compounds. Mass sampling and gas chromatography were applied to quantify the stable intermediates present during ignition. The results of our hexene isomers study clearly show the significant changes (greater than a factor of 2 for some species concentrations) in reaction pathways that occur due to the differences in the location of the carbon-carbon double-bond in these C₆H₁₂ compounds. Despite excellent agreement with predictions of

reactivity, existing reaction mechanisms do not appear to accurately capture the quantitative differences in reaction pathways. These studies emphasize the need for accurate reaction mechanisms for these fundamental building blocks of real fuels. Another highlight of 2014 was a study to revisit n-butanol ignition chemistry led by Dr. Darshan Karwat (a graduate of UM, now with the DOE) in partnership with Drs. Stephen Klippenstein and Michael Davis of Argonne National Laboratory. The outcomes highlight the utility of theoretical chemical kinetics studies for combustion modeling.

Isomer-specific Spectroscopy and Pyrolysis of Model Aromatic Fuels

Institution: Purdue University
Point of Contact: Timothy Zwier
Email: zwier@purdue.edu
Principal Investigator: Timothy Zwier
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$574,773 (2014-2017)

PROGRAM SCOPE

The chemical complexity of hydrocarbon fuels and the fast-expanding list of potential plant-derived biofuels offer a challenge to the scientific community seeking to provide a molecular-scale understanding of their combustion. The development of accurate combustion models stands on a foundation of experimental data on the kinetics and product branching ratios of individual reaction steps. Spectroscopic tools need to continue to be developed to selectively detect and characterize the widening array of fuel components and the reactive intermediates they generate upon pyrolysis and combustion. There is growing recognition that a key component of future progress in the field is the development of detection schemes that are isomer-specific and even conformation-specific. This project uses an array of laser-based and broadband microwave methods to carry out conformation-specific and isomer-specific spectroscopy on key fuel components and the reactive intermediates formed during their pyrolysis and combustion.

FY 2014 HIGHLIGHTS

During FY 2014 we recorded alkyl CH stretch infrared spectra of a series of hydrogenated naphthalenes and naphthyl radicals formed and cooled in a supersonic expansion. Collaborating with Ned Sibert's group, we are developing a theoretical model that accounts quantitatively for the stretch-bend Fermi resonance in this traditionally challenging region of the spectrum to understand. We completed studies of the unusual spectroscopy of sinapoyl malate and its derivatives, which serves as a "sunscreen" for plants, and of model lignin dimers, both as neutrals and in complexes with alkali metal cations. These spectra show that sinapoyl malate is uniquely suited to its task, possessing an inherently broad UV spectrum that results in complete coverage of the UV-B region even under jet-cooled conditions in the gas phase. We have also used the combination of a hyperthermal nozzle and a broadband chirped-pulse Fourier transform microwave spectrometer to characterize the rotational spectroscopy and molecular structure of cyclopentadienone, a model anti-aromatic molecule that is a pyrolysis intermediate common to many biofuels. Finally, we have characterized state-specific vibronic coupling effects in asymmetric bichromophores that shed light on the electronic energy transfer between close-lying excited states.

DOE National Laboratories

Chemical Dynamics Beamline Facility

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Musahid Ahmed
Sr. Investigator(s): Stephen Leone; Lawrence Berkeley National Laboratory
Kevin Wilson; Lawrence Berkeley National Laboratory
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,164,000 (2014)

PROGRAM SCOPE

The primary purpose of this program is to support studies in chemical physics at the ALS by providing state-of-the-art experimental resources for visiting scientists and staff to undertake studies of fundamental chemical processes:

- To determine the microscopic details of the mechanisms and dynamics of primary dissociation processes and elementary chemical reactions.
- To explore the properties and decay dynamics of molecules in highly excited, transient, or metastable states.
- To study the structure, energetics and chemical reactivity of highly reactive polyatomic radicals, unusual transient species, droplets, aerosols, large biomolecules and clusters.
- To develop new spectroscopic and dynamical tools with charged particle imaging, molecular beams, and 2 color laser synchrotron pump-probe techniques.
- To pioneer new directions and developments in photoionization and photoelectron spectroscopy for the enriched understanding of fundamental properties of ions and molecules to improve thermochemical parameters.
- To investigate macroscopic systems such as flame dynamics in order to develop more precise models for real combustion systems.

Anticipated benefits to the program in particular are to provide a predictive understanding of combustion systems and a deepened understanding of chemical physics in general.

FY 2014 HIGHLIGHTS

A chemical reactor to probe unimolecular and bimolecular chemical reactions under combustion relevant conditions was developed. By probing the reactions of hydrocarbon free radicals (phenyl) with acetylene under combustion-like conditions by synchrotron based photoionization mass spectrometry, the very first direct experimental evidence for a combustion mechanism proposed over 30 years ago, but never observed, is reported. In another set of experiments, a complete identification of the reaction of the phenyl radical with molecular oxygen, which plays a central role in the degradation of poly- and mono- cyclic aromatic radicals in combustion systems was completed. Mechanistic insight into pyrolysis of biofuel compounds (dimethyl furan, cyclopentadienone, & benzyl radical) was obtained using the high temperature chemical reactor. A miniature shock tube & jet stirred reactor was interfaced to synchrotron radiation and results obtained for high temperature and pressure systems. Two dimensional gas phase chromatography with VUV photoionization mass spectrometry has revealed new details about complex hydrocarbon samples (fuel) as well as isomer level product distributions of

heterogeneous oxidation reactions. The viability of the technique was demonstrated for the analysis of diesel fuel, a prototypical environmental pollutant whose chemical complexity itself is a stringent test of any new analytical technique. Insights into the influence of molecular structure and thermodynamic phase on chemical mechanisms are obtained by identifying products of the OH-initiated oxidation of submicron particles composed of either n-octacosane (a linear alkane) or squalane (a highly branched alkane). Experimental investigations of soot precursors and incipient particle characteristics with the development of a predictive model for the chemical composition of soot nanoparticles was completed.

Gas-Phase Molecular Dynamics

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: Gregory Hall
Sr. Investigator(s): Trevor Sears; Brookhaven National Laboratory
Hua-Gen Yu; Brookhaven National Laboratory
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$1,429,000 (2014)

PROGRAM SCOPE

Members of the Gas Phase Molecular Dynamics group develop and apply high resolution spectroscopic and quantum theoretic tools to study the structure, dynamics and chemical reactivity of molecular species relevant to hydrocarbon combustion. Our overlapping interest and expertise in spectroscopy, dynamics, theory, and kinetics allow collaborative approaches to frontier topics in chemical physics. Current interests include studies of the collisional dynamics of CN radicals, understanding the relationship between collisional energy transfer processes and observed spectroscopic line shapes, and modeling of fast chemical reactions using *ab initio* potential energy surfaces computed on the fly. High resolution spectroscopic measurements of sub-Doppler molecular spectra provide both insights into electronic wavefunctions through the hyperfine interaction, as well as precision frequencies for the analysis of complex, overlapping spectra. New work includes the development of efficient algorithms for full-dimensional calculations of anharmonic vibrational levels of polyatomic free radicals as a guide to new spectroscopic measurements, the development of very precise and accurate methods for line shape and position measurements and new optical double resonance methods for sub-Doppler collisional energy and momentum transfer measurements in free radicals.

FY 2014 HIGHLIGHTS

High resolution saturation spectroscopy of free radicals A collinear sub-Doppler double-resonance method has been developed to measure the pattern of energy splitting of nuclear spin states in reactive radicals. By frequency locking a tunable sideband of one laser to an optical cavity, which in turn is frequency locked to a second laser, we have implemented a scheme to record velocity-tagged and probed optical transitions in the near infrared region with linewidths of 2-3 MHz and splitting patterns that can be measured with typical errors of 0.5 MHz for radicals that last for a fraction of a millisecond in a room temperature gas cell. Efficient algorithm for calculating molecular resonance energies, lifetimes and wavefunctions A resonance state is a configuration of atoms with too much total energy to exist as a stable molecule, but possessing a specific energy and configuration that may make it persist for longer than a molecular vibrational period, and play a subtle role in collisions important in energy transfer and chemical reactions. We have developed a general and problem-independent algorithm to efficiently

calculate all bound and hundreds of the lowest-lying resonance states of molecules. The method produces not only the energies and lifetimes, but also the wavefunctions, if desired. The algorithm has been developed using a complex guided spectral transform Lanczos approach, where the transform spectral functional is expanded in a series of complex formal orthogonal Lanczos polynomials. The algorithm has been demonstrated on resonance states of HO₂, where resonances can influence the chain branching reaction of H + O₂ to give O + OH or be stabilized to form HO₂. Sub-Doppler frequency-comb referenced measurements in acetylene hot bands Doppler-free transition frequencies for hot bands involving the lowest two vibrational fundamental vibrations have been measured in the symmetric + antisymmetric stretching combination band of acetylene.

Gas-Phase Chemical Physics (Experiment and Theory)

Principal Investigator: Martin Head-Gordon
Sr. Investigator(s): Daniel Neumark; Lawrence Berkeley National Laboratory
Stephen Leone; Lawrence Berkeley National Laboratory
William Lester; Lawrence Berkeley National Laboratory
William Miller; Lawrence Berkeley National Laboratory
Students: 5 Postdoctoral Fellow(s), 6 Graduate(s), 1 Undergraduate(s)
Funding: \$1,728,000 (2014)

PROGRAM SCOPE

The objectives of these programs are to develop the basic knowledge and understanding of the mechanisms and dynamics of elementary chemical reactions that have a major impact on combustion and advanced energy production technologies. Recent emphasis has been to determine the structure and photochemical reaction dynamics of free radicals, unusual transient species, heterogeneous chemistry, and highly-excited polyatomic molecules, and to provide microscopic details of primary dissociation and bimolecular processes. These objectives are achieved with a strongly-coupled experimental and theoretical computational approach, using emerging technologies. Experimental dynamics studies use advanced molecular beam and laser techniques, photofragmentation translational spectroscopy, and ion and electron imaging. Kinetics studies involve heterogeneous dynamics, mass-selective product detection and UV-VUV synchrotron and laser spectroscopy, and coherent dynamics. New theoretical methods and models are developed both to provide insight into chemical reactivity and the dynamics of reactive processes and also to develop methods to carry out forefront calculations to guide and model these experimental studies. Studies taking advantage of the chemical dynamics beamline comprise multiple molecular beam machines, aerosol equipment, and high resolution monochromators in the vacuum ultraviolet spectrum, in conjunction with a range of commercial laser systems and associated resources. A new initiative incorporates nano-imaging of materials with chemically specific synchrotron detection. This beamline, providing the world's brightest source of continuously-tunable vacuum ultraviolet light, is a National User Facility initiating a new era in the study of primary photochemistry, spectroscopy, photoionization processes and reaction dynamics.

FY 2014 HIGHLIGHTS

Using a multiplexed photoionization mass spectrometer at the ALS, formation of fulvene in the reaction of C₂H with 1,3-butadiene was observed, and the reactive potential energy surface was studied

computationally. Low temperature combustion product species were analyzed with tunable-synchrotron photoionization spectroscopy in a collaborative study relevant to the Korcek mechanism of decomposition of intermediate ketohydroperoxide species into acid, ketone and aldehyde pairs. Using the fast reactive beam instrument, ozone photodissociation was studied at 193 and 157nm. Particularly at the shorter wavelength, the data corresponds to equal energy partitioning in two of the recoiling O atoms, consistent with a synchronous concerted mechanism in which the two O-O bonds in ozone dissociate symmetrically at the same time. Phenyl photodissociation at 193 nm was reinvestigated to explore whether acetylene loss occurs statistically or is directed via conical intersections. Carefully controlling reaction conditions to keep the radicals cold and minimize 2-photon processes leads to branching between the two channels consistent with statistical ground state dissociation. With regard to understanding reaction dynamics of aerosols, the reaction of iodine atoms with submicrometer squalane and squalene droplets was studied. A number of significant theoretical developments were accomplished, including development of a new density functional, omegaB97X-V, which was designed by a novel survival of the most transferable approach, and outperforms all existing functionals tested for accuracy in intermolecular interactions. Additionally, the recently developed attenuated MP2 method was improved to attain greater accuracy for thermochemistry in finite basis sets, by spin-component scaling. A new semi-classical approach to non-adiabatic dynamics, based on an Ehrenfest approach with a novel binning procedure, showed accuracy as well as efficiency in tests on pilot systems.

An Expert *Ab Initio* Transition-State-Based Master Equation Code

Institution: Sandia National Laboratories-Livermore
Point of Contact: Dawn Manley
Email: dmanley@sandia.gov
Principal Investigator: Ahren Jasper
Sr. Investigator(s): Judit Zador; Sandia National Laboratories-Livermore
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$248,000 (2014)

PROGRAM SCOPE

The *ab initio* transition-state-theory-based master equation (AITSTME) approach has proven to be an extremely useful procedure for predicting the rate coefficients of gas phase chemical reactions. Such calculations consist of four components: (1) electronic structure calculations of the potential energy surface, (2) microcanonical TST calculations, (3) a model for energy transfer, and (4) the solution of the master equation representing the time dependence of the energy resolved populations. Current software implementations of the AITSTME approaches have various limitations that constrain their utility in several aspects. This project is developing a new state-of-the-art, open-source, user-friendly AITSTME software package that incorporates recent theoretical advances. A modular framework will facilitate continued development and couplings to other codes. This AITSTME code will allow for the routine prediction of multiwell, multichannel thermal rate coefficients at the highest levels of accuracy. Correspondingly, it would contribute to the continued increase in the fidelity of chemical models for combustion and thus to the predictive simulation of internal combustion engines. The overall goal of the project is to provide a code that plays the same role in the prediction of rate coefficients for elementary reactions that CHEMKIN plays in chemical kinetic modeling.

FY 2014 HIGHLIGHTS

The main goal of AITSTME is the development of a suite of integrated codes for accurately predicting elementary kinetics. A new method and code, One-Dimensional Minimizations (1DMIN), for predicting transport, and newly modified codes and methods for accurate calculations of energy transfer, Direct Nonadiabatic Trajectories (DiNT), are available and being used in the larger scientific community.

PROGRAM SCOPE

The goal of this project is to explore the fundamental effects of high pressure on the chemical kinetics of combustion and to use that knowledge in the development of accurate models for combustion chemistry at the high pressures of current and future engines. We design and implement novel experiments, theory, and modeling to probe high-pressure combustion kinetics from elementary reactions, to submechanisms, to flames. The work focuses on integrating modeling, experiment, and theory (MET) through feedback loops at all levels of chemical complexity. We are currently developing and testing the methodology for propane, small alcohols, and dimethyl ether as key prototype fuels. The consortium expands and enhances collaborations between Argonne's Dynamics in the Gas Phase Group and the Combustion Chemistry Group in Sandia's Combustion Research Facility.

FY 2014 HIGHLIGHTS

We have made considerable progress in applying the MET paradigm to propane combustion, to the development of mechanisms for small oxygenated hydrocarbons, and of a core mechanism. Synchrotron based multiplexed photoionization mass spectrometry studies of Cl initiated propyl oxidation chemistry have been performed and the data has been employed in a novel multiscale modeling approach. Studies exploring non-thermal effects for propane oxidation were published. High pressure rate measurements were made for OH + alkene reactions. We recently detected ketohydroperoxide (KHP), an important product of QOOH + O₂ reactions, in butane oxidation at pressures up to 2 atm. A high repetition rate shock tube has been developed and tested at both the Advanced Light Source at Berkeley and the Advance Photon Source at Argonne. Preliminary results were obtained for dimethyl ether decomposition. The reflected shock tube technique with H-ARAS detection was used to study the

reactions of CH₃ radicals with C₂H₆, C₂H₄, and C₂H₂ over the T-range 1100-1350 K. Measurements of H/D-atoms that result from shock heating mixtures of CH₃OH and tert-butylhydroperoxide (as a thermal source for OH) were used to probe the kinetics of OH + CH₃OD/CD₃OH. Modeling efforts suggest an important role for direct decomposition of the initially formed radicals. A long-term project developing a high accuracy core mechanism is nearing completion. This mechanism will include our emerging understanding for low-temperature propane oxidation and of non-thermal Boltzmann effects.

PROGRAM SCOPE

This work proposal covers fundamental combustion research being conducted in the Combustion Research Facility (CRF) at Sandia National Laboratories, Livermore, CA. This research attacks challenging scientific issues that are crucial to a better understanding of combustion phenomena. In experimental studies, emphasis is on the development and application of advanced, laser-based detection technologies. In chemistry, studies include chemical dynamics, chemical kinetics, flame chemistry and combustion modeling. In diagnostics, emphasis is given to development and application of spatially and temporally precise, non-perturbing methods that provide chemical or gas-dynamical information, and that are applicable in harsh combustion environments. Theoretical efforts range from basic molecular structure calculations to quantitative simulations of diagnostic signals to detailed modeling of multicomponent, chemically reacting turbulent flows. Research activities emphasize the examination of fundamental gas-phase reaction and fluid dynamic processes in controlled combustion environments. Projects include experimental and numerical studies of premixed and non-premixed flames in both laminar and turbulent flow. Theoretical efforts are directed at the modeling of multicomponent reacting flows. Experiment and theory are closely coupled as new thrusts are designed. The overall long-term goal is to provide sufficient fundamental understanding of reaction and fluid dynamics processes in combustion to arrive at detailed predictive, physical models of practical combustion systems. This research program serves three key functions. First, it provides critical expertise in the fundamental

sciences of combustion; second, it provides information and new technologies that directly impact applied research combustion efforts; and third, it attracts scientists to the CRF to participate in ongoing research and to share in technological advances.

FY 2014 HIGHLIGHTS

Diagnostic developments allow broader & less intrusive measurements of key combustion properties. We invented a new 2D hyperspectral coherent anti-Stokes Raman spectroscopy technique, allowing single-shot, spatially resolved detection of multiple species & temperature. Varying soot properties in different regions of a flame suggest that *in situ* optical diagnostics can infer composition without extraction. We developed a polarization-separation Raman spectroscopy line imaging system that enables virtually interference-free spectroscopy in fuel-rich flames. We performed the first high-speed tomographic particle image velocimetry measurements, providing new insight into flame extinction & re-ignition. Chemical reaction and transport computations have become more efficient & accurate. Stationary points on the C_3H_5O potential energy surface have been fully characterized by an automated method. We used classical trajectories and *ab initio*-based force fields to yield first-principles diffusion coefficients accurate to within 2%. Synchrotron photoionization probe details of combustion mechanisms. Carbonyl oxide reactions with organic acids were remarkably rapid, near the gas-kinetic collision limit. Isomer-resolved measurements in 1-hexene flames showed that benzene is formed via a fulvene intermediate. We characterized initial oxidation reactions using time-resolved & isomer-specific product concentrations from the pulsed-photolytic Cl-initiated oxidation of n-butanol. A new density-weighted analysis of the direct numerical simulation of a premixed turbulent flame demonstrated a 'diffusive-reactive' range of small scales. We determined the effect of uncertainty in chemical reaction rates on flame ignition using a novel intrusive uncertainty quantification technique that remained stable in highly nonlinear computations. The first non-equilibrium theory of two-phase interfaces under trans-critical conditions was developed & applied to high-pressure fuel injection.

Chemical Composition of Soot Nanoparticles

Institution: Sandia National Laboratories-Livermore
Point of Contact: Dawn Manley
Email: dmanley@sandia.gov
Principal Investigator: Hope Michelsen
Sr. Investigator(s): Nils Hansen; Sandia National Laboratories-Livermore
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$139,000 (2014)

PROGRAM SCOPE

The goal of this program is to develop a comprehensive and predictive computer code for the chemical composition of nanoparticles produced in diffusion and premixed flames. To this end, a new generation of the multiscale AMPI code will be developed to describe the formation of soot nanoparticles as a combination of chemical and physical reaction pathways for various fuels. This development will require close collaboration between modeling and state-of-the-art experimental techniques that will guide and validate the model. This FWP includes the experimental studies that will be conducted at Sandia National Laboratories and the Advanced Light Source (ALS) to provide a rigorous basis to guide the modeling efforts at the University of Michigan. The underlying combustion chemistry of target fuels will be investigated using flame sampling molecular-beam mass spectrometry employing single-photon and resonantly enhanced multi-photon schemes. A counterflow burner will be built to provide a better

platform for controlling flame conditions. To follow the kinetics of soot particle inception and growth, we will use an online particle sampling technique followed by measurements of particle size distribution functions using a scanning mobility particle sizer. The chemical composition of soot nanoparticles will be characterized using aerosol mass spectrometry at the ALS. These results will be directly compared with the data obtained from the new version of the AMPI code developed at University of Michigan.

FY 2014 HIGHLIGHTS

Measurements of isomeric distributions of soot precursors suggest that soot formation may involve isomers of polycyclic aromatic hydrocarbons beyond the most thermodynamically stable species, contrary to traditional assumptions.

PROGRAM SCOPE

Our goal is to develop an understanding of the chemical reactions, energy transfer processes, and coupled kinetics processes involved in combustion. This effort will ultimately provide the foundation for predictive combustion modeling. Our approach combines a theoretical effort in the energetics, dynamics, and kinetics of chemical reactions with an experimental effort in thermochemistry, dynamics, and kinetics under both chemically isolated conditions and the more complex conditions of flames and engines. The effort is split ~50/50 into theory and experiment. The theoretical effort embraces both applications of existing theoretical methods and the development of new theoretical methods. Electronic structure techniques that determine intermolecular forces, dynamics techniques that determine molecular responses to these forces, and kinetics techniques to determine the rates of the resulting reactions are all being pursued. Simulations of more complex combustion environments involving coupled kinetics and transport are being developed, along with approaches for uncertainty analysis and sensitivity analysis. The experimental effort encompasses state-resolved measurements at low temperatures, thermal reaction kinetics measurements at high temperatures, and photoionization and photodissociation measurements of thresholds and state-resolved product distributions. Reaction rates, branching ratios, product distributions, the effect of initial vibrational excitation on reactivity, and ion-cycles for thermochemical information are all being examined. Both the theoretical and experimental components of the program are vertically integrated to span the range of phenomena relevant to the study of chemical reactivity. The group's greatest asset is the synergy that results from

the strong interaction between the theoretical and experimental efforts. The group's work is designed to provide a fundamental understanding of both major and trace reactions of importance in combustion.

FY 2014 HIGHLIGHTS

Over the past year, we have performed new experimental and theoretical studies addressing a wide range of problems relevant to the thermochemistry, dynamics, kinetics, and modeling of combustion processes. A few highlights from the past year are mentioned here. (1) A new version of the Active Thermochemical Tables (ATcT) was released (see the website: www.atct.anl.gov) providing accurate thermochemistry for nearly 1000 species of relevance in combustion. (2) A combined experimental and theoretical study of abstraction reactions involving OH and methanol or propane revealed that the product radicals can be very 'hot' (internally excited). These hot radicals can have a significant effect on subsequent reactions, and the general implications of this phenomenon are now being explored. (3) A new miniature shock tube for high-temperature studies of combustion chemistry was tested at both the Advanced Photon Source and the Advanced Light Source. The portable nature of this device is unique, and will allow many powerful tools based on x-rays and vacuum-ultraviolet light to be applied to shock-tube experiments for the first time. Such studies should provide new insight into high-temperature chemistry, as well as into processes such as soot and particle formation. (4) An approach for performing sparse global sensitivity analysis (GSA) was developed that greatly reduces the number of simulations required to achieve accurate results. This advance has allowed GSA for problems that previously would have required intractable computational resources. For example, sparse GSA was applied to the combustion of an n-heptane/methyl butanoate blend in a compression ignition engine, allowing the identification of key sensitive reactions and, ultimately, the improvement of the simulations. The approach can be applied not only to the chemistry, but also to the investigation of sensitivities to other engine parameters.

Adsorption Equilibrium and Kinetics at the Goethite-Water Interface

Institution: Ohio State University
Point of Contact: Heather Allen
Email: allen@chemistry.ohio-state.edu
Principal Investigator: Heather Allen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$124,697 (2014)

PROGRAM SCOPE

We are developing an approach for metal surface complex prediction to predict adsorption behavior. We combine the use of several techniques including bulk adsorption experiments, X-ray absorption, infrared, total internal reflection Raman, and vibrational sum frequency generation (XAS, IR, TIR-Raman, VSFG) spectroscopies, and molecular modeling to investigate ion adsorption at mineral surfaces. XAS and TIR-Raman provides data on how the metal binds to the surface (e.g., monodentate, bidentate), IR provides data on bulk anion adsorption at mineral surfaces from aqueous solutions, and VSFG provides surface specific data on anion adsorption at the mineral surface as well as impact of adsorbed metal-anion pairs on water structure at the mineral surface. Molecular modeling is used to guide spectroscopic data interpretation by providing information on water structure around ions in solution and the structure of metal-anion complexes in aqueous solutions. In addition, molecular modeling is used to provide insight into water structure at mineral surfaces, the surface sites involved in ion adsorption, and the distribution of ion pairs between aqueous solution and the mineral surface. Our studies have focused on systems involving alkaline earth metal (Mg^{2+} , Ca^{2+} , Sr^{2+} , Ba^{2+}) and heavy metal (Co^{2+} , Cd^{2+}) cations. The anions we have selected for study include Cl^- , NO_3^- , ClO_4^- , SO_4^{2-} , SeO_3^{2-} , and SeO_4^{2-} . Ion adsorption and the potential formation of ternary complexes on silica (quartz, amorphous silica), alumina (corundum and gibbsite), and ferric iron oxides (goethite and hematite) are under investigation.

FY 2014 HIGHLIGHTS

Research taking place in the Allen Lab of Ohio State has primarily been focused on using TIR-Raman spectroscopy for the investigation of (1) the effects of adsorption of simple oxyanions (ClO_4^- , NO_3^- , SO_4^{2-}) on the interfacial pH at the aqueous/silica (SiO_2) interface, and (2) the selenium oxyanions (SeO_3^{2-} , SeO_4^{2-}) adsorption to silica and ferric iron oxides (e.g., hematite ($\alpha-Fe_2O_3$)), two common mineral oxides relevant to geochemistry. TIR-Raman spectroscopy is analogous to attenuated total reflection infrared (ATR-IR) spectroscopy in that it uses the evanescent electric field generated under the TIR condition to probe the mineral/aqueous interface. The evanescent field scatters by interacting with ions bound to mineral surface groups and dissolved in the bulk. In comparison to ATR-IR, TIR-Raman spectroscopy has the advantage of increased surface specificity as the probing depth of the evanescent field in the aqueous phase at visible wavelengths (400–800 nm) will be 200–400 nm. The adsorption of geochemically relevant oxyanions (perchlorate (ClO_4^-), nitrate (NO_3^-), and sulfate (SO_4^{2-})) on the interfacial pH of the silica/aqueous interface was investigated. As the adsorption at the charged silica/aqueous interface is characterized by the protonation of oxyanions, these results suggest that they

have different abilities to modify the silica surface as their affinities for protonation are different in the interfacial region. By applying the Henderson-Hasselbach model and using the areas of the peaks associated with the deprotonated and protonated oxyanion species, we estimate the interfacial pH at the silica/aqueous interface for each oxyanion solution: SO_4^{2-} (3.2 ± 0.6) > ClO_4^- (0.0 ± 0.3) \sim NO_3^- (-0.2 ± 0.1), which differs significantly from the bulk pH (2.0 ± 0.2). This result suggests that nitrate and perchlorate oxyanions tend to modify the silica surface to be more positively charged, whereas sulfates leave it relatively neutral.

Towards a Predictive Thermodynamic Model of Oxidation States of Uranium Incorporated in Fe(Hydr)Oxides: the Role of Coordination Environments and Charge Compensation Mechanisms

Institution: North Texas, University of
Point of Contact: Paul Bagus
Email: bagus@unt.edu
Principal Investigator: Paul Bagus
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$54,000 (2014)

PROGRAM SCOPE

The overall objective of the joint efforts with the collaborators at PNNL is to understand the role of the U environment, including its coordination, on the reduction of U(VI) to U(V) and U(IV) at the ferrous mineral-fluid interface. Key experimental techniques used include x-ray photoemission spectroscopy, XPS, and x-ray adsorption near edge structure, XANES. The theoretical efforts summarized here are directed toward understanding the chemical interactions from the analysis of these core-level spectra. These efforts have had substantial recognition and impact. The review describing how XPS can give insights into materials properties published by Bagus, Ilton, and Nelin in Surface Science Reports in 2013 continues to be among the 25 most downloaded papers. While the initial efforts have involved the theoretical interpretation of XPS; the focus has been extended to stress XANES. We expect to extract a wealth of geochemical information because the methods we use take full account of the contributions to the XANES of multiplets, intermediate coupling, and covalent mixing. The scope of the theoretical efforts is twofold. (1) To improve the theoretical and computational capabilities for the electronic structure of initial and core-excited states, especially for many-body effects. And, (2) to apply these unique theoretical capabilities to resolve key issues for U and for ferrous minerals. In this period, there have been computational breakthroughs that have allowed us to treat more complex and more realistic models of geochemical systems. These have included a new diagonalization program faster by over a factor of 6 to allow including the additional many-body effects needed to more accurately describe XPS satellites. We have also extended our ability to determine XANES intensities so that we could study distorted octahedral models of UO_x ; see highlights. Further enhancements planned for FY 2015 will give capabilities to treat the XPS and XANES for complex species.

FY 2014 HIGHLIGHTS

New methods developed to accurately characterize the extent of covalent mixings in heavy metal oxides and to determine how core-level spectra reflect this chemical bonding were reported. An important feature of this methodology is that, for the first time, estimates can be made of the uncertainty in the assignment of effective charges. The essence is that the number of electrons to be assigned to anions and cations are determined separately by projection of sub-unit orbitals without, as is normally done,

imposing the constraint that the total number of electrons be fixed. The deviation of the gain in cation charge and the loss of anion charge from equality is a direct measure of the uncertainty of the assignment. Two important results for XPS have been found. First, there is substantial covalent character, especially for heavier, lanthanide and actinide, cations and, second, the closed shell screening, a concept first introduced by Bagus and Ilton, is much more important than expected. This methodology has been applied to XANES. The analysis of XANES with Ilton, PNNL, was initiated to study how the broadening of deep edge U XANES depends on the U oxidation state. The broadening was explained by the different covalent mixing for different oxidation states. This initial work has been extended in FY2014. The NEXAFS for distorted crystal geometries has a direct relationship to covalency. The role of embedding of the local cluster for UO_x has been examined using methods developed for simpler MgO. More realistic embeddings have led to differences in the XANES; work will be continued in FY 2015. Studies of the Fe 2p XANES edges have been initiated with the goals of understanding the sensitivity to XANES to Fe charge state and to the environment. New effects, not key in UO_x , are multiplet splitting and intermediate angular momentum coupling, which can bring a dramatic richness to the XANES. The promising initial results will be investigated further in FY 2015.

Aqueous Geochemistry at High Pressures and Temperatures

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Jay Bass
Email: jaybass@illinois.edu
Principal Investigator: Jay Bass
Sr. Investigator(s): Daniel Farber; Lawrence Livermore National Laboratory
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This project is aimed at experimental characterization of the physical nature of aqueous solutions and carbon dioxide at extreme pressure and temperature conditions relevant to processes occurring in the interior of the Earth. Research in this area has long been limited by the extreme experimental challenges and lack of data under the appropriate conditions. The vast majority of studies of aqueous geochemistry relevant to terrestrial problems of fluid-rock interactions have been conducted at 0.3 GPa or less, and the widely used Helgeson-Kirkham-Flowers equation of state for aqueous species is applicable only at $\sim < 0.5$ GPa. These limits are unfortunate because fluid flow and reactions plays a central role in many deeper environments. Recent efforts including our own, have resulted in new experimental techniques that now make it possible to investigate properties of homogeneous and heterogeneous equilibria involving aqueous species and minerals over a much broader range of pressure and temperature appropriate for deep crustal and upper mantle processes involving water-rich fluids. We are carrying out 1) Brillouin scattering measurements of the equations of state and molar volume of water and carbon dioxide to over 10 GPa and 870K using precise resistance heating of samples under pressure in the diamond anvil cell, and 2) the phase diagrams of the water and CO_2 , and 3) Exploring new experimental approaches to measurements of sound velocities, EOS, and phase relations by Brillouin scattering to far greater pressures and temperatures.

FY 2014 HIGHLIGHTS

Our earlier work revealed that there are significant differences in the equation of state (EOS) and especially the phase diagrams of water, depending on the experimental details of resistance heating

experiments using the diamond anvil cell. New experimental approaches are needed to accurately determine the EOS and phase relations of water and related substances at extreme pressure-temperature conditions. Our most recent highlights include: 1) Development of new gas pressure membrane diamond cells for fine and accurate control of pressure; 2) Determination of the elastic properties and EOS parameters of solid carbon dioxide by Brillouin scattering measurements at high pressure across the CO₂ I-III phase transition at ~10 GPa. Our results are in agreement with recent synchrotron X-ray diffraction measurements of the I-III transition, and Raman measurements of a high-pressure electronic transition in CO₂; 3) Development of a new apparatus for Brillouin scattering sound velocity and EOS measurements at ultra-high pressure-temperature conditions. With this new system, heating of pressurized samples in the diamond cell is achieved via a carbon dioxide laser. Initial Brillouin scattering measurements were successfully made on liquid water to temperatures of 2500K, greatly exceeding the P-T limits of previous measurements using resistance heating. This experimental advance will allow a new generation of measurements of the properties and phase relations of water and other materials under pressure-temperature conditions that were previously unattainable.

Deformation and Fracture Properties of Shale at Nanoscale

Institution: Stanford University
Point of Contact: Ronaldo Borja
Email: borja@stanford.edu
Principal Investigator: Ronaldo Borja
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$142,576 (2014)

PROGRAM SCOPE

Shale is a fine-grained sedimentary rock composed of clay and organic materials forming a heterogeneous matrix or composite. Shales are often rich in unconventional oil and natural gas, but their low permeability makes the extraction of this energy resource difficult. The permeability of shales can be increased by hydraulic fracturing, a technique that paved the way for most of the several giant natural gas fields now in operation. The deformation and fracture properties of shales depend on the mechanical properties of their basic constituents, including the solid clay particles and the nanoscale porosity forming the porous clay composite. A great deal of understanding of the overall mechanical properties of shales can be gained by studying the deformation and fracture properties of these constituents. This project will build upon our recently acquired ability to image (using FIB-SEM) the 3D geometry of a porous shale sample to nanometer resolution, as well as test this sample on a nanoindenter at both the particle and (sub-micron) composite scales, to develop a 3D mechanistic model that will interpret the results of nanoindentation tests. We will use the finite element method to model the clay particle as well as the shale composite. We will capture the effects of the elasticity of the particle, plastic yielding, and damage induced by the indenter, including the fracturing and chipping within the mineral grains and around the perimeter of the indent. We will use an enhanced finite element formulation based on the assumed enhanced strain finite element method to capture damage emanating from the indentation tests.

FY 2014 HIGHLIGHTS

Nanoindentation tests, spanning various length scales ranging from 200 nanometers to 5 micrometers deep, were performed on a sample of organic-rich Woodford shale in both the bedding plane normal

and bedding plane parallel directions. Focused ion beam milling (FIB), scanning electron microscopy (SEM), and energy dispersive X-ray spectroscopy (EDX) were utilized to characterize the shale at the scale of the nanoindentation testing as being comprised predominantly of clay and other silicate minerals suspended in a mixed organic/clay matrix. The nanoindentation tests reveal the mechanical properties of the relatively homogeneous constituent materials as well as those of the highly heterogeneous composite material. Loads on the order of a few milliNewtons produced shallower indents and demonstrated the elastic-plastic deformation response of the constituent materials, whereas higher loads of as much as a few hundred milliNewtons produced deeper indents revealing the response of the composite matrix. In both cases, significant creep was observed. We use nonlinear finite element modeling utilizing an isotropic critical state theory with creep to capture the indentation response by calibrating plastic material parameters to the laboratory measurements. The simulations provide a means of extracting plastic material parameters from the nanoindentation measurements, and reveal the capabilities as well as limitations of an isotropic model in capturing the response of an inherently anisotropic material. The results are reported in a recently published paper: Bennett, K.C., Berla, L.A., Nix, W.D., Borja, R.I. (2015). Instrumented nanoindentation and 3D mechanistic modeling of a shale at multiple scales, *Acta Geotechnica*, DOI:10.1007/s11440-014-0363-7.

Computational and Experimental Investigations of the Molecular Scale Structure and Dynamics of Geologically Important Fluids and Mineral-Fluid Interfaces

Institution: Alfred University
Point of Contact: Geoffrey Bowers
Email: bowers@alfred.edu
Principal Investigator: Geoffrey Bowers
Sr. Investigator(s): R. James Kirkpatrick; Michigan State University
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$28,551 (2014)

PROGRAM SCOPE

Research supported by this grant and the closely linked DE-FG02-08ER15929 (R.J. Kirkpatrick, PI, Michigan State University) focuses on addressing fundamental scientific questions regarding the structure, dynamics, and reactivity of geochemically important fluids, fluid-mineral interfaces, and confined fluids on a molecular scale using a combination of computational molecular modeling and spectroscopic methods, primarily nuclear magnetic resonance (NMR) spectroscopy. The Bowers group handles the wet chemistry, much of the basic sample characterization, and drives a majority of the NMR spectroscopic investigations. The Kirkpatrick group is responsible for the computational modeling and part of the NMR experiments. Collaboration between the two groups is very close, with computational modeling motivating our spectroscopic studies and spectroscopic results helping to identify key questions for computational modeling. The combination of computational and spectroscopic approaches is highly effective in addressing otherwise intractable molecular-scale problems concerning the fundamental physical and chemical behavior of fluids and interfaces, which are central to understanding such geological problems as the migration of chemicals in soil, sediments, and rocks, and the processes by which fluids alter sediment and rocks. The objectives during this grant period focus specifically on developing a deeper understanding of molecular-scale structure and dynamics in smectite-natural organic matter (NOM) composite materials that are ubiquitous in the soils, sediments, and many sedimentary rocks. We are providing key new insights into how NOM, a key sink for many inorganic and organic contaminants, influences the binding and dynamics of cations, aqueous fluids, and

supercritical CO₂ in the composites; the binding structures and mechanisms of NOM-mineral association under a variety of geochemical conditions; and how NOM influences the physics of composite hydration.

FY 2014 HIGHLIGHTS

Our work focused principally on understanding how pH, charge-balancing cation (CBC), and solution ionic strength influence the structures and molecular-scale ion and fluid behaviors in pure flocculated NOM and in hectorite (a trioctahedral smectite)-Suwannee River NOM composites. Helium-ion microscopy (HeIM) and X-ray diffraction (XRD) reveal a variety of morphologies in flocculated NOM depending on the ionic strength of the preparatory solution, pH, and CBC present. In contrast, HeIM and XRD show that homogeneous composites of hectorite and NOM form at pH 12 independent of the ionic strength and CBC. We also find that the NOM-rich features in composites examined last year have identical morphologies to pure flocculated NOM. The composite hydration physics reflect the hydration behavior of the base hectorites, with NOM exerting a minor influence on composite retention of 2H₂O when exposed to a dry atmosphere. Associated NMR experiments show similar cation coordination behavior and dynamics as the base clays, suggesting that most Cs⁺, K⁺, Na⁺, and Ca²⁺ remain associated with the smectite and mobile regardless of pH, ionic strength, or presence of NOM. However, subtle variations in the NMR results indicate some influence of NOM on the cation coordination environment. Related computational studies are in progress at MSU. Composites equilibrated at 43% RH and exposed to supercritical CO₂ (scCO₂) at conditions relevant to geological CO₂ sequestration show that the ¹³³Cs chemical shift is highly influenced by the presence of both NOM and scCO₂, but that the MHz-scale dynamics are unaffected (unlike Na-hectorite composites). In contrast, the ⁴³Ca NMR results are not influenced significantly by NOM or scCO₂, suggesting little direct interaction with Ca²⁺. We observe no evidence of carbonate mineral formation in any composite exposed to scCO₂ to date. Again, molecular modeling is beginning to shed new light on these results (see highlights in DE-FG02-08ER15929).

An Investigation of Roughness and Weathering at the Bedrock-Regolith Interface

Institution: Pennsylvania State University
Point of Contact: Susan Brantley
Email: brantley@eesi.psu.edu
Principal Investigator: Susan Brantley
Sr. Investigator(s): Marina Lebedeva; Pennsylvania State University
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$600,000 (2014-2017)

PROGRAM SCOPE

Research funded by the Department of Energy Office of Basic Energy Science aims to develop understanding of geological systems that are important to our national well-being. For example, to understand the evolution of nuclear waste repositories or hydraulically fractured rocks requires projections of the evolution of rock-water systems forward in time. The geochemical community has developed the capability to provide numerical simulations of rock-water systems but often the underlying conceptual models are not adequate descriptors of the natural systems or the appropriate parameterizations for model phenomena are lacking. In this DOE-OBES project, conceptual models are tested for the most well studied examples of geochemically evolving systems found at earth's surface: weathering rocks. The approach incorporates numerical modelling and field measurements of different rocks in different climates at different spatial scales. Researchers in this project are testing this conceptual model: rocks start as fractured porous materials which increasingly break into smaller

fragments during weathering. Inside the fragments, reactants move to mineral grain surfaces by diffusion, but in the soils surrounding the fragments, advection dominates transport. To parameterize models for a few targeted weathering systems, depth profiles are being measured for these reactants: i) the mineral-water interface; ii) CO₂, the main weathering acid; and iii) O₂, the ultimate electron acceptor. The project incorporates i) analyses of strategically-chosen regolith profiles developed on ridgetops and hillslopes; ii) measurements of O₂ and CO₂ in boreholes on crystalline and shale rock; iii) an investigation to determine if oxidation causes fracturing in cores of granite and diabase; and iv) a study targeting how O₂ and CO₂ affect deep weathering of a rock type that can be considered as “pre-fractured” – shale. With these efforts, deeper understanding of weathering systems is emerging.

FY 2014 HIGHLIGHTS

We are planning to complete neutron scattering on regolith developed on PA diabase and on new regolith profiles we will sample on ultramafic rocks. We have gathered samples of the diabase; to sample ultramafics we are planning to drill in summer 2015. We have been developing a collaboration with Beth Parker and John Cherry at Univ of Guelph (Canada) as we learn to use their i) back pack core drill; ii) Winkie drill; and iii) Hydra drill. We have continued to monitor our boreholes in Virginia and Pennsylvania that are instrumented with soil gas sensors. We are currently writing up these results for publication in summary form and are developing a second paper describing temporal variations in gas–depth data with more specifics. L. Anovitz at Oak Ridge National Laboratory has heated granite core samples with selenious acid to manufacture samples that show increasing oxidation of the ferrous iron. The high temperatures and acid concentrations used in our initial experiment were chosen to maximize oxidation. These samples have been cored and are being prepared for chemical analysis and neutron scattering. We are now gathering samples of shale for analysis of nano-porosity as a function of depth. We target shales from two well-characterized sites: (1) the Rose Hill shale in central PA, (2) the Yager terrain shale in the Eel River Critical Zone Observatory, in the coastal range of northern California. Neutron scattering on other shales from depth or from weathering systems (Marcellus and Rose Hill Formations) is also ongoing. Finally, we continue to test the idea that the weathering advance rate depends on the curvature and roughness of the reaction front: specifically, the thickness and depth of the bedrock/regolith interface is larger where curvature is larger.

Pathways for Oxygen-Isotope Exchanges in Nanometer-Size Aqueous Clusters

Institution: California-Davis, University of
Point of Contact: William Casey
Email: whcasey@ucdavis.edu
Principal Investigator: William Casey
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$140,413 (2014)

PROGRAM SCOPE

The project employs isotope-exchange methods and spectroscopy to elucidate mechanisms of reactions affecting oxide ions in water. The work is now focused on extending NMR spectroscopy to pressures of up to 20 kbars. High pressures are useful for detailing changes in coordination and solvation in reaction mechanisms. We have invented such an NMR probe and use it to measure activation volumes for isotope-exchange reactions and changes in molecular conformations in aqueous solutions.

FY 2014 HIGHLIGHTS

The major accomplishment this year was the publication of the inaugural paper on NMR spectroscopy to 20 kbars, which was identified as a 'Very Important Paper' by the journal *Angewandte Chemie* and used as a cover figure. DOI: 10.1002/anie.201404994. In this work we extended by at least a factor of two the pressure range over which NMR spectroscopy can be accomplished on aqueous solutions. We ran experiments to such pressures that not only the volume of reaction, but also the compressibility of the reaction, were measurable. It was a stunning advance to the field of reaction mechanisms in aqueous reaction kinetics. This NMR probe is now being used to extend the measurements of T1 (longitudinal relaxation) of D₂O and ¹³⁹LaCl₃ solutions in order to demonstrate our bone fides to the community. We have matched the work of Jonas at lower pressures and extended it to 1.6 GPa. These measurements are important to geochemists because the influence of changes in the solution dielectric constant diminish beyond about 0.8 GPa and the intrinsic reaction volumes and compressibilities can be measured at pressures beyond this point, which contributes directly to geochemical theories of electrolyte solutions at high pressures. Because of recent extension of the dielectric constant of water to 6.0 GPa via simulation, new methods of verifying the predictions are needed. With this technology, we can measure reaction volumes and speciation directly and simply at pressures of up to 2.0 GPa in aqueous solutions. A second advance is by the research team. We have designed and built a high-pressure NMR probe that allows simultaneous measurements of ¹H and ¹³C NMR spectra at pressures of up to 2.0 GPa in aqueous solutions. The design and fabrication is complete and we are now testing it. The design is easily adapted to spectroscopies beyond NMR. Several other publications were also accepted during the funding period, but nothing as spectacular as the *Angewandte Chemie* result.

Nanopore Confinement of C-H-O Mixed-Volatile Fluids Relevant to Subsurface Energy Systems

Institution: Ohio State University
Point of Contact: David Cole
Email: cole.618@osu.edu
Principal Investigator: David Cole
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

The overarching objective of this effort is to obtain a fundamental atomic- to macro-scale understanding of the sorptivity, structure and dynamics of simple and complex C-H-O fluids at mineral surfaces or within nanoporous matrices over temperatures, pressures and compositions encountered in near-surface and shallow crustal environments. To achieve this goal we (a) assess the adsorption-desorption behavior of methane, related hydrocarbons and CO₂ on a variety of mineral substrates and in nanoporous matrices, (b) characterize the microstructure and dynamical behavior of methane and related HC volatiles at mineral surfaces and within nanopores with and without H₂O present at relevant P-T-x subsurface conditions, and (c) utilize molecular-level modeling to provide critically important insights into the interfacial properties of these mineral-volatile systems, assist in the interpretation of experimental data and predict fluid behavior beyond the limits of current experimental capability. A scientifically diverse, multi-institutional team (Ohio State University, University College London, Oak Ridge National Lab, Pacific Northwest National Lab, Hunter College) are utilizing novel experimental and analytical techniques in concert with state-of-the-art theory, modeling and simulation approaches to address these issues. There is a special emphasis on building synergistic links between results obtained

from various neutron scattering and NMR studies which are integrated into our research portfolio with molecular dynamics modeling, to provide new phenomenological insights.

FY 2014 HIGHLIGHTS

Our research focuses on the behavior of simple and mixed volatile species such as CO₂, CH₄, C₂H₆, C₃H₈, H₂O and their mixtures confined to silica, alumina, titania and montmorillonite pores ranging in size from 1.5 to 35 nm. We use a combination of NMR and neutron scattering spectroscopy coupled with MD to probe the molecular behavior in the fluid-solid systems. Key results from these studies include: (1) Even for weak to moderate wetting fluids like the light alkanes and CO₂, respectively, the surface chemistry as well as pore size has a significant impact on changes in fluid density and volume of the adsorbed layer of a pure fluid as pressure and temperature increase. (2) The addition of a second carbon-bearing phase has a profound effect on the competition for sorption sites, phase chemistry and the dynamical properties of all phases present in the pore. (3) In addition to pores size, the extent of hydrophilicity (as -OH or H₂O) influences the selectivity of adsorption and associated hydrogen bonding of weakly interacting carbon-bearing species. (4) Low solubility phases such as methane may exhibit profound increases in concentration in nanopores in the presence of water at elevated pressures and ambient temperature compared to bulk values and even form clathrate cage structures.

A New Probe for Rock Elasticity - Time-of-flight Modulation (TOFM)

Institution: Nevada, University of
Point of Contact: Timothy Darling
Email: darling@unr.edu
Principal Investigator: Timothy Darling

Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This project uses acoustic and vibrational spectroscopic measurements to isolate physical properties of porous rocks and finite-element modeling (FEM) to explore structure effects. The motive is the large reversible, (RNL) and irreversible, hysteretic, (HNL) nonlinear (NL) mechanical response of such materials and their fluid reservoir properties. The experimental program focused on fluids in a Berea sandstone sample. An extended experiment of removing and adding volatiles during measurements explored the mechanical-chemical interaction. Our experiments demonstrated that both RNL and HNL effects remain in the Berea sample when the vast majority of volatiles have been removed by heating and evacuation to UHV. Changing water content in clay components needs more study, but it seems the NL response is dominated by the silica structural network, which led us to study the link between the grain-bond-void scale and the macroscopic scales of the network. An FEM study was used to attempt to link the network and scaling of voids and bonds to the acoustic spectrum. Our model of grains and random bonds suggests that the identification of an elastic network with an equivalent homogeneous elastic solid is nontrivial, in that the modeled spectrum of vibrations of a random network are not reproduced by an homogeneous, isotropic, linear elastic solid with best-fit moduli, of the same boundary size and average density, up to the current size of the network model matrix (8x8x8). Clearly this requires more study since it is widely assumed that a sufficiently large number of randomly connected grains will behave as a homogeneous, isotropic solid.

FY 2014 HIGHLIGHTS

In the course of this project, two undergraduate students were trained, one continuing to a degree in geology at UNR and one moving to graduate work in geophysics at CalTech. The experiments and models produced large quantities of data, from which results were presented in talks and poster presentations at the AGU Fall Meetings in 2011-2013 and at two BES Geosciences meetings. The primary results are: that the fluid content influences, but is not responsible for nonlinear effects in Berea sandstone, and that the assertion that every porous network structure can be replaced with an equivalent linear homogeneous, isotropic elastic solid must be treated carefully since initial results suggest geometric nonlinearity and irreversibility of force-chain paths create deviations. Some related prior experimental results were analyzed and published as a book chapter [1] under the auspices of this project.

Time-Lapse Seismic Monitoring and Performance Assessment of CO₂ Sequestration in Hydrocarbon Reservoirs

Institution: Texas A&M University
Point of Contact: Akhil Datta-Gupta
Email: datta-gupta@pe.tamu.edu
Principal Investigator: Akhil Datta-Gupta
Sr. Investigator(s): Richard Gibson; Texas A&M University
Yalchin Efendiev; Texas A&M University
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$213,520 (2014)

PROGRAM SCOPE

Our work focuses on fully integrating fluid flow and seismic data for monitoring injected CO₂ fronts by developing robust methods for reservoir characterization via coupled seismic and fluid flow modeling and joint inversion of seismic and fluid flow data. For computational efficiency and suitability for large-scale field applications, we are developing novel streamline-based compositional modeling of CO₂ sequestration including compressibility, stress-sensitivity, compositional and geochemical effects. We perform comprehensive simulations of the gas injection process accounting for the phase behavior of CO₂-reservoir fluids, the associated precipitation/dissolution reactions and the accompanying changes in porosity and permeability. The simulation results are then used to model the changes in seismic response with time. For data integration and uncertainty assessment, we adopt an efficient Bayesian framework using reversible jump multistage Markov Chain Monte Carlo (MCMC) methods.

FY 2014 HIGHLIGHTS

Our recent research efforts emphasized the development of reversible jump MCMC stochastic inversion algorithms for the automated upscaling (blocking) of acoustic well logs and for estimation of seismic impedance from seismic images. This approach has several practical advantages, one of the most important being automatic determination of the optimal parameter space during inversion. The routine application of the rjMCMC, however, can be computationally prohibitive for inversion of 4-D seismic data utilized for monitoring of fluid movements in the subsurface where data volumes are large. We have, therefore, investigated several approaches for accelerating computations. Some of the most

promising results apply novel multiscale finite element methods for simulating seismic wave propagation in heterogeneous reservoirs with changing fluid distributions. We have also continued our advancement of streamline based compositional modeling of CO₂ injection in hydrocarbon reservoirs. The novel aspect is the ability to incorporate gravity and capillary effects without adversely impacting computational efficiency. We use an orthogonal projection method to reformulate the streamline transport equations so that the fluxes of capillary and gravity are separated into components parallel and orthogonal to the total velocity defining the streamline trajectories. The orthogonal terms are calculated on the underlying three dimensional grid. The ability to effectively incorporate transverse fluxes in streamline transport calculations will be a step change in streamline simulation in general. We will demonstrate our proposed treatment of transverse fluxes using high resolution simulation of CO₂ migration in the subsurface with potential applications to both improved oil recovery as well as carbon sequestration.

Investigating the Physical Basis for Biomineralization

Institution: Virginia Polytechnic Inst. and State U.
Point of Contact: Patricia Dove
Email: dove@vt.edu
Principal Investigator: Patricia Dove
Sr. Investigator(s): James De Yoreo; Pacific Northwest National Laboratory
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$460,000 (2014-2015)

PROGRAM SCOPE

This project is directed at determining principles that govern interactions of simple protein analogs and key inorganic impurities with carbonate minerals to direct the formation of hierarchical structures, polymorphs, and chemical signatures. The long-term goal is to establish the physical basis of biomineralization for applications to natural and engineered Earth systems.

FY 2014 HIGHLIGHTS

We made new insights into mechanisms of CaCO₃ nucleation in the pure system (Nielsen *et al.*, 2014, Science) and on organic templates (Hamm *et al.*, 2014, PNAS). The conventional assumption of the biomineral community is that an organic matrix templates nucleation by providing a stereochemical match that lowers the nucleation barrier during cooperative organization of ions. In contrast, materials disciplines view that simple binding assays can identify good promoters of nucleation. Our experimental study demonstrates low energy barriers correlate with strong crystal-substrate binding and reconciles the concept of stereochemical matching with the conventional wisdom that 'good binders are good nucleators'. The alternative perspectives become internally consistent through the lens of crystal-substrate binding. Using a novel *in situ* TEM approach, we also show that multiple pathways of nucleation occur simultaneously during homogeneous nucleation of CaCO₃, including direct and indirect formation of all crystalline polymorphs. Amorphous CaCO₃ (ACC) particles appear first, then are consumed by vaterite or aragonite that nucleate on ACC. Using isotopic labeling and mass spectroscopy, we also investigated factors that regulate ACC composition and the resulting crystalline products and Ca isotopic fractionation in ACC, calcite growth through an ion-by-ion process, and ACC that transformed to calcite while in contact with solution (Blue *et al.*, 2014; submitted; Giuffre *et al.*, submitted). Other pubs report direct observations of ACC nucleation, coalescence and crystallization via *in situ* TEM using an electrochemical fluid cell design developed with supplemental funding to this project. These are the first

measurements of their kind on natural mineral systems. We also applied this method to studying particle-mediated growth. The mechanism—as opposed to ion-by-ion attachment—is now recognized as a common phenomenon in diverse natural and synthetic systems.

Experimental Investigation of Flow-Induced Fabrics in Rocks at Upper-Mantle Pressures: Application to Understanding Mantle Dynamics and Seismic Anisotropy

Institution: Massachusetts Institute of Technology
Point of Contact: William Durham
Email: wbdurham@mit.edu
Principal Investigator: William Durham
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$44,100 (2014)

PROGRAM SCOPE

Our project is an experimental approach to relevant Earth problems involving the flow of olivine-rich rocks in the upper mantle. We aim to quantify the rheological behavior of mantle rocks under simulated mantle conditions of high temperatures and high pressures. Measurements of stress, deformation rate, and deformation-induced crystallographic preferred orientation, which are components of the rheological relationship we seek to constrain, are carried out on samples inside the deformation-DIA using X-ray synchrotron radiation, and are conducted at beam line X17B2 at the National Synchrotron Light Source (NSLS) at Brookhaven National Laboratory. The goal of our research is to provide a better understanding of the flow strength and anisotropic features of both the lithospheric and asthenospheric mantle.

FY 2014 HIGHLIGHTS

We completed experimental runs on dry olivine during the past year and added to our database additional MTEX (Matlab)-derived information on *in situ* development of crystallographic preferred orientation (CPO) of grains during deformation, a valuable source of information related to seismic anisotropy in the upper mantle. Graduate student Nathaniel Dixon completed his thesis based on these data, and was awarded his Ph.D. degree in June, 2014. For dry, polycrystalline San Carlos olivine we find that at 1373 K and pressures from 1.5 to 9 GPa, the pressure dependence of flow in olivine is characterized by a value of the so-called activation energy of $14 \pm 3 \text{ cm}^3/\text{mol}$. This is a substantial effect, and given the >10 GPa pressure range of Earth's upper mantle, it is likely to have a pronounced effect on the thermal structure of the mantle, perhaps requiring temperatures to be warmer than otherwise expected. Shortly before the final shutdown and decommissioning of the NSLS synchrotron at Brookhaven, where we have carried out the bulk of our experimental runs over the past few years, we were able to do preliminary testing of a novel simple shear configuration in the deformation-DIA, which we hope to use in future runs at other synchrotron facilities (APS, NSLS-II). We are pleased to report that the new shear assembly performed nominally, and we should be able to employ it during our next beam time opportunity.

Collaborative Research: Evolution of Pore Structure and Permeability of Rocks Under Hydrothermal Conditions

Institution: Massachusetts Institute of Technology
Point of Contact: J. Brian Evans
Email: brievans@mit.edu
Principal Investigator: J. Brian Evans
Sr. Investigator(s): Yves Bernabe; Massachusetts Institute of Technology
Ulrich Mok; Massachusetts Institute of Technology
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$463,838 (2014)

PROGRAM SCOPE

Program scope: The transport properties of rocks can be altered by diagenetic, metamorphic, and tectonic processes. For example, porosity and transmissivity may be either increased or decreased by cataclasis, temperature or pressure cycling, pressure solution, plastic flow, crack healing, crack sealing or cementation. Similar processes are also critically important in industrial applications, including resource recovery, carbon-dioxide sequestration, and waste isolation. Often these mechanisms operate concurrently. In this project, we investigated the changes of permeability and pore geometry, owing to elastic deformation and inelastic straining of rocks by solution-transfer, pressure solution, and brittle fracturing, with and without metamorphic reactions. Better understanding of either the engineering or scientific applications requires the formulation of kinetics laws for each mechanism and the specification of the interactions among them. Thus, if loading conditions, mineralogy and kinetics laws were known, rates of porosity change for each process could be compared. But the relation between rate of porosity change and bulk properties must also be understood, because some processes are more efficient in changing permeability than others, e.g., neo-mineralization and microfracturing versus creep compaction. In this project, we used a combination of laboratory experiments, numerical calculations, and observations of microstructure to measure changes in pore volume, permeability, axial and volumetric strain rates under isostatic and conventional triaxial loading at elevated confining and pore pressures. The pore microstructure was observed using micro-CT, scanning electron microscopy, and laser confocal scanning optical microscopy. The data we obtained were used in network, finite difference and other numerical models to elucidate relations between permeability and other rock properties

FY 2014 HIGHLIGHTS

Pressure solution: We numerically simulated pressure solution creep of a three-dimensional, random pack of quartz spheres saturated with solvent fluid using a distinct element method, a non-linear contact model, and a model relating convergence rate at asperity contacts to local stress. Strain rates in the simulation were inconsistent with generic constitutive models characterized by constant activation energy and stress exponent. Instead, the data were better fit by two successive power laws proportional to t^ξ , where ξ was equal to 1 at very early times, but subsequently was as low as 0.3. The sensitivity of strain rate to stress in the simulations was significantly lower than 1 and varied with time. The apparent activation enthalpy was intermediate between that assumed for dissolution and diffusion, and decreased with time. Similar creep curves, including low values of the stress exponents, have been observed in unconsolidated packs of spherical NaNO_3 beads subjected to stresses low enough to prevent microcracking. Pressure dependence of transport properties and changes in pore connectivity and heterogeneity: In collaboration with workers from Southwest Petroleum University, Chengdu, we

performed permeability measurements on several tight sandstones to determine a non-linear, effective pressure law for permeability. We used network simulations to quantify the effect of pore connectivity and pore size heterogeneity on electrical formation factor during drainage of brine by a non-wetting and electrically non-conducting fluid (oil or gas) and to relate these changes to the geometrical and topological characteristics of the portion of the pore space saturated with brine. We also studied carbonate reservoir rocks with a bimodal distribution of large secondary, diagenetic pores contained within a porous, micro-granular matrix. Our current research studies the inter-relationship between permeability and the flow of an undersaturated fluid through carbonate rocks.

Impact of Micro- to Meso-Scale Fractures on Sealing Behavior of Argillaceous Caprocks on Carbon Sequestration

Institution: Utah State University
Point of Contact: James Paul Evans
Email: james.evans@usu.edu
Principal Investigator: James Paul Evans
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$107,000 (2014)

PROGRAM SCOPE

Wastewater and CO₂ injection may result in felt seismic events. We have pioneered a conceptual model/hypothesis that argues that a statistically significant number of the Mb 3.8–5.7 “induced” earthquakes are associated with injection into basal reservoirs or direct injection into crystalline basement rocks. Conductive basement faults are likely activated by injection due to the propagation of anomalous fluid pressures from the reservoir into the crystalline basement. Their occurrence in “tectonically quiet” regions indicates that in some cases we have an incomplete understanding of the dynamics and fate of fluids in the subsurface. In this proposal, we test our hypotheses that: 1. Injection into basal reservoirs promotes downward propagation of fluid pressure into crystalline basement rocks and increases the risk of induced seismicity, 2. Injection into overlying reservoirs with both top and bottom fine-grained seals will have a prophylactic effect. 3. We further hypothesize that conductive basement faults facilitate the propagation of elevated fluid pressures below sedimentary basins. We examine the geologic settings of injection site analogs, and characterize the structural and sedimentological features of the basal sedimentary rock–crystalline basement rock interface. We determine the rock properties at the bedrock–reservoir interface and evaluate the implications of these geomechanical characteristics for induced seismicity. We conduct field-based investigations of analog sites to assess the stratigraphic and structural controls on fluid pressure transmission at the bedrock–basal reservoir interface. Core samples collected from this basal reservoir will be used for laboratory geomechanical analysis. We will use data mining and statistical analysis for states with seismicity and those without to assess whether there is a statistical correlation between induced seismicity and basal reservoir injection.

FY 2014 HIGHLIGHTS

To date, we have:

- Conducted field work for basement-sediment interfaces to examine how small faults and fractures traverse the basement-sediment interface

- Defined cores from Michigan, Missouri, Kansas and Oklahoma that have the appropriate geological relationship, and we will visit these core this spring to study and sample
- Worked with an environmental nongovernmental organization to collate a wide range of data regarding injection rates and volumes for Class II injector wells in Ohio, West Virginia, Oklahoma, and Arkansas, and are mapping these injectors onto geologic basemaps
- We have mapped microseismicity in these states and are searching for spatial and temporal correlations between injection and seismicity

Physiochemical Evidence of Faulting Processes and Modeling of Fluid Flow in Evolving Fault Systems in Southern California

Institution: Tufts University
 Point of Contact: Grant Garven
 Email: Grant.Garven@tufts.edu
 Principal Investigator: Grant Garven
 Sr. Investigator(s):
 Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
 Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Objectives: This is a collaborative study to quantify basinal fluid flow, submarine gas migration and diagenetic effects within deforming faults in a transpressional setting that is seismically active. The field application emphasis is on faulted basins in southern California. Project Description: We have mainly targeted active faults and young (Tertiary) petroleum fields in southern California for study. Faults include the Refugio Fault in the Transverse Ranges, the Ellwood Fault in the Santa Barbara Channel, and the Newport-Inglewood in the Los Angeles Basin. Subsurface core and tubing scale samples, outcrop samples, well logs, reservoir properties, pore pressures, fluid compositions, and published structural-seismic sections are being studied to characterize the tectonic/diagenetic history and geochemical signatures in carbonate that characterize rapid CO₂ degassing. These data provide constraints for finite element models that are being developed to predict fluid pressures, flow patterns, rates and patterns of deformation, subsurface temperatures and heat flow, and geochemistry associated with large fault systems.

FY 2014 HIGHLIGHTS

Measured gas flow data from a natural submarine seep area in the Santa Barbara Channel helps constrain fault permeability $k \sim 30$ millidarcys for the large-scale upward migration of methane-bearing formation fluids along one of the major fault zones. At another offshore site near Platform Holly, pressure-transducer time-series data from a 1.5 km deep exploration well in the South Ellwood Field demonstrate a strong ocean tidal component, due to vertical fault connectivity to the seafloor. Based on tidal-signal amplitude attenuation and phase shift at depth, we estimate permeability $k \sim 40$ millidarcys (hydraulic conductivity $K \sim 3 \times 10^{-8}$ m/s) and specific storage $S_s \sim 3 \times 10^{-6}$ m⁻¹. The tidal-derived hydraulic properties also suggest a low effective porosity for the fault zone, $n \sim 1$ to 3%. Our studies of faults in the Los Angeles basin, suggest an important role for the trapping of petroleum along the Newport-Inglewood fault zone (NIFZ). We constructed 2-D numerical models to characterize large-scale multiphase flow in this system. Our two-phase flow models replicated formation-scale patterns of petroleum accumulation associated with the basin margin, where deep faults resulted in stacked petroleum reservoirs, over time scales of ~ 300 kyr. The models also predict a strong preference for

focused upward flow along the NIFZ, confirming the structural controls. Furthermore, helium isotope data collected by my co-PI (J.R. Boles) document elevated leakage of fluids from the Earth's mantle along sections of the NIFZ near Long Beach, and our calculations indicated a fault permeability of about 2 to 20 microdarcys for ultra-deep fluid flow of 6 to 60 mm/yr.

Early Stages of Sea Urchin Biomineralization

Institution: Wisconsin-Madison, University of
Point of Contact: Pupa Gilbert
Email: PUPA@PHYSICS.WISC.EDU
Principal Investigator: Pupa Gilbert
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$225,000 (2014)

PROGRAM SCOPE

Biominerals are crystalline, complex mineral systems formed by organisms. They master particle-by-particle rather than ion-by-ion crystal growth, thus they grow 100x faster and larger than synthetic crystals, with precise nano-, meso-, macro-morphology control, in environmentally-friendly conditions. Such skills, refined by 530 million years of evolution, could be harnessed for energy production, nanofabrication, or CO₂ sequestration. But first we must understand how natural biominerals form. Therefore, biomineral formation mechanisms, termed biomineralization, are of fundamental and applied interest. Here we study how sea urchin biominerals grow, and in particular the early stages of sea urchin biomineral formation mechanisms, collectively termed biomineralization.

FY 2014 HIGHLIGHTS

We identified that there is more than one mechanism at play in sea urchin biominerals as well as synthetic systems, forming by crystallization of amorphous precursor phases. Ion-by-ion and by particle-by-particle crystal growth take place concomitantly. This research was published in Gal *et al.* *Adv. Funct. Mater.* 24, 5420-5426, 2014.

Our subcontractors identified the role of Ca from seawater in the early stages biomineralization in sea urchin embryos. This work was published in Vidavsky *et al.* *Procs. Natl. Acad. Sci. USA* 111, 39-44, 2014.

Comparative Reactivity of Bacteriogenic and Abiogenic Mineral Nanoparticle Analogs

Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$143,899 (2014)

PROGRAM SCOPE

The nanoscale forms of metal sulfides constitute a major fraction of the metal and/or sulfur loads in natural and anthropogenic systems. The origin, transport, and fate of nano-metal sulfides are relevant for a multitude of geological and environmental processes including biogeochemical cycling of elements,

environmental remediation, resource recovery, ecotoxicity evaluation, and biomineralization. Both biological and abiotic activities may contribute to the natural inventory of nano-metal sulfides. Yet, a basic understanding for the difference between the biogenic and abiogenic nanosulfides in terms of size, morphology, crystal structure, and surface reactivity is completely unavailable. And further, the mechanisms involved during the biological formation processes are poorly understood. This lack of information provides major motivation for our current project, which is composed of three major tasks. In Task 1, we compare the physicochemical properties (with an emphasis on size, crystallinity, crystal structure, and surface reactivity) of the metal sulfides (i.e., Zn-, and Fe-sulfides) produced via low-temperature aqueous pathways involving/not involving bacterial sulfate-reduction. Based on the results, we also aim to reveal the underlying formation mechanisms for the biogenic and abiogenic metal sulfides. As a follow-up (Task 2), we investigate the in-situ transformation/aging processes of the biogenic versus abiogenic nano-metal sulfides. And in Task 3, we examine and combine the findings of our experimental studies with field observations. The ultimate goal of the project is to obtain a systematic knowledge for the (trans)formation mechanisms of nano-metal sulfide and to illuminate the role of microbial activities in contributing to the inventory of nanoparticles in nature. The specific metal sulfides to be studied include Zn- and Fe-sulfides.

FY 2014 HIGHLIGHTS

In the past year, we have completed the major experimental work concerning the Zn-S system. Importantly, we have demonstrated that biological and abiotic processes at the same P-T conditions cause distinctive particle sizes, morphology, and crystal structure in the formed zinc sulfide nanoparticles. Briefly, the bacterial activities of dissimilatory sulfate reduction led to the formation of nanocrystals of mixed sphalerite and wurtzite phases resulting in high-density structural disorder (i.e., twins and stacking faults in the resulting nanocrystals). The primary size for the biogenic particles is in a range of ~3 - 12 nm. By contrast, the abiotic processes via titration/diffusion-controlled precipitation produced polycrystalline aggregates of ZnS. High-resolution images showed that these abiogenic aggregates are composed of randomly-oriented crystals with a primary size of ~1 - 2 nm. The aggregate size for the abiogenic ZnS is in a range of 15-30 nm. Further, we have revealed the underlying mechanisms involved during the biological and abiotic formation of ZnS nanoparticles. Overall, the formation of ZnS from aqueous solutions is a nucleation-dominated, crystallization-restricted process, manifested in the exclusive occurrence of ZnS nanoparticles in the biological and various abiotic systems. The difficulty in the ZnS crystallization likely stems from the surface instability of the ZnS growth units. This instability likely results from the permanent dipole moments on various important growth surfaces. In the biological system, the presence of polyanionic ligands may effectively screen dipolar surfaces by interacting with the polar faces of the growth units, and thus, the crystallization of the biogenic ZnS is significantly enhanced. We also found that the occurrence of structural dislocations (e.g., twins) in the biogenic ZnS is a direct consequence of the fore-mentioned crystallization pathway. All of this work is described in our latest manuscript.

Non-Darcian Flow, Imaging, and Coupled Constitutive Behavior of Heterogeneous Deforming Porous Media

Institution: Clarkson University
Point of Contact: Kathleen Issen
Email: issenka@clarkson.edu
Principal Investigator: Kathleen Issen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)

Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Porous geomaterials exhibit a range of deformational responses under stress conditions typical of the earth's subsurface. Understanding these responses and quantifying the behavior mathematically is necessary to predict response of porous geomaterials for a variety of sub-surface geo-engineering pursuits for oil and gas production and exploration, as well as carbon sequestration in deep saline sandstone formations and depleted oil and gas reservoirs. Excluding time-dependent effects, porous rocks exhibit elasticity, have cohesion, are dilatant or compactant, fail with pressure dependence, and are frictional. These phenomena are collectively included in elastic-plastic constitutive modeling. This project consists of theoretical work aimed at improving constitutive descriptions of the elastic-plastic deformation of porous geomaterials in general and sandstone deformation in particular. The specific goal is to develop a thermodynamically rigorous constitutive framework that represents experimentally known behaviors of porous sandstone. In particular, the model seeks to capture two fundamental behaviors. First, the well-known experimental result that the plastic strain increment is not perpendicular to the yield surface. Second, the elastic moduli evolve with stress and with plastic strain. Commonly, the first is often modeled using non-associated flow with a plastic potential; however, this approach is not thermodynamically stable, since it admits the possibility of negative work. Capturing the second in a constitutive model is required to accurately predict plastic (permanent) deformation for a loading path of interest (e.g., field scale modeling of energy related activities).

FY 2014 HIGHLIGHTS

This work adapts the thermomechanics approach of Collins, Houlsby and colleagues (e.g., Collins and Houlsby, 1997), in which strains are determined from Gibbs free energy. Recent experiments on Castlegate sandstone reveal that the elastic moduli evolve with stress and plastic strain. The elastic strain consists of three components: 1) strain due to change in stress at a constant moduli, 2) strain due to stress dependence of the moduli, and 3) coupled strain due to plastic strain dependence of the moduli. The fourth component of total strain is the plastic strain, which is determined using a plasticity-like approach; however, the yield surface is represented in dissipative stress space, where the plastic strain increment is perpendicular to the yield surface. Subsequently, the yield surface in traditional stress space is found to be a translation and distortion of the yield surface in dissipative stress space; this distortion causes the plastic strain increment to be non-normal to the yield surface in traditional stress space. Preliminary expressions were developed for the evolution of the shear modulus (depends on shear stress and plastic shear strain) and the bulk modulus (depends on mean stress and plastic volume strain), using an existing Castlegate sandstone data set. These expressions were found to be not integrable. Therefore, we developed revised expressions for these moduli, which are integrable; the expressions include fitting constants which are being determined via curve fitting of the data set. The revised moduli expressions were integrated to obtain an expression for Gibbs free energy, with the caveat that a function of integration that depends only on plastic strain is yet to be determined. This function will be determined from the mapping function that maps the yield surface in traditional stress space to the yield surface in dissipative stress space, which will be completed in the next project year.

Fundamental Research on the Fractionation of Carbon Isotope During Photosynthesis: New Interpretations of Terrestrial Organic Carbon Within Geological Time

Institution: Hawaii, University of
Point of Contact: A. Hope Jahren
Email: jahren@hawaii.edu
Principal Investigator: A. Hope Jahren
Sr. Investigator(s): Brian Schubert; Louisiana-Lafayette, University of
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 4 Undergraduate(s)
Funding: \$122,000 (2014)

PROGRAM SCOPE

This research will quantify how pCO₂-dependent changes in plant carbon isotope fractionation affects the geochemical interpretation of the rock record. Our overarching goal is to produce a unified quantitative approach to the interpretation of carbon isotopes in the terrestrial organic record of the Phanerozoic specific to, and indicative of, the pCO₂ level of the time.

FY 2014 HIGHLIGHTS

We have performed multiple growth experiments involving both C₃ and C₄ plants that have quantified the relationship between pCO₂ and net carbon isotope fractionation across the levels of atmospheric pCO₂ hypothesized for the entire Phanerozoic using previous proxies. Our work has revealed an increase in net fractionation within increasing pCO₂ which is quite different for C₃ and C₄ plants, reflecting the different role of respiration between the two photosynthetic types. We have clearly demonstrated that the nature of carbon isotope fractionation in C₄ plants is quantitatively different from that seen in C₃, particularly over ambient-to-slightly-elevated levels (i.e., 400-1000 ppm). As of this writing we are in the middle of experiments designed to investigate levels up to 12,000 ppm, the level at which a hyperbolic model predicts near-asymptotic levels for C₄ plants. We have also suggested a new geochemical proxy for reconstructing paleo-pCO₂ based upon the carbon isotope value of C₃ plant content within terrestrial organic matter. Our recent work has focused upon demonstrating that this method accurately predicts pCO₂ level across a wide range of temporal resolutions and depositional environments via three independent tests. We tested the proxy's ability to reconstruct small (<100 ppm) changes in pCO₂ from carbon isotope measurements made on fossil leaves, bulk organic matter, and n-alkanes across the Last Glacial Maximum through the Holocene (30,000 to 100 years BP). We also tested the proxy's potential for improving models of atmospheric carbon release during carbon isotope excursions events by constraining estimates for the absolute minimum and maximum pCO₂ levels reached during these brief intervals of rapid pCO₂ rise and global warming.

EARLY CAREER: Nonequilibrium Physics and Phase-Field Modeling of Multiphase Flow in Porous Media

Institution: Massachusetts Institute of Technology
Point of Contact: Ruben Juanes
Email: juanes@mit.edu
Principal Investigator: Ruben Juanes
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Carbon capture and geologic storage, dissociation of methane hydrates in permafrost, enhanced oil recovery, and water dropout in low-temperature fuel cells, all have something in common: two or more fluids flow simultaneously through a porous medium; and the displacement of one fluid by another is often unstable (either due to gravity or viscous forces). Yet, our ability to model multiphase flow mathematically at the macroscale has remained a challenge. The traditional equations are unable to predict, explain, or even reproduce, the formation of the complex patterns observed in experiments. The overarching goal of this proposal is to develop a new continuum theory of multiphase flow in porous media following a phase-field modeling approach, which recognizes that the system is out of thermodynamic equilibrium. The specific objectives are organized in three main thrusts: - Immiscible fluid displacements in a capillary tube and a Hele-Shaw cell. - Multiphase flow in porous media. - Application to CO₂ storage in saline aquifers. We propose a radical new approach---phase-field modeling---to advance our fundamental understanding and predictive capabilities of multiphase porous media flow. The basic tenet, with origins in the mathematical description of solidification processes, is that the system is far from equilibrium, and the energy of the system is a function of the inhomogeneous distribution of fluid phases in the pore space. This leads naturally to higher-order terms in the mass conservation equations. In recent work, we have used this formalism to develop a theory that explains and quantitatively predicts the formation of gravity fingers during infiltration into dry soil. The success of this application suggests that continuum models derived using the phase-field modeling framework have the potential to predict unstable multiphase flow in porous media.

FY 2014 HIGHLIGHTS

The project has led to the following publications and preprints during FY 2014:

EARLY CAREER: In-Situ Thermodynamics Measurements at Metal Oxides-Solution Interfaces Using Flow Adsorption Microcalorimetry

Institution: Georgia State University
 Point of Contact: Nadine Kabengi
 Email: kabengi@gsu.edu
 Principal Investigator: Nadine Kabengi
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
 Funding: \$750,000 (2014-2019)

PROGRAM SCOPE

Chemical reactions at interfaces between metal oxides and aqueous solutions play a fundamental role in environmental, geological, planetary and technological settings. Our ability to harness metal oxides (MO) potential in technological applications and safeguard the future of our environmental resources under realistic operating and environmental conditions hinges on our ability to adequately model interfacial chemical reactions – protonation, deprotonation, ion exchange, adsorption, desorption, etc. A host of theoretical principles, experimental techniques and computational methods have been utilized to the study of the complex spectrum of interfacial reactions. Yet conspicuously missing are thermodynamics data, specifically those coming from direct measurements. The overarching goal of this project is to complete a systematic study of the thermodynamics properties of interfacial reactions at four MO surfaces (Rutile (α -TiO₂), Quartz (SiO₂), boehmite (γ -AlOOH) and goethite (α -FeOOH)) through the application and construction of novel flow adsorption microcalorimetry techniques and instrumentations. These unique and specialized microcalorimeters will operate at various temperatures and solution chemical compositions allowing for in-situ measurements across metal oxides and ligands of various characteristics. The overall research goal will be accomplished by completing the following three specific objectives (O): O₁) Determine the energetics of surface protonation and deprotonation, ion exchange and ligand sorption reactions; O₂) Investigate the surface charge thermodynamic properties under a range of temperature and solution chemical compositions; and O₃) Develop predictive trends of the interplay between MO structure, surface coverage and surface reactivity. In addition to key thermodynamics parameters, calorimetric measurements provide a wealth of mechanistic information about reactions energetics and kinetics, surface charge characteristics, and structure-reactivity relationships.

FY 2014 HIGHLIGHTS

The project start date was July 15, 2014. The major accomplishments of the project within the 2.5 months of fiscal year 2014 were:

- 1) expanding the calorimetry operations to a newly upgraded and larger laboratory space to accommodate the building of the proposed instrumentations,
- 2) hiring a postdoctoral fellow and one master student. Both started on August 4th,

- 3) completing the redesign of the microcalorimeter electronic board, and
- 4) concluding the construction of the first upgraded flow adsorption microcalorimeter which was dedicated to collecting data on rutile.

Adsorption Equilibrium and Kinetics at Goethite-Water Related Interfaces

Institution: Texas-Austin, University of
 Point of Contact: Lynn Katz
 Email: lynnkatz@mail.utexas.edu
 Principal Investigator: Lynn Katz
 Sr. Investigator(s):
 Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
 Funding: \$90,141 (2014)

PROGRAM SCOPE

The comprehensive project, GEOCHEMISTRY OF INTERFACES: FROM SURFACES TO INTERLAYERS TO CLUSTERS, to which this research is a component seeks to identify and evaluate the critical molecular phenomena at the metal-oxide interface that control many geochemical and environmental processes. Specific tasks include the analysis of surface speciation, adsorption phenomena, surface complexation modeling, ion pairing, interlayer structures, parameterization of edge surfaces of clay minerals, and synthesis of molecular clusters as well as the structure and reactivity of their surfaces sites. Theoretical efforts emphasize the use of large-scale molecular dynamics simulations, *ab initio* molecular dynamics, and related density functional theory and classical methods to address structure and thermodynamics of mineral-water systems. Spectroscopic evidence is provided by X-ray absorption, second harmonic generation, sum frequency generation, infrared and Raman vibrational spectroscopies. Macroscopic data in traditional batch and column experiments is used in conjunction with molecular techniques to develop predictive models that characterize sorption in complex systems containing a wide range of background solution compositions. Our studies have focused on systems involving alkaline earth metal (Mg^{2+} , Ca^{2+} , Sr^{2+} , Ba^{2+}) and heavy metal (Hg^{2+} , Co^{2+} , Cd^{2+} , Cu^{2+} , Zn^{2+} , Pb^{2+}) cations. The anions we have selected for study include Cl^- , NO_3^- , ClO_4^- , SO_4^{2-} , and CO_3^{2-} , SeO_3^{2-} because these represent a range of potentials for forming ion-pairs or ternary complexes with the metal ions studied. Ion adsorption and the potential formation of ion pairs and ternary complexes on clays and clay minerals such as silica (quartz, amorphous silica), alumina (corundum and gibbsite), and ferric iron (goethite) oxides have been examined as part of this project and the overall comprehensive project.

FY 2014 HIGHLIGHTS

Research in FY 2014 focused on collection and analysis of adsorption data for the alkaline earth metal ions. Macroscopic adsorption studies were conducted over a range of ionic strengths, pH values, and cation-to-sorbent concentration ratios in order to elucidate the surface complexation reactions of these cations. One significant trend that was found from our test results was that the impact of ionic strength on metal cation adsorption on goethite increases proportionally with the crystal radii of the cations, which follows: $Mg^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+}$. This trend differs from that observed in our previous molecular modeling and macroscopic data work with gibbsite. The cause of these different trends is likely due to the relative adsorption affinity relative to the pH_{pzc} of the aluminum and iron oxide. Preliminary surface complexation modeling indicated that Mg sorption could be described over a range of ionic strengths using the same CD-MUSIC electrolyte and surface ionization parameters used for our Pb, Cd and selenite modeling on goethite. Mg^{2+} and Ca^{2+} adsorption on goethite were also tested at reduced temperature

(4°C) in order to examine the relationship between hydration energies and adsorption behaviors of the cations. In general, reduced temperatures should reduce the removal of waters from the hydration shell of cations, and hence lead to less adsorption and more outer-sphere complexes. In this study, the lower temperature slightly reduced the adsorption of Mg^{2+} , whereas Ca^{2+} was not affected. The reduced adsorption of Mg^{2+} is consistent with molecular modeling results and previous macroscopic data in which adsorption of metal ions was enhanced by elevated thermal energy and there was a concomitant shift from outer sphere to inner sphere with increasing temperature.

Interfaces Under Extreme Conditions: Stable Isotope Behavior of Redox Reaction and Hydrothermal Reactivity of Transition Metals.

Funding: \$137,999 (2014)

PROGRAM SCOPE

The goal of this research program is to develop and test predictive theories for isotope fractionation during electrochemical reactions. Measurements in a wide variety of metal deposition systems including Fe, Zn, Li, Mo, and Cu have led to observations of large, tunable isotope fractionations as a function of rate and temperature. In our previous studies, we have separated the influences of mass transport and electrode behavior on the overall observed isotope signature. Our next set of studies will be designed so that mass-transport processes are not the rate-limiting reaction step in order to study the isotope signature of electron transfer reactions. We will undertake a combination of computational studies, experiments, and analytical work that will predict, generate, and measure stable isotope fractionation during electrochemical reactions. We will investigate the electrochemical isotope effect of the following systems that are interesting in the environmental and geological sciences. We will measure isotope fractionations associated with the reactions between ferric (Fe^{+3}) and ferrous (Fe^{+2}) iron in a variety of aqueous environments, including salt water. We will examine isotope fractionation during electro-reduction of mercury to examine the multi-stable isotope behavior of heavy elements during chemical reactions. Finally, we will examine the temperature-dependent electroreduction of lithium, in order to investigate processes to optimize separation of lithium isotopes.

FY 2014 HIGHLIGHTS

Abstract: Stable isotopes are sensitive indicators of physical and chemical processes at solid/liquid interfaces away from equilibrium. The goal of this research program is to study how and why stable isotopes of metals fractionate during electrochemical reactions. Summary of Progress: Measurements in a wide variety of metal deposition systems including Fe, Zn, Li, Mo, and Cu, have led to observations of large isotope fractionations that strongly vary as a function of rate and temperature. We interpret our observations in terms of a competition between two rate-limiting steps: mass transport to the interface, which results in small isotope signatures, and the electrochemistry step, which results in much larger isotope signatures. Our results are consistent with a theory predicting isotope-dependent electrochemical reaction rates that is based on Marcus electrochemical theory, and imply that isotope behavior at a heterogeneous interface is sensitive to the kinetic behavior of the interface. Based on ours

and others' observations and existing chemical kinetics theories we are developing theories of isotope-dependent interface reactivity that can explain our observations and predict isotope fractionations in a wide variety of interfacial chemical processes.

Computational and Experimental Investigations of the Molecular Scale Structure and Dynamic of Geologically Important Fluids and Mineral-Fluid Interfaces

Institution: Michigan State University

Point of Contact: R. James Kirkpatrick

Email: rjkirk@msu.edu

Principal Investigator: R. James Kirkpatrick

Sr. Investigator(s): A. Ozgur Yazaydin; Michigan State University

Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)

Funding: \$184,459 (2014)

PROGRAM SCOPE

Research supported by this grant and the closely linked DE-FG02-10ER16128 (G. M. Bowers, PI, Alfred University) focuses on addressing fundamental scientific questions regarding the structure, dynamics, and reactivity of geochemically important fluids, fluid-mineral interfaces, and confined fluids on a molecular scale using a combination of computational molecular modeling and spectroscopic methods, primarily nuclear magnetic resonance (NMR) spectroscopy. The Michigan State group is responsible for the computational modeling and part of the NMR experiments. The Alfred group is responsible for the wet chemistry and most sample synthesis, much of the basic sample characterization, and much of the NMR spectroscopy. Collaboration between the two groups is very close, with computational modeling motivating the spectroscopic studies and the spectroscopic results helping to identify key questions for computational modeling. The combination of computational and spectroscopic approaches is highly effective in addressing otherwise intractable molecular scale problems concerning the physical and chemical behavior of fluids and interfaces, which are central to understanding such geological problems as the migration of chemicals in soils, sediments, and rocks, and the processes by which fluids alter these host materials. The objectives during this grant period include developing a deeper understanding of molecular-scale structure and dynamics in clay-natural organic matter (NOM) composite materials that are ubiquitous in soils, sediments, and many sedimentary rock types. We are providing key new insights into how NOM, a key sink for many inorganic and organic contaminants, influences the binding and dynamics of cations, aqueous fluids, and supercritical CO₂ in the composites; the binding structures and mechanisms of NOM-mineral association under a variety of geochemical conditions; and how NOM influences the physics of composite hydration.

FY 2014 HIGHLIGHTS

During 2014, research supported by this grant focused on fundamental understanding of the structural environments and dynamics of water and cations in swelling clays, how chemical conditions control the structures and molecular-scale ion and fluid behaviors in composites composed of the smectite mineral hectorite and Suwannee River natural organic matter (NOM), and the molecular scale interactions of mineral surfaces, aqueous fluids, and CO₂ at pressure and temperature conditions relevant to geological C-sequestration reservoirs. Variable temperature ²H NMR of smectite containing different exchangeable interlayer cations shows that the hydration energy of the cation controls the rate of exchange of water molecules between different types of structural environments in the interlayer galleries. Computational molecular modeling of the rate of water exchange between the cation hydration shell and bulk solution explain these results well. Helium-ion microscopy (HeIM) and X-ray diffraction (XRD) show that the nano-scale structure of clay-NOM composites depend sensitively on the chemical properties of the cation, pH and the ionic strength of the aqueous solution in which they form. Composites with both homogeneous and heterogeneous nano-scale structures form. ¹³C, ²³Na, ⁴³Ca, and ¹³³Cs NMR data provide direct evidence of the close interaction of CO₂ with clay-NOM composites and show that the chemical properties of the cations significantly influence CO₂ dynamics. Computational modeling is beginning to provide a molecular scale understanding of these results. Model results show that with Na as the exchangeable cation, NOM molecules are not tightly held to the mineral surface when only water is present, whereas with only CO₂ present they are. With both water and CO₂ present, the NOM molecules migrate away from the water-saturated mineral surface and accumulate and aggregate at the H₂O-CO₂ interface.

Experimental Investigation of Flow-Induced Fabrics in Rocks at Upper-Mantle Pressures: Application to Understanding Mantle Dynamics and Seismic Anisotropy

Institution: Minnesota, University of
Point of Contact: David Kohlstedt
Email: dlkohl@umn.edu
Principal Investigator: David Kohlstedt
Sr. Investigator(s): Shenghua Mei; Minnesota, University of
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$147,747 (2014)

PROGRAM SCOPE

The focus of this study is to quantify the rheological behavior and deformed-induced fabric of mantle rocks under simulated mantle conditions including experiments at high temperatures and high pressures. The goal of our research is to provide a better understanding of the rheological behavior and its anisotropic features of both the lithospheric and asthenospheric mantle.

FY 2014 HIGHLIGHTS

Quantification of low-T plasticity of garnet: The low-temperature plasticity of polycrystalline garnet has been experimentally investigated at high pressures (~4 to 9 GPa) and relatively low temperatures (773 ≤ T ≤ 1273 K) under anhydrous conditions. Experiments were carried out using a deformation-DIA apparatus on the beamline at Brookhaven National Laboratory. In a run, differential stress and sample displacement were monitored in-situ using synchrotron x-ray diffraction and radiography, respectively. The low-temperature plasticity of garnet is constrained by our data with a value for the Peierls stress of

9.8 ± 0.3 GPa, a critical constraint on the rheological properties of subducted lithosphere. Creep behavior of enstatite at high pressures: The deformation behavior of fine-grained enstatite was investigated at high pressures (4.2 to 6.9 GPa) and high temperatures (1373 to 1573 K). Based on results from this study, the creep behavior of enstatite under anhydrous conditions has been quantitatively presented in the form of a flow law that describes the dependence of deformation rate on stress, temperature, and pressure. Specifically, a non-linear, least-squares fit of our data yields the dependence of creep rate on stress with an exponent of $n \approx 1$, indicating that samples were deformed in the diffusion creep regime. Experimental results also yield the dependences of creep rate on temperature and pressure with an activation energy of ~ 250 kJ/mol and an activation volume of $\sim 3.5 \times 10^{-6}$ m³/mol, respectively. The flow laws for enstatite, one important constituent component for the upper mantle, quantified from this study provides a necessary database for modeling the dynamic activities occurring deep within Earth's interior.

Transport and Clogging of Particulate Flow in in Fracture Systems

Institution: New York-City College, City University of
Point of Contact: Joel Koplik
Email: koplik@sci.ccny.cuny.edu
Principal Investigator: Joel Koplik
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$130,919 (2014)

PROGRAM SCOPE

Fluids recovery from subsurface reservoirs is complicated by the presence of suspended solid particles which can reduce throughput and contaminate the efflux, and may even accumulate locally to form a jammed or clogged structure which blocks the flow. Transport via connected fracture networks provides the most effective means of fluids recovery in practice, but fracture flow is typically dominated by channeling into a limited number of flow paths and is particularly sensitive to clogging. A detailed understanding of the conditions under which jams form, their response to controlled perturbations in the flow, and their global effects on transport will enhance our understanding of the dynamics and improve our ability to extract subsurface fluids. In previous work we have used numerical simulations based on the lattice-Boltzmann method to study the transport of non-colloidal suspensions in open fracture joints, with realistic self-affine surface roughness. More recently, we considered the contrasting case of a tight fracture, where the mean aperture is so small that sub-regions of width comparable to or smaller than the particle size are present. In this case particles are prone to jam - fixed single particles or clusters of immobilized particles appear and partially block the fracture. We studied the stress distribution and investigated flow protocols which can release jammed particles.

FY 2014 HIGHLIGHTS

A key aspect of flow in fracture systems is the behavior at the junctions where individual fracture joints intersect. We have begun with the simplest case of two self-affinely rough fractures meeting at a right angle, each containing a packet of suspended particles which collide near the intersection. The motion of a particulate suspension in this geometry is calculated by lattice-Boltzmann methods, which allow us to monitor flow and stress fields as a function of time and at fine resolution, below the particle size. The system is periodic in all three directions, so that the particle packets repeatedly pass through the fractures after crossing the boundary and recollide at the junctions, simulating the effect of multiple

junctions in a fracture network. We observe gradual fragmentation of the packets of particles, in general in an asymmetric manner despite the geometrical symmetry of the system, although the detailed mixing behavior varies in different realizations. One striking observation is that, as with the single-fracture jamming case studied previously, varying either the initial particle positions or the fracture surfaces can qualitatively alter the behavior. A second notable feature is that the extra space provided by the junction and the collisional interaction combine to broaden and dilute a particle packet, a point very relevant for unblocking particle jams.

Internal Erosion, Particle Transport, and Channelization Drive by Fluid Flow

Institution: Clark University
Point of Contact: Arshad Kudrolli
Email: akudrolli@clarku.edu
Principal Investigator: Arshad Kudrolli
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$63,260 (2014)

PROGRAM SCOPE

The goal of the project is to investigate internal erosion and transport of particles in sediment beds leading to heterogeneity and channelization of the sediment bed driven by fluid flow. Understanding this system is of fundamental importance to a number of geophysical processes, and in the extraction and sequestration of hydrocarbons in the subsurface. The project builds on a three-phase model to describe development of channel networks in a bed composed of particles through erosive instabilities. A fluid flowing through a solid disordered medium is considered to slowly convert a small amount of solid phase to a mobile phase because of hydrodynamic phases. This mobile phase is then advected by the fluid phase and can also get deposited further downstream. The resulting changes in porosity can then lead to a feedback loop resulting in instabilities and development of inhomogeneities in the spatial field. In order to calibrate and refine the model, experiments are developed to observe the evolution of the erosive features as a function of driving parameters and the bed composition. Of particular importance to obtain physically relevant results is accurate local erosion laws and rheology of the fluid phase due to the presence of the eroded material. We perform complementary experiments with simplified erodible porous interfaces under prescribed normal and tangential fluid flow conditions corresponding to the bed compositions in the first series of experiments. These investigations will provide the erosion and deposition rates under well-defined normal and shear stress conditions. This multi-faceted approach will enable us to obtain an integrated picture of internal erosion of an erodible medium starting from the pore scale to the scale approaching that of a reservoir.

FY 2014 HIGHLIGHTS

We performed a systematic investigation of the erosion threshold of sedimented beds driven by a fluid flow as a function of grain size and grain roughness. Experiments were performed with a bed in a model enclosed cylindrical channel under laminar flow conditions. The shear rate at threshold for a prescribed flow rate is obtained from the height of the fluid above the bed as it comes to rest, and used along with the grain size to determine the particle Reynolds number. We calculated the critical Shields number given by the ratio of the viscous shear stress and the normal gravitation and buoyancy stresses at the threshold of motion. We found that bed armoring leads to a systematic significant increase in the critical Shields number independent of the grain roughness. This observed increase is of the same order of

magnitude as scatter reported in the literature when the critical Shields number is drawn from different data sets. While comparing similarly prepared beds with increasing particle size, we found that the critical Shields number decreases systematically with the particle Reynolds number, in contrast with the Shields curve which is constant at low particle Reynolds number. We found that particles rotate out of the pockets in the bed rather than sliding out. Accordingly, we used the condition of torque balance at threshold to determine the critical torque needed to dislodge grains due to viscous drag. This torque is found to be significantly lower than the value needed to dislodge a spherical grain on the bed surface which is fully exposed to a linear shear flow. Thus, we are able to obtain the degree of exposure that particles experience at threshold for freshly prepared as well as for armored beds. These experiments provide a complete picture of the threshold for erosion which we can now use to obtain sediment flux rates as a function of Shields number.

Reaction-Infiltration Instabilities in Fractured and Porous Rocks

Institution: Florida, University of
Point of Contact: Tony Ladd

Principal Investigator: Tony Ladd
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$156,135 (2014)

PROGRAM SCOPE

We are using numerical and analytical methods to investigate the dissolution of fractures and porous media. The knowledge obtained from these investigations will be used to construct models for the change in fracture permeability in dissolving rocks. Our goal is a model that incorporates the key feature of dissolution -- namely its strong spatial inhomogeneity -- in a sufficiently simple way that it can be used to improve the accuracy of permeability models at the reservoir scale.

FY 2014 HIGHLIGHTS

The final paper in our extensive study of the stability of dissolution fronts in fractures and porous media was published in the Journal of Fluid Mechanics [Reactive infiltration instabilities in rocks. Part 2. Dissolution of a porous matrix J. Fluid Mech.,738, 591-630, 2014]. There are two further manuscripts in preparation (i) Mechanisms for volume preserving replacement under review for Geophysical Review Letters (ii) Dependence of dissolution patterns on the initial aperture distribution in rough fractures - in preparation for Journal of Geophysical Research. We have completed a Darcy-scale solver for reactive transport in two and three dimensions. It is coupled to the LLNL HyPre library for a rapid parallel solution of the linear equations. The code can has been used to track the dissolution of two and three dimensional systems containing up to 10^8 elements. We are developing fully three-dimensional solver for fracture dissolution, based on the OpenFOAM toolkit. We have made a number of extensions to the OpenFOAM library to model the motion of dissolving surfaces in 3D. The code currently solves fracture dissolution problems in parallel, using linear reaction kinetics. Extensions to more realistic chemistry are in progress.

Predicting Fracture Porosity Evolution in Sandstone

Institution: Texas-Austin, University of
Point of Contact: Stephen Laubach

Sr. Investigator(s): Jon Olson; Texas-Austin, University of
Robert Lander; Texas-Austin, University of
Linda Bonnell; Texas-Austin, University of
Peter Eichhubl; Texas-Austin, University of
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 1 Undergraduate(s)
Funding: \$288,000 (2014)

PROGRAM SCOPE

Evidence of how fracture growth and diagenesis interact to create and destroy fracture porosity is preserved in quartz cement deposits in otherwise open fractures. Using textures and fluid inclusion data combined with burial histories allows inference of duration and rates at which fractures open, testing of a structural diagenetic model that accounts for how fracture porosity and rock properties change as a function of thermal exposure. Results include accurate prediction fluid flow characteristics of fractured rocks based on coupled effects of diagenesis and deformation. Experiments measure how rock and fracture properties evolve with diagenesis. Current research is documenting and modeling the opening histories of entire fractures and fracture arrays in contrasting tectonic and thermal regimes and developing and testing a fully coupled diagenetic-geomechanical model.

FY 2014 HIGHLIGHTS

The capacity of a structural diagenetic approach to unravel previously indistinguishable fracture causes was demonstrated in several integrated studies. A Colorado example shows fractures formed in response to gas generation in adjacent shales and coals under high pore fluid pressure; a Mexico example shows fractures opened primarily under tectonic extension. Two studies using outcrop and core data, kinematic and dynamic structural models and fracture growth reconstructions show complex fracture growth. A two-stage non-linear growth history was demonstrated in a Texas example using textural reconstruction and fluid inclusion microthermometry. We described how rock type and diagenesis governs near-fault fracture size, openness and fault strength. We published our model that accounts for crystal growth patterns and internal textures in quartz cement in fractures, including massive sealing deposits and veneers on open fracture surfaces and bridge structures that span otherwise open fractures. A new code predicts extent of fracture bridging by quartz cement, accounting for euhedral/non euhedral nucleation surfaces, crystal size, temperature, and fracture opening and allows efficient accounting for these effects in our geomechanical model. A new technique to quantify fracture spacing applied to fracture arrays where we are testing a model that predicts size scaling based on fracture cohesion explores how fracture spatial arrangement and cementation may be related. Diagenetic modeling and laboratory experiments show how fractures, cement textures, and mechanical properties evolve with progressive diagenesis. Experimental fracture diagenesis in the laboratory created artificial cement using a wide range of pore fluids and host minerals to test elements of fracture growth and diagenesis models. In the context of project findings we published reviews of fracture size-scaling in sandstone, microfractures and fractures in shale. Papers: www.jsg.utexas.edu/sdi/

Porous Rock with Fluid: Heterogeneity, Scale of Measurement and Transforms

Institution: Stanford University
Point of Contact: Gary Mavko
Email: mavko@stanford.edu
Principal Investigator: Gary Mavko
Sr. Investigator(s): Jack Dvorkin; Stanford University
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014-2016)

PROGRAM SCOPE

Rock properties, such as porosity, permeability, electrical conductivity, and the elastic moduli vary in space and, hence, lack spatial stationarity within a selected rock volume. As a result, such data depend on the scale and position of measurement. This natural variability renders ambiguous the concept of a data point, simply because the datum will be different just a few inches away, or if assigned to encompass a larger volume. Yet, there is no alternative to using the results of controlled experiments conducted at one scale for interpreting data acquired at a very different scale. Therefore, our main question is: How to apply a rock physics operation throughout a range of scales. Based on previous results, we assume that transforms between a pair of rock properties exhibit much less scale sensitivity than the properties themselves. To test this hypothesis, one needs to conduct the same experiment on different portions of a rock volume by changing both the size and location of the test. This is problematic in the physical lab. Hence, the main experimental tool we selected is computational rock physics. The common thread of the proposed effort is utilization of digital experiments in exploring the scale dependence of relations between rock's porosity and permeability; porosity and electrical conductivity; porosity and elastic moduli; as well as cross-property relations among the said rock properties. This approach will guide us in using rock physics laws obtained in the digital and/or physical laboratory (at a scale of mm and cm) at the field scale of feet and meters. The basic-science deliverable will be a quantitative insight into the impact of the scale of a process on relations between rock properties that govern this process. The practical deliverable will be a basis for using the digital and physical laboratory data at a practical field scale.

FY 2014 HIGHLIGHTS

The highlights of FY 2014 are: (a) macroscopic permeability-porosity behavior in composites constructed from elements with given permeability-porosity transforms; (b) effects of fabric heterogeneity in cemented particulate medium – computational study using the discrete element method; and (c) stress heterogeneity in pore space – computational study using the finite-element method. In the first investigation, the percolation through porous media was analyzed by using a Darcy flow simulator in a random composite with properties taken from two data sets: Ottawa sand with kaolinite and Fontainebleau sandstone. Percolation has two distinctive regimes: one stable, for composites with a large number of elements where adding more elements has weak effect on percolation; and the other, for smaller composites, where both the number of the elements and the amount of low- and high-permeability elements control percolation. In the second investigation, we conducted numerical simulations on granular media targeting the effects of cementation on stress heterogeneity in pre-compacted granular media. We show the existence of stress heterogeneity even if the strain is homogeneous. Cementation mechanism where cement is deposited evenly on grain surfaces acts to increase this heterogeneity for low cement volume and to reduce it for higher cement volume. Where cement is only deposited at the grain contacts, the impact on effective elastic heterogeneity depends on

the heterogeneity of cement distribution among the contacts. In the third investigation, we explored how stress heterogeneity affects fluid and solid substitution in porous rock. We numerically estimated and compared the stress variation inside idealized ellipsoidal inclusions and realistic pore space. We observed significant stress variation in the pore space of Fontainebleau digital samples, which appears to have an effect on parameters used in theoretical fluid and solid substitution.

Multiscale Modeling of Multiphase Flow, Transport, and Reactions in Porous Medium Systems

Institution: North Carolina, University of
Point of Contact: Cass Miller
Email: casey_miller@unc.edu
Principal Investigator: Cass Miller
Sr. Investigator(s): William G. Gray; North Carolina, University of
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$187,043 (2014)

PROGRAM SCOPE

Our work is directed at constructing models of multiphase porous medium systems that are consistent across length scales. Because it is the only method employed ensuring that thermodynamic relations as well as conservation equations can be related to smaller scale precursors, we are advancing the thermodynamically constrained averaging theory (TCAT) in this work. TCAT has the features that (i) all macroscale variables are defined explicitly in terms of microscale properties; (ii) closure relations are advanced that are consistent with the second law of thermodynamics; (iii) models can be constructed at a range of length scales, up to the system scale; (iv) hierarchical families of models can be developed with varying degrees of sophistication consistent with physical system of interest; and (v) interscale consistency facilitates the use of simulations and experimental studies performed at one scale to support the findings at a different scale. The specific objectives of this project include formulating, closing, and applying three types of models: (1) a two-fluid-phase flow model, (2) a two-fluid-phase flow and species transport model, and (3) a three-fluid-phase flow model. This work involves a theoretical component to formulate candidate models, a pore-scale modeling component to guide the formulation of specific closure relations, and a continuum-scale numerical methods component to approximate the formulated macroscale models.

FY 2014 HIGHLIGHTS

Highlights for this year's accomplishments include: (1) publication of a book detailing the development of the thermodynamically constrained averaging approach; (2) completion of a book chapter that validates aspects of the theory for two fluid phase flow using high resolution lattice Boltzmann computations and microfluidic experiments; (3) advancement of computational methods for performing large-scale simulations at the pore scale that provides a means to directly connect the microscale quantities with macroscale quantities that appear in the theory; and (4) extension of the theory to the case of two fluid phase flow and species transport.

Thermodynamics of Minerals Stable Near the Earth's Surface

Institution: California-Davis, University of
Point of Contact: Alexandra Navrotsky
Email: anavrotsky@ucdavis.edu
Principal Investigator: Alexandra Navrotsky

Sr. Investigator(s):

Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)

Funding: \$241,888 (2014)

PROGRAM SCOPE

This project uses specialized calorimetric techniques in the Peter A. Rock Thermochemistry Laboratory at UC Davis to obtain new thermochemical data for materials, often of nanoscale dimensions, encountered in the Earth's "critical zone," the near surface region of the planet most directly affecting and affected by human activity. This project focuses on the transformations from ions in solution to clusters, to nanoparticles, to precipitates, and finally to well crystallized minerals (and the reverse transformations during weathering and dissolution) representing a continuous spectrum of events. This project expands on our previous studies of the energetic driving forces for such transformations, with a strong emphasis on transition metals and redox reactions, especially involving iron and manganese oxides. We continue exploring the gradual transformation from nanoclusters in solution to nanoparticles to crystalline minerals, with an emphasis on transition metal oxides of variable valence, especially iron and manganese. A new area is the large effect of particle size on the thermodynamics of redox reactions. To succeed in calorimetry on the above problem, we must fine tune calorimetric, analytical, and structural techniques to control and delineate oxidation states, water contents, and structural features of materials containing one or more transition elements of variable valence and structural and adsorbed H₂O. In particular, we are confident now that we can do reliable oxide melt solution calorimetry on phases which simultaneously contain ferrous and ferric iron and water, as well as materials containing several transition metals. This capability opens the door to detailed studies of minerals containing these combinations of elements, for which enthalpies of formation are still surprisingly poorly known. These include spinels containing Cr, Mn, Fe, Co, Ni, and Cu, as well as complex sulfides, silicates, and borates containing transition metals.

FY 2014 HIGHLIGHTS

Nancy Birkner completed her Ph.D. thesis on manganese oxides and is now a postdoc with Prof. Peggy O'Day at UC Merced. The final part of her thesis concerned layered and tunnel structured phases. These manganese oxides (birnessite, etc.) contain Ca, Na, and/or K, as well as water. They are typically nanophase and charge balance is achieved by interlayer or tunnel cations and by vacancies. Our earlier studies determined the energetics of formation of several of these phases using synthetic sample but did not consider the effects of particle size and surface energy. We returned to these materials with the hypothesis that they, like the CaMnO catalyst phases which have higher Ca content than natural materials, have low surface energies which help stabilize them as fine grained materials. By controlling the ionic strength of the electrolyte during synthesis, Birkner synthesized several series of materials with virtually identical cation contents and average manganese oxidation states but different particle sizes. The surface energies of the layered and tunnel structure complex manganese oxides are confirmed to be significantly lower than those of the binary manganese oxide phases. The surface energy of the complex manganese oxides appears to decrease with decreasing manganese average oxidation state, with greater mixed manganese valence. We are exploring whether the measured thermodynamic properties allow us to understand the sequence of formation and transformation of these phases in natural and industrial settings. Lili Wu completed her Ph.D. thesis on the energetics of zeolite formation by studying heats of formation of aluminosilicate zeolites containing transition metals. The energetic trends are similar to those for other ternary transition metal oxide materials, e.g spinels. Dana Reusser is

completing her thesis on the energetics of aluminum Keggin clusters in the solid state and in solution. New data are being analyzed and prepared for publication.

The Physics of Swarms in Fractures: Functionalization Particles and Programmable Seismic Scatters

Institution: Purdue University
Point of Contact: Laura Pyrak-Nolte
Email: ljpn@purdue.edu
Principal Investigator: Laura Pyrak-Nolte
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 2 Undergraduate(s)
Funding: \$121,264 (2014)

PROGRAM SCOPE

The objective of this research is to determine how to control the injection and retrieval of sensor swarms within fracture networks. Understanding the physics of sensor swarm distributions in fracture networks will have important implications for the future use of collaborative sensors to characterize the subsurface. Our research objectives are: (1) to explore the maintenance and control (hydrodynamic, electro-kinetic, magneto-kinetic) of particle swarms and to identify the key features of the fracture, fluids, particles and control mechanisms that affect swarm transport in fractures; and (2) to determine the best seismic imaging modality (e.g. P-S converted modes) for identifying scattered wave field phenomenon caused by fractures, fracture intersections, matrix anisotropy and non-uniform immiscible fluid distributions in fractures to enable the best sensor swarm release strategies in fracture networks.

FY 2014 HIGHLIGHTS

Contrary to theories for drag on a particle adjacent to a wall, there exists an optimal range of fracture apertures where swarm bifurcations are suppressed and swarms travel farther and faster than outside of this range. In this optimal range, the fracture surfaces maintain the swarm density through confinement that prevents expansion of the swarm and maintains the speed of transport. Experiments were performed to determine the effect of particle size, fluid viscosity and boundary conditions on enhanced transport of swarms in fractures. Enhanced swarm transport in the optimal range is unaffected by (1) bead size distribution (mono- vs poly- dispersions) and (2) a 100x increase in fluid viscosity. An increase in viscosity shifted the optimal range from 2.5 - 15 fracture aperture/swarm diameter ratios to 10 - 20. Local swarm behavior is affected by the resistance to flow in a fracture. When a fracture is confined (no flow boundary conditions), swarms did not exhibit enhanced transport. Enhanced transport only occurs in a fracture that is partially unconfined. Fracture intersections are a major difference between working with single fractures and orthogonal fracture sets. A theoretical and experimental study was performed to examine seismic wave propagation along a fracture at the surface, i.e., along the intersection of two quarter-spaces. A theoretical model that couples two wedges, using displacement discontinuity boundary conditions, gives rise to a new guided waveform that is dispersive, depends on specific stiffness of the intersection of a fracture with a free surface, and exhibits velocities that range from the single wedge-mode velocity to the Rayleigh wave velocity at a free surface. The existence and behavior of this new guided-mode was verified using a synthetic fracture created between two aluminum blocks. This new guided-mode enables the characterization of fractures, joints and other discontinuities at the surface of an outcrop.

Structural Basis for Stabilization and Transformation Behavior of Amorphous Calcium Carbonate

Institution: New York-Stony Brook, State University of
Point of Contact: Richard Reeder
Email: rjreeder@stonybrook.edu
Principal Investigator: Richard Reeder
Sr. Investigator(s): Brian Phillips; New York-Stony Brook, State University of
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$78,918 (2014)

PROGRAM SCOPE

Calcium carbonate biomineralization is one of the most important processes in the carbon cycle, and it has been demonstrated that biologic and inorganic formation of calcium carbonate minerals commonly occurs via a metastable amorphous precursor: amorphous calcium carbonate (ACC). A limitation in our ability to integrate the role of ACC into quantitative geochemical modeling is the challenge in evaluating its structural properties, including the distinct types of molecular water in ACC and their role in its stabilization and transformation. Our present research program builds on our previous work combining synchrotron X-ray total scattering methods and NMR spectroscopy by adding the unique capability of neutron total scattering to overcome the poor sensitivity of H for X-rays. Combined with deuterium substitution, neutron total scattering and pair distribution function analysis permit direct evaluation of molecular water components. Parallel NMR experiments that also take advantage of deuterium substitution and employ double resonance techniques will permit assignment of distinct types of molecular water and their functional roles in the stabilization and transformation of ACC. *In situ* transformation studies will allow direct characterization of ACC crystallization kinetics. The structural information obtained in this study will provide a basis for understanding energetic and kinetic differences among varieties of ACC and associated transformation pathways. Structure models that result from this research will be used as a basis for computational modeling that examines structural interactions of ACC with inorganic and organic additives, with templates, and transformation to different crystalline forms of calcium carbonate. A long-term goal is to develop structural data for different forms of ACC that enable their inclusion in quantitative modeling of geochemical processes.

FY 2014 HIGHLIGHTS

The primary accomplishments in this period focused on the *in situ* determination of ACC transformation kinetics and reaction pathways. Transformation kinetics varied according to ACC synthesis method, and transformation pathway was affected strongly by kinetics. Experiments with slower transformation kinetics showed ACC transforming directly to calcite, while experiments with the fastest transformation rates yielded a mixture of calcite and vaterite. In experiments where transformation produced a mixture of phases, the initial crystallization of vaterite and calcite was simultaneous. Transformation of ACC directly to calcite and the simultaneous formation of vaterite and calcite both indicate that vaterite is not an essential precursor phase in the formation of calcite. However, *ex situ* analysis of capillaries long after *in situ* analysis did show a secondary transformation from vaterite to calcite, with slower reaction kinetics than either of the initial crystallization reactions from the amorphous phase. Reactions involving calcite-equilibrated solution and partially dehydrated ACC both correlated with an overall decrease in the transformation kinetics. These effects are attributed to different populations of hydrous components and their distinct structural roles, which is the focus of ongoing work. The *in situ* structural analyses used in this study shed light on the possible controls manipulated by organisms to direct transformation *in vivo* with potential applications for biomimetic synthesis.

Kinetic Isotope Fractionation by Diffusion in Liquids

Institution: Chicago, University of
Point of Contact: Frank Richter
Email: richter@geosci.uchicago.edu
Principal Investigator: Frank Richter
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$206,400 (2014)

PROGRAM SCOPE

The research supported by the DOE Geoscience Program has had three broad goals:

- 1) To use laboratory experiments to document and quantify kinetic isotopic fractionation effects due to particular mass transport mechanisms such as volume diffusion and grain boundary diffusion.
- 2) To use the experimentally derived isotopic 'fingerprints' to infer the dominant transport processes and the extent to which they operated in natural settings such places volcanic systems were melts of different composition were juxtaposed.
- 3) Once chemical gradients in natural settings have been demonstrated to have been the result of diffusion, the length scale of the diffusion is used to place constraints on the cooling history of the system.

FY 2014 HIGHLIGHTS

During fiscal year 2014 we expanded our research documenting the rate of chemical diffusion and associated isotopic fractionation from liquids to silicate minerals and metal alloys. The kinetic isotope fractionation by diffusion in minerals is especially important because different elements (i.e., lithium versus magnesium) diffuse at very different rates in different minerals and thus they can provide constraint on different periods of a system's cooling history. We have completed and published our work on lithium diffusion and isotopic fractionation in pyroxene minerals and have completed a parallel study of lithium diffusion into olivine, which is being prepared for publication. We also completed and published our work on thermal isotope fractionation (i.e. isotopic fractionation of an initially homogeneous silicate liquid by an imposed temperature gradient) and showed that the isotopes of all the major elements of a silicate liquid are isotopically fractionated to an easily resolved degree by a temperature difference of only a few tens of degrees. We completed a series of Fe-Ni interdiffusion experiments and high temperature evaporations of Fe, Ni, and Fe-Ni alloys, and as in the case of silicates, very large isotopic fractionation were found in the diffusion couples and in the evaporation residues. All of the work either directly or as an illustrative analogue system provides ways of discriminating between the various processes responsible for mass transport in condensed systems.

Physics of Channelization: Theory and Observation

Institution: Massachusetts Institute of Technology
Point of Contact: Daniel Rothman
Email: dhr@mit.edu
Principal Investigator: Daniel Rothman
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$187,000 (2014)

PROGRAM SCOPE

We study the growth of channel networks incised by groundwater flow. Our objective is to quantitatively relate mechanisms and rates of channel growth to the geometry of channel networks. Our investigations involve physical reasoning, mathematical theory, and empirical analysis of real drainage networks. Our empirical work focuses on a hundred-square kilometer channel network located on the Florida Panhandle, where channel incision by groundwater seepage is unequivocal. We also study drainage networks at lower resolution throughout the contiguous United States.

FY 2014 HIGHLIGHTS

Work performed during the current grant cycle has shown, by both theory and observation, that channels growing in groundwater fields bifurcate at a characteristic angle of $2\pi/5 = 72$ degrees. To better understand this result, we have created a family of numerical models in which channel tips grow at a rate and direction determined by the two leading-order terms of an expansion of the groundwater field near tips. When augmented by a bifurcation rule, interesting structures, including logarithmic spirals similar to features seen in the Florida network, are obtained. Our recent work hypothesizes that channel tips grow according to the principle of local symmetry. This concept, adopted from fracture mechanics, suggests that streams grow in the direction in which the groundwater field is locally symmetric. An alternative view, which we previously adopted to predict the 72-degree bifurcation, suggests that tips grow in the direction of the streamline entering tips. By comparing streams grown according to the two different growth laws (both analytically and numerically) we find that the two formulations are equivalent. Moreover, they are equivalent to stating that streams grow in the direction that maximizes flux to tips. Consequently we now have a mathematical interpretation of flux-maximizing growth that can be implemented numerically. We have used such a procedure to reconstruct the evolution of the Florida network and determine how its growth rates scale with the groundwater flux to tips. We have also recently initiated a project in which seek to determine the geographical extent of erosion driven by subsurface flow. Preliminary results suggest that the influence of groundwater seepage on network growth is widespread, and that it is controlled by climatic factors that determine groundwater recharge.

Collaborative Research: Damage and Burst Dynamics in Failure of Complex Geomaterials

Institution: California-Davis, University of
Point of Contact: John Rundle
Email: rundle@physics.ucdavis.edu
Principal Investigator: John Rundle
Sr. Investigator(s): William Klein; Boston University
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$125,000 (2014)

PROGRAM SCOPE

Objectives: 1. Determine the dynamics of failure in complex geomaterials, specifically focusing on the role of defects, damage and asperities in the catastrophic failure processes (now popularly termed “Black Swan events”). 2. Examine fracture branching and flow processes using models for invasion percolation, focusing particularly on the dynamics of bursts in the branching process. 3. Understand the fundamental dynamics of nucleation in complex geomaterials, specifically in the presence of

inhomogeneous structures. We use numerical simulations and theory, together with new classes of models, to obtain answers to the project objectives described above. Modeling these types of processes requires consideration of fully interacting fields of dislocations, defects, damage, and other material disorder. Observations of rock masses over a range of spatial scales indicate that the failure modes of these systems demonstrate scale invariant deformation, or power law behavior. These are observed in both laboratory settings in acoustic emission experiments, as well as in large scale field settings associated with tectonic faults. In much of the previous work over the last decades on these types of systems, disorder fields were assumed to be non-interacting or dilute, allowing classical solid-solid mixture theories to be employed. An important new topic we consider in detail is models of the invasion percolation (“IP”) type. The model has been previously researched for applications of extracting oil and gas from reservoirs, and also in the context of the computation of scaling exponents. Notable among the physical processes of IP is the concept of bursts, defined as rapid changes in the configuration of the percolation lattice. Understanding the dynamics of bursts is critical to illuminating the metastable (nucleation) processes by which natural fracture networks evolve and grow, and from which catastrophic failure originates.

Electrical and Mechanical Properties of Rocks at the Sub-Millimeter Scale

Institution: Colorado School of Mines
Point of Contact: John Scales
Email: jscales@mines.edu
Principal Investigator: John Scales
Sr. Investigator(s): Manika Prasad; Colorado School of Mines
Michael Batzle; Colorado School of Mines
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$139,366 (2014)

PROGRAM SCOPE

Our main scientific contributions have been 1) the development of quasi-optical THz scanning techniques for high-spatial-resolution retrieval of the complex dielectric properties of rocks, whether thin-sections or bulk samples, and 2) The construction of a high-Q THz open cavity resonator, which allows us via perturbation techniques to retrieve the complex permittivity of samples that are too small or low-loss to be feasible in a quasi-optical geometry. We established collaborations with Purdue University (Mechanical Engineering), Colorado School of Mines (Geophysics and Petroleum Engineering), Colorado State University and the National Renewable Energy Laboratory, as a major effort in technology transfer.

FY 2014 HIGHLIGHTS

Main Scientific Results:

- 1) The ability to measure complex dielectric permittivity at sub-100 micron scale. Thus we can produce a high resolution spatial map of mineralogy and other properties derivable from permittivity.
- 2) The ability to measure complex dielectric permittivity of thin films (less than 1 micron).
- 3) This allows us to characterize geologic thin films nondestructively, as well as the kinds of films used in renewable energy such as photovoltaics.
- 4) Application of this technology to characterizing the chemical properties of rocks and fluid filled porous media. This is a joint effort with Manika Prasad's group in Petroleum Engineering.
- 5) Due to the noncontacting nature of the measurements, we can study fluid flow and pyrolysis in real time.

Shale Gas: Geochemical and Physical Constraints on Genesis, Storage, and Producibility

Institution: Indiana University
Point of Contact: Arndt Schimmelmann
Email: aschimme@indiana.edu
Principal Investigator: Arndt Schimmelmann
Sr. Investigator(s): Maria Mastalerz; Indiana Geological Survey
Juergen Schieber; Indiana University
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$300,000 (2014-2015)

PROGRAM SCOPE

Shales are important source and reservoir rocks for hydrocarbons (shale gas, oil). The three research goals of this project encompass: (1) Quantification of the character and development of porosity in organic-rich rocks as a function of organic matter content, type of organic matter, thermal maturity, and the degree of compaction; (2) evaluation of the natural outgassing of methane from shales into the atmosphere and its potential contribution to global warming by delivering potent methane greenhouse gas; and (3) testing of shales' ability to generate thermogenic gas (or natural gas via catalysis) at relatively low temperatures (60, 100 and 200°C) and different pressures (ambient, 100 MPa, 300 MPa) over months to years. A variety of porosimetric methods was used to assess macro- meso- and

microporosity in shales. Porosity in shales at low maturity initially diminishes due to ongoing compaction, but incipient thermal cracking at the beginning of the oil window generates new porosity. Further into the oil window, the generation of additional liquid hydrocarbons fills pores and reduces the open pore space available for gas storage. At even higher maturity, secondary cracking and gas generation expels some liquid hydrocarbons from pores and opens new pore spaces for gases. Natural outgassing of shale gas into the atmosphere in the absence of drilling and fracking was evaluated during field work in several states. A naturally occurring spectacular “eternal flame” and associated non-burning shale gas seeps in western New York State mark a gas macroseepage system of dominantly thermogenic origin emanating directly from deep shale source rocks. The hypothesis of catalytic gas generation from shales at low temperatures in the absence of methanogenic microbes is being tested by sterile incubation of shales in the presence of deuterium-enriched waters under different temperatures and pressures.

FY 2014 HIGHLIGHTS

High-resolution chemical mapping of organic matter in macerals and pore fillings (as well as of inorganic components) in shales by novel micro-FTIR techniques proved to be a valuable tool for assessing shales’ microstructure (methodology developed and applied by our PhD student Yanyan Chen; Chen *et al.*, 2013, 2014). The occurrence of shale gas seepages through tectonically-induced conduits proves that strong fluxes and point sources of shale gas can indeed contribute to atmospheric greenhouse gas loading, although much ascending methane seems to be microbially oxidized to carbon dioxide by methanotrophs. This is well demonstrated in limestone caves in Kentucky and Indiana that overlie deeper shales. Our results show that the semi-stagnant air in caves typically contains less methane and more carbon dioxide than in the atmosphere, presumably because methanotrophic microbes are lining the walls of underground gas passageways and intercept hydrocarbons (research project of our PhD student Kevin Webster). The hypothesis of catalytic gas generation from shales at low temperatures in the absence of methanogenic microbes is being tested by sterile incubation of shales in the presence of deuterium-enriched waters under different temperatures and pressures. Experiments by our PhD student Lin Wei last from 6 months to two years due to slow kinetics. Low-temperature methanogenesis is indeed observed from some shales and decreases with increasing hydrostatic pressure.

Mineral-Fluid Interactions: Synchrotron Radiation Studies at the Advanced Photon Source

Institution: Illinois-Chicago, University of
Point of Contact: Neil Sturchio
Email: sturchio@uic.edu
Principal Investigator: Neil Sturchio
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$105,392 (2014)

PROGRAM SCOPE

This proposal seeks to develop a fundamental molecular-scale understanding of mineral-water interface processes that control the geochemical transport and cycling of elements in Earth's near-surface environment. Processes of interest (including adsorption/desorption, growth/dissolution, and oxidation/reduction) play a critical role in controlling the bioavailability of nutrients and the sequestering or transport of toxins. The program emphasizes direct molecular-scale observations of fundamental geochemical processes through *in situ* studies at mineral-fluid interfaces. This is done using the unique characteristics of the Advanced Photon Source (APS) at Argonne National Laboratory, where the unprecedented x-ray beam properties available at this 3rd generation synchrotron facility (e.g., beam brilliance, flux, and tunability) allow fundamentally new types of *in situ* experiments of mineral-fluid interfaces to be performed, including the ability to visualize the interfacial structure with sub-Å vertical resolution and <100 nm lateral resolution, with unique elemental and chemical sensitivities, and in real-time. These experiments will (1) help bridge the gap between the actual processes and the idealized conceptual models that are used to interpret field-scale observations, (2) further define kinetics and reaction mechanisms at the atomic scale in key mineral-fluid systems, and (3) provide results that can test computational studies of mineral-fluid interface processes through direct comparison to theoretical results. The emphasis of these studies will be to understand the interrelationships between structural, thermodynamic, and kinetic controls of interfacial processes related to ion adsorption and growth/dissolution processes at mineral-water interfaces.

FY 2014 HIGHLIGHTS

The interaction of monovalent cations with the muscovite-water interface reveal the inter-relationships between the adsorption structure and adsorbed ion distribution through a systematic study of alkali metal cations (Li⁺ through Cs⁺, along with H₃O⁺).

PROGRAM SCOPE

GeoSoilEnviroCARS, a national user facility at Sector 13 of the Advanced Photon Source (APS, Argonne National Laboratory), provides earth scientists with access to the high-brilliance hard X-rays from this third-generation synchrotron light source. The research conducted on this sector is advancing our knowledge of the composition, structure and properties of earth materials, the processes they control and the processes that produce them. A variety of analytical techniques are being brought to bear on earth science problems: (1) powder, single crystal and interface diffraction; (2) inelastic X-ray scattering;

(3) X-ray absorption fine structure (XAFS) spectroscopy; (4) X-ray fluorescence microprobe analysis and microXAFS; (6) microtomography; (7) high-pressure/high-temperature crystallography and spectroscopy using the diamond anvil cell; and (8) high-pressure/high-temperature crystallography using the multi-anvil press. Upgrade of the GSECARS sector to a dual canted undulator configuration doubled the available undulator beam time, allowed the upgraded X-ray microprobe to operate in a dedicated station with access to the sulfur K edge, and provided an optimized high energy insertion device for interface/surface and high pressure diffraction. All the available user operations beam time is allocated through the proposal-based, peer-reviewed, APS General User Program. GeoSoilEnviroCARS is jointly supported by DOE – Basic Energy Sciences (Chemical Sciences, Geosciences & Biosciences) and NSF – Earth Sciences (Instrumentation and Facilities).

FY 2014 HIGHLIGHTS

The FY14 GeoSoilEnviroCARS user program involved 647 unique users and 343 experiments were conducted resulting in 120 publications. Science highlights include the following:

- 1) Thermodynamic geochemical modeling and bioreactor experiments showed that bacteria *S. oneidensis* MR-1 can enzymatically reduce elemental sulfur but not goethite (α -FeOOH). The HS– produced subsequently reduces goethite abiotically. Fe(III) reduction in aquifers may thus proceed via elemental sulfur-mediated electron-shuttling pathways. (Flynn, T. M., *et al.*, Science 344, 1039-1042, 2014.)
- 2) Images of drainage experiments at extreme conditions demonstrated that super-critical carbon dioxide invades the pore space in Bentheimer sandstone in a capillary-fingering regime. The data support the applicability of previous micromodel studies and ambient condition experiments in predicting flow regimes occurring during super-critical carbon dioxide injection. (Herring, A. L., *et al.*, Int. J. Greenh. Gas Con. 25, 93-101, 2014.)
- 3) Significant sorption of U onto Savannah River Site wetland sediments was observed at pH 8. The primary oxidation state of U in these oxidized sediments was U(VI). The results suggest that U may be strongly bound to wetland sediments, not only under reducing conditions by reductive precipitation, but also under oxidizing conditions through NOM-uranium bonding. (Li, D., *et al.*, J. Environ. Radioactiv. 131, 40-46, 2014.)
- 4) Synthetic garnet, a promising nuclear waste form, incorporates Ce predominantly in the trivalent state at low substitution levels, while a mixture of trivalent and tetravalent states was observed at higher concentrations. In combination with electronic structure calculations, the spectroscopy results suggest a strategy for designing materials in the garnet system possessing thermodynamically favorable substitution properties for actinides. (Guo, X., *et al.*, Chem. Mater. 26 (2), 1133-1143, 2014.)

Synchrotron X-ray Microprobe and Microspectroscopy Research in Low Temperature Geochemistry

Institution: Chicago, University of
Point of Contact: Stephen Sutton
Email: sutton@cars.uchicago.edu
Principal Investigator: Stephen Sutton
Sr. Investigator(s): Antonio Lanzirotti; Chicago, University of
Mark Rivers; Chicago, University of
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$203,000 (2014)

PROGRAM SCOPE

The project focuses on low temperature geochemistry applications of the X-ray Fluorescence Microprobe on Beamline X26A at the National Synchrotron Light Source (NSLS), Brookhaven National Laboratory. The microprobe can be used to determine the composition, structure, oxidation state, and bonding characteristics of earth materials with trace element sensitivity and micrometer spatial resolution. The following techniques are available for earth and environmental science research: (1) microfocused X-ray absorption spectroscopy, (2) X-ray fluorescence microprobe analysis, (3) microdiffraction, and (4) X-ray fluorescence computed microtomography. A bending magnet source at the NSLS is used along with Si(111) and Si(311) channel-cut monochromators, dynamically-bent silicon mirrors arranged in a Kirkpatrick-Baez geometry for microfocusing, and silicon-drift and Ge energy-dispersive detectors. Focal spots of 5-10 micrometers (FWHM) are achieved resulting in a gain in flux density of about 1500 over a pinhole of comparable size. Research areas include the geochemistry of toxic metals and metalloids in contaminated sediments and particulates, efficiencies of contaminant remediation strategies, speciation of toxic metals in mine tailings, bio-accumulation processes affecting the distribution of trace toxic metal species in soils, iron valence determinations used to infer the oxidation states of magmatic systems, and mineral surface controls on metal partitioning.

FY 2014 HIGHLIGHTS

- 1) Research on the role of cerium dioxide nanoparticle (NP) surface charge and the presence of natural organic matter (NOM) in determining bioavailability and toxicity to the model soil organism *Caenorhabditis elegans* suggested that environmental transformations (specifically coating with natural organic matter) rendered cerium dioxide NPs significantly less toxic. (Collin, B., *et al.* "Influence of natural organic matter and surface charge on the toxicity and bioaccumulation of functionalized ceria nanoparticles in *Caenorhabditis elegans*." ES&T 48, 1280-1289, 2014.)
- 2) Transformation of 30 nm ZnO manufactured nanomaterials (MNMs) in the presence of different concentrations of phosphate as a function of time and pH was examined using a variety of orthogonal analytical techniques. The data revealed that ZnO MNMs react with phosphate at various concentrations and transform into two distinct morphological/structural phases: a micrometer scale crystalline zinc phosphate phase (hopeite-like) and a nanoscale phase that likely consists of a ZnO core with an amorphous zinc phosphate shell. (Rathnayake, S., *et al.*, "A multi-technique investigation of the pH dependence of phosphate-induced transformations of ZnO nanoparticles." ES&T 48, 4757-4764, 2014.)
- 3) Roasting pretreatment of arsenic-bearing ores was evaluated in a broad context and related to the specific operations at the Giant gold mine, Yellowknife, NWT, Canada. The lack of oxidation of the arsenite in the tailings after 50 years is due largely to arsenite incorporation within the maghemite framework associated with structural vacancies. These results suggest that it is crucial to understand the effect of ore processing on the solid As form before investigating the geochemical response of As-bearing wastes in the environment. (Walker, S., *et al.*, "The effect of ore roasting on arsenic oxidation state and solid phase speciation in gold mine tailings." *Geochemistry: Exploration, Environment, Analysis*; in press, 2014)

Predictive Surface Complexation Modeling

Institution: Johns Hopkins University
Point of Contact: Dimitri Sverjensky
Email: sver@jhu.edu
Principal Investigator: Dimitri Sverjensky
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$96,511 (2014)

PROGRAM SCOPE

The proposed research aims to integrate the results of the work of many experimentalists into a theoretical model that can be used to extrapolate experimental studies to provide estimates of surface chemistry for systems not yet studied experimentally and for natural and anthropogenically perturbed systems. Three overall goals include: (1) finish the development of a predictive model for silica adsorption on all oxides, (2) investigate the applicability of a general two-site approach built on the PI's previous studies, and (3) improve theoretical relations for predicting metal and oxyanion adsorption, including an investigation of extending the ETLM to higher temperatures and pressures.

FY 2014 HIGHLIGHTS

The geologic complexity affecting the chemistry of mineral-water interactions in shallow subsurface conditions involves a wide variety of variables. These include a wide variety of minerals, and poorly crystalline precursors to minerals, and a very wide range of aqueous species. My previous studies have shown that surface complexation can be applied in a predictive mode for many of the different types of minerals and mineral precursors. Using the extended triple-layer model (ETLM), the application of Born solvation theory enables prediction of adsorption onto many types of solids. Despite this, the geologic reality is that most near-surface and shallow subsurface waters on the continents are predominantly Ca-bicarbonate-silica waters. Consequently, it is essential to be able to model the chemistry of the mineral-water interface in such waters. Remarkably, there is not much experimental information about how such waters behave at the surfaces of minerals. Recent efforts in the present project have been oriented towards developing predictive surface complexation models to address this issue. One example that was completed shows the surprising effect of an organic acid anion (glutamate) on Ca adsorption on rutile. The surface charge on the rutile is completely reversed at pH values of about 7 to 9 by the adsorption of Ca. Under these circumstances, an organic anion can adsorb strongly when it would normally not adsorb. Experimental results are consistent with this behavior. This type of cooperative effect illustrates the need to account for the chemical and geologic complexity of the mineral-water interface in natural systems.

EARLY CAREER: Defining Fe and H Speciation During Olivine Carbonation Under Highly Reducing Conditions

Institution: Colorado, University of
Point of Contact: Alexis Templeton
Email: alexis.templeton@colorado.edu
Principal Investigator: Alexis Templeton
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The water-rock reaction pathways that occur during the anoxic alteration of mafic and ultramafic rocks are not currently well constrained in either theoretical models or laboratory experiments, particularly at shallow subsurface temperatures below 100°C that occur in many hard-rock aquifers hosted in peridotites, gabbros or basalts. In particular, there are wide discrepancies in the predicted amount of H₂ and/or energy that will be generated through the oxidation of Fe during olivine and pyroxene hydration and carbonation, and ongoing debate about the possible pathways of associated CO₂ consumption. The overarching goal of this DOE EC project is to examine the connections among the geochemical behavior of iron, and the extent of hydrogen, methane or carbonate mineral formation during the aqueous alteration of olivine and pyroxene bearing rocks at near surface temperatures and pressures. We are using an integrated suite of microscale x-ray scattering and spectroscopic techniques to interrogate the reactivity and progressive alteration of peridotites during water/rock interaction. We are also measuring the stable isotope composition (δD and $\delta^{13}C$) of hydrogen, water and methane from our experiments to determine whether the water-rock reaction pathways (including biologically influenced systems) can be detected and interpreted in-situ.

FY 2014 HIGHLIGHTS

We are pursuing several unexpected but significant experimental findings that suggest that substantial mineral-driven CO₂-reduction occurs during low-temperature peridotite hydration, resulting in the production of small molecular weight organic acids, particularly during the alteration of partially-serpentinized rocks. These observations have been derived from water/rock alteration experiments in CO₂-bearing fluids reacting with San Carlos peridotite, Cedars peridotite and Oman peridotite, and we are now testing whether we can observe similar processes in-situ in subsurface aquifers, as well as in further experiments with ¹³C labeled substrates. In water/rock alteration experiments with Oman peridotite, we have also shown substantial generation of molecular hydrogen at temperatures between 55-100°C, and tracked the subsequent consumption of rock-derived hydrogen during reaction with dissolved CO₂. We can identify and localize the key Fe-redox reactions occurring during low temperature serpentinization using synchrotron-based microXRF mapping and Fe XANES microspectroscopy. These x-ray spectroscopic approaches are part of an integrated suite of chemical imaging approaches we have developed that utilize QEMSCAN, hyperspectral Raman imaging and multiple-energy x-ray fluorescence mapping to determine changes in Fe speciation during alteration of ultramafic rocks, and to track the extent of in-situ mineral carbonation. We are also developing a low-temperature H₂ isotopic geothermometer and measuring δD of hydrogen gas produced from water/rock interaction in the presence and absence of CO₂ at near-surface temperature. Comparative isotopic data for H₂ generated during low temperature serpentinization reactions has also been obtained from numerous subsurface H₂ and CH₄ rich hyperalkaline fluids collected from deep wells in Oman peridotite that are undergoing modern water/rock interaction.

Disequilibrium Controls on ¹³C-¹⁸O Bond Order in Carbonate Minerals

Institution: California-Los Angeles, University of
Point of Contact: Aradhna Tripathi
Email: aradhna.tripati@gmail.com
Principal Investigator: Aradhna Tripathi
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$132,159 (2014)

PROGRAM SCOPE

The underlying mechanisms for isotopic disequilibrium in carbonate minerals can be studied using: 1) precipitation experiments that have been carefully designed to study under what conditions disequilibrium isotope signatures are observed, and 2) theoretical modeling of disequilibrium and equilibrium processes using principles of quantum chemistry and molecular dynamics. Clumped isotope geochemistry represents a new research frontier, and has the potential to be a powerful tool in the geosciences. We are examining controls on the occurrence of heavy isotope pairs, or other multiple rare isotope substitutions, in molecules. The development of analytical instrumentation and methods for high-precision measurements of clumped isotope signatures is creating new sets of geochemical tools - geothermometers, biosynthetic signatures, forensic fingerprints. Our work is focused on investigating the underlying mechanisms for isotopic disequilibrium in carbonate minerals. We are building a solid framework from which to interpret clumped isotopic signatures in carbonate minerals from a variety of conditions, which would enable applications to study processes as wide-ranging as oil and gas reservoir development, carbon capture and storage, tectonics, climate change, and biomineralization.

FY 2014 HIGHLIGHTS

We have conducted precipitation experiments, measured samples grown from our precipitation experiments and those samples provided by collaborators at both low and high ionic strength and different growth rates, conducted theoretical calculations, tested kinetic models for isotopic fractionation, and used these results to interpret data from geological samples. Key results include:

- (1) Using witherite precipitation experiments to determine the clumped isotope composition of bicarbonate and carbonate ions in a solution.
- (2) Carrying out MD simulations to predict the isotopic composition of different DIC species to compare with experimental data.
- (3) Quantification of mineral-specific acid digestion fractionation factors.
- (4) Using experimental data for calcite from growth reactors to evaluate the influence of DIC speciation, ionic strength, growth rate, and enzymatic activity on isotope signatures in calcite.
- (5) Determining kinetic trajectories in a multi-isotope space (clumped and oxygen isotopes) using both theory and experimental data, and fingerprinting the occurrence of different processes in natural systems.
- (6) Discovering factors that have the potential to drive disequilibrium clumped isotope and oxygen isotope signatures of carbonate minerals. These factors include solution variables including pH, salinity, and cationic composition, the timescale for DIC equilibration, and reactions at the mineral-solution interface, and mineral growth rate.

Improved Sims Analysis of D¹⁸O and D¹³C in Low Temperature Carbonates

Institution: Wisconsin-Madison, University of
Point of Contact: John Valley
Email: valley@geology.wisc.edu
Principal Investigator: John Valley
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$243,085 (2014)

PROGRAM SCOPE

We are refining techniques for microanalysis of stable isotope ratios at intracrystalline-scale in carbonate minerals by SIMS and applying them to diagenetic cements in the Mt. Simon, Eau Claire, and St. Peter formations of the Illinois Basin. The Mt. Simon and St. Peter sandstones are under active evaluation, including drilling and injection, for their potential to store super-critical CO₂ in deep brine-saturated reservoirs. Objectives include:

1. Improve techniques for accurate and precise analysis of O & C isotope ratios by SIMS using ultra-small beam spots (<10µm).
2. Develop standards necessary for O & C isotope analysis of Ca-Mg-Fe-Mn carbonates by SIMS.
3. Measure O & C isotope growth zoning in individual carbonate cements.
4. Determine the zoning, genesis, and timing of porosity reducing carbonate cements.
5. Test our new “δ¹⁸O-microstratigraphy” model for carbonate, feldspar, and quartz cementation in the Illinois basin. We proposed that δ¹⁸O varies with temperature and depth during burial and that microanalysis of δ¹⁸O can be used to correlate the timing of cements throughout the basin.
6. Collaborate in related studies including: experiments on carbonates and quartz to calibrate O, C, & Si isotope fractionations, APT studies of radiation damage, and studies of biocarbonates.

These studies constrain the timing and distribution of cements and of primary vs. secondary porosity. This information is important for predicting the formation of cements that are layer parallel vs. crosscutting and thus for confinement and size of high permeability reservoirs. Better understanding of genesis and timing of diagenetic cements contributes to larger goals of DOE including: CO₂ sequestration in sedimentary basins, geothermal energy, groundwater resources and remediation, and reservoir properties for oil, gas, and drinking water.

FY 2014 HIGHLIGHTS

We published a new model for genesis of quartz cements and evolution of the Illinois basin (Hyodo *et al.* 2014, Chem. Geol.; Sliwinski *et al.* 2013 Penrose Conf.). Our combined SIMS, EMP, and SEM studies of the Eau Claire (Sliwinski *et al.* 2014 Goldsch. Conf; 2015 AAPG) and St. Peter Fms. (Denny *et al.* 2015 AAPG) reveal consistent growth zoning in diagenetic carbonates and feldspars that conform to patterns established for quartz cements, confirming our model for evolution of the Illinois basin. Two papers are in preparation. We completed experiments to calibrate O and Si isotope fractionation between quartz and water at 275°C (Pollington *et al.* 2013 AGU; paper in review by Pollington *et al.*) We obtained promising specimens varying from dolomite to ankerite and evaluated them as SIMS standards. This required SEM imaging of 67 samples, quantitative chemical analysis by electron probe (22 samples), calibration of O & C isotope ratios by conventional bulk-analysis (15 samples), and detailed stable isotope analysis by SIMS in different sessions for O and C (20 samples/each, 40-50 spot analyses/each). This massive undertaking has yielded 13 standards of dolomite-ankerite. This new calibration demonstrates significant curvature of SIMS bias (IMF) vs. Mg#, showing that studies using pure dolomite as a standard would be in error by up to 8%. A paper is in preparation by Sliwinski *et al.* We completed SIMS studies of cultured foraminifera for O isotopes (Vetter *et al.* 2013 GCA) and C isotopes (Vetter *et al.* 2014 GCA). SIMS data resolve 12-hour growth bands and correlate to Ba & Sr, demonstrating new approaches to study biomineralization and paleoecology. We completed the first atom-probe studies of minerals. The effects of radiation damage are determined at single-atom scale in 4 zircons (Valley *et al.* 2014 Nature Geo.; 2015 Am. Mineral; UW grad-student, Blum *et al.* 2014 AGU).

The Role of Water in Grain Boundary Diffusion

Institution: Rensselaer Polytechnic Inst.
Point of Contact: Bruce Watson
Email: watsoe@rpi.edu
Principal Investigator: Bruce Watson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$231,000 (2014)

PROGRAM SCOPE

This project represents a continuing program of experimental research at RPI aimed at furthering our knowledge of chemical transport in the lithosphere, focusing on grain-boundary diffusion of elements that are largely excluded from mineral grains. We are targeting in particular the role of H₂O in grain boundary transport in the absence of a free fluid phase, because field-based studies suggest that trace amounts of hydrous species in grain boundaries increase grain boundary diffusivities by several orders of magnitude. This possibility is significant because the P-T evolution of many solid-Earth systems probably occurred under “moist” but water-unsaturated conditions. Nearly all previous experimental studies of grain-boundary diffusion have targeted either “wet” (free H₂O) or “dry” systems. It is generally believed that the presence of H₂O molecules enhances grain boundary diffusion, but the dependence on H₂O concentration has not been systematically explored. There is also a lack of information on the quantities of excluded diffusants that can be stored in grain boundaries, how the presence of water might affect the temperature dependence (activation energy) for diffusion, and the extent to which different isotopes of the same element might diffuse at different rates. The challenges in this work include: 1) determining the “dry” baseline in diffusion behavior; 2) adding known small quantities of H₂O to grain-boundary diffusion experiments; 3) stabilizing the system against grain-boundary migration and/or grain growth; and 4) understanding the role of lattice diffusion in bulk transport. We have learned to work with excluded elements by developing what we call the “detector-particle” method for grain-boundary diffusion; we are now applying this method, along with more traditional approaches to grain-boundary diffusion of key elements, to determining the influence of H₂O and quantifying any effects of isotope mass on diffusion of geochemically strategic elements.

FY 2014 HIGHLIGHTS

We completed and published an investigation of grain-boundary diffusion of Mg in nominally dry quartzite, obtaining some of the highest grain-boundary diffusivities reported to date. This study involved olivine and pyroxene detector particles dispersed in synthetic quartzite samples for the purpose of “scavenging” Mg from the grain boundaries. This technique enabled us -- in addition to obtaining estimates of grain-boundary diffusivities and activation energies for diffusion -- to show that the partition coefficient for Mg between pyroxene and quartz grain boundaries is remarkably high, probably close to 1. Large quantities of “ghost” Mg (and probably other incompatible elements) can be transported and stored in quartz grain boundaries of this simple analog system. The same conclusion can probably be generalized to more realistic rock compositions. In December, 2014, Veronika Homolova successfully defended her doctoral thesis, which includes chapters on diffusive fractionation of Li isotopes in the grain boundaries of polycrystalline olivine, and also by lattice diffusion in olivine single crystals (characterizing lattice diffusion was necessary to understand bulk diffusion and separate the contribution of grain boundaries). In the Li grain-boundary diffusion experiments, ⁷Li/⁶Li ratios systematically dropped by up to ~6% along ~1-mm long diffusion profiles, indicating that ⁷Li diffuses

significantly more slowly than ${}^6\text{Li}$. Equally large differences in ${}^7\text{Li}/{}^6\text{Li}$ were produced within large single crystals of olivine over distances of only 0.1-0.2 mm. Clearly, both lattice- and grain-boundary diffusion of Li have significant potential to fractionate Li isotopes in natural systems at a variety of scales. This is probably true of higher-Z elements as well, but to a lesser degree because of the proportionately smaller mass difference among isotopes. In polycrystalline samples, most of the diffusive isotope fractionation appears to take place within the grain boundaries.

Anisotropy and Residual Stresses in Sedimentary Rocks: A Synchrotron and Neutron Diffraction Study

Institution: California-Berkeley, University of
Point of Contact: Hans-Rudolf Wenk
Email: wenk@berkeley.edu
Principal Investigator: Hans-Rudolf Wenk
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014-2015)

PROGRAM SCOPE

First a major effort is the investigation of elastic anisotropy in phyllosilicate-rich rocks. This is motivated by a need to understand and develop predictive models for the acoustic anisotropy in mudstones and shales. We are analyzing shales from a wide variety of environments to better understand crystal alignment during sedimentation, compaction and diagenesis. Also, sedimentary shales will be compared with fault gouge of similar composition (from the SAFOD project), slates and metamorphic schists, where phyllosilicate alignment was produced by recrystallization. We have relied on synchrotron hard X-ray diffraction, neutron diffraction and X-ray microtomography to quantify crystallite preferred orientation and pore space geometry. Second, we are exploring the *in situ* state of stress by measuring residual stresses that are still present in minerals of deformed rocks by local lattice distortion. This effort will focus on quartz, where we have exciting preliminary results. Experiments are performed with microfocus X-ray diffraction using the Laue imaging technique at the ALS synchrotron. The project provides data that are critical for interpreting macroscopic seismic observations. The methods in synchrotron and neutron diffraction that will be developed, as well as advanced methods of data analysis, are relevant for a broad range of physical sciences. The experimental as well as modeling methodologies that are developed will become available to other researchers and the still very confined texture research will be promoted for a broad range of earth sciences through workshops, training and publication of tutorials.

FY 2014 HIGHLIGHTS

The past year has been very productive, providing exciting new insight about anisotropy and stress patterns in rocks. 11 journal publications describe the results. Below are some highlights. With a newly developed self-consistent averaging method we can now predict anisotropic properties of shales based on microstructure, grain and pore geometry, preferred orientation and volume fractions. The modeling results are in excellent agreement with ultrasonic measurements of wave velocities (Kanitpanyacharoen *et al.* 2013, *J. Syn. Rad.* 20, 1-9; Vasin *et al.*, 2013, *J. Geophys. Res.* 118, 1-26; Vasin *et al.* 2014, *Geophysics* in press; Kanitpanyacharoen *et al.* 2014, *Geophysics* in press). In collaboration with geophysicists at Prague we are developing methods to measure P and S velocities on spheres, which allows complete derivation of the aggregate elastic tensor. Comparison with the microstructurally modeled tensor there is amazing agreement (Wenk *et al.* *J. Geophys. Res.* 2015, submitted). Perhaps

most exciting has been the quantification of stress in quartz from the San Andreas Fault observatory at Depth. Stresses of 300 MPa are still preserved. This will be reported in *Geology* (Chen *et al.* 2015, *Geology* in press). The educational aspect is also important, especially to train users in the sophisticated data analysis. A workshop at ALS in December 2013 attracted a large audience and two publications with tutorials received much attention, including Journal cover pages (Lutterotti *et al.* 2014, *Powder Diffraction* 29, 76-84; Wenk *et al.* *Powder Diffraction* 29, 220-232).

A Detailed Study of the Physical Mechanisms Controlling CO₂-Brine Capillary Trapping in the Subsurface

Institution: Oregon State University
Point of Contact: Dorthe Wildenschild
Email: dorthe@enr.orst.edu
Principal Investigator: Dorthe Wildenschild
Sr. Investigator(s): Marcel Schaap; Arizona, University of
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$145,215 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Capillary trapping is a somewhat under-explored mechanism in geologic sequestration of CO₂. Central to capillary trapping is its pore-scale nature: pore-scale geometry, fluid velocities, as well as brine- CO₂ interfacial physics will strongly determine the magnitude of capillary trapping. Because of its stable immobilization characteristics, capillary trapping has several advantages over structural trapping; advantages include not being affected by potentially compromised reservoir caprock, facilitating enhanced dissolution of gaseous CO₂ into the brine, and allowing gaseous CO₂ to be distributed over a larger reservoir volume. Compared to most current large-scale reservoir studies, our research takes several steps back in scale to observe and model trapping at the pore-scale and to learn how these findings translate into continuum scale properties that can subsequently support improved modeling of sequestration at large spatio-temporal scales. Two parallel but strongly interacting approaches are followed in our research (DE-FG02-11ER16278 and DE-FG02-11ER16277). The Oregon State University group, under leadership of Dr. Dorthe Wildenschild, conducts x-ray micro-tomography measurements of the capillary trapping process using proxy fluids to explore the effect of varying interfacial tension, viscosity, and flow rate on the resulting trapped amount of CO₂. The group at the University of Arizona, under leadership of Dr. Marcel Schaap, is developing functionality into lattice Boltzmann models that allow for the physical conditions found in the experiments as well as relevant pressure and temperatures found in candidate geological reservoirs.

FY 2014 HIGHLIGHTS

The OSU portion of this research has utilized x-ray computed microtomography to investigate nonwetting (NW) phase fluid movement and trapping on a pore-scale basis. We have utilized both ambient-condition and supercritical condition experiments to focus on three areas of study which are of significant importance to geologic sequestration of supercritical phase CO₂: (1) Variation of wetting (W) and NW fluid/engineering/medium properties and the resulting transitions in pore-scale force dominance; (2) Impact of the post-drainage, initial state of the system on the post-imbibition, residual state of the system; (3) Influence of wettability state on NW phase fluid flow and mobilization. In addition, supercritical-condition CO₂ injection experiments have been successfully conducted and used to relate the results to ambient condition studies to demonstrate the applicability of flow theories and models. The UA portion of the research has focused on 1) optimizing the lattice Boltzmann micro scale

code for computational speed (source code refinements) and implementation of parallelization routines to enable the code to run on high-performance clusters. 2) We found that the segmentation algorithms have huge (orders of magnitude) effect on computed flow rates for porous media obtained with broad spectrum x-ray tomography. 3) Development, parametrization and testing of multi-component equation of states capable of simulating the brine-CO₂ system under reservoir conditions. We found that we are able to reach the large density ratios and interfacial tension ranges required for this project and demonstrated that multiphase conditions (gas/liquid) of both single and multicomponent can be simulated in a stable fashion using numerically inexpensive algorithms.

DOE National Laboratories

Geochemistry of Interfaces: From Surfaces to Interlayers to Clusters

Sr. Investigator(s): Louise Criscenti; Sandia National Laboratories-Albuquerque
Jeffrey Greathouse; Sandia National Laboratories-Albuquerque
Anastasia Ilgen; Sandia National Laboratories-Albuquerque
Kevin Leung; Sandia National Laboratories-Albuquerque
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$690,000 (2014)

PROGRAM SCOPE

Mineral-water interfaces provide the critical setting for many geochemical processes in the environment. Surface properties of mineral substrates and the modified behavior of water molecules near the interface relative to bulk water remain difficult to characterize despite the best efforts of modern analytical methods. Although the science of interfacial chemistry has advanced significantly in recent years, there remain significant gaps in our knowledge of structure, reactivity, dynamics, and molecular mechanisms at both mineral surfaces (including the confined interlayers of clay minerals) and nanoscale molecular clusters (that consist predominately of surfaces comprised of oxygen, hydroxyl, and water ligands). This project combines computational, synthetic, and spectroscopic tasks to examine the nature of complex geochemical interfaces. Specific tasks address surface speciation, adsorption phenomena, surface complexation modeling, ion-pairing, interlayer structures, edge-site parameterization for clay minerals, and molecular cluster synthesis. Computational efforts emphasize the use of large-scale molecular dynamics simulations, *ab initio* MD, and related density functional theory and classical methods to address structure and thermodynamics of mineral-water systems. A suite of experimental and spectroscopic approaches are used to complement the computational efforts.

FY 2014 HIGHLIGHTS

We made significant progress in classical force field development for species on the edges of clays using hydrated oxide models. Vibrational frequencies from normal mode analysis of classical models are matched to DFT calculations. We used MD simulation and inelastic neutron scattering to study water vibrational behavior in smectite minerals. We collected INS spectra of hydrated and dehydrated montmorillonite and beidellite at LANSCE at LANL, and recently at the Spallation Neutron Source at ORNL, for samples exchanged with various alkali and alkaline earth cations. We examined organic dye

methylene blue at kaolinite surfaces to assess adsorption and aggregation of large cations on clays. We examined interfaces between goethite (α -FeOOH) and aqueous $MgCl_2$ or $BaCl_2$ solutions using classical MD. Mg^{2+} adsorbs as an outer-sphere complex complete with its hydration shell, and Ba^{2+} adsorbs as outer sphere on the (100) goethite surface and as both inner- and outer-sphere complexes on the (101) surface. These results are consistent with MD results for alkaline earth metal adsorption onto gibbsite ($Al(OH)_3$), but seem inconsistent with bulk adsorption data from UT Austin. *ab initio* MD for (101) goethite determine the energetic viability of the $PbSeO_3$ ion pairs proposed by UT Austin surface complexation models. Integration with data and models from Ohio State & UT is challenging our prior conceptions of the relationship between the strength of metal adsorption and metal solvation. To study the reactivity of the Fe(II)/Fe(III) couple in clay structures, we synthesized pure Fe-phyllosilicate and characterized it using X-ray diffraction, small-angle X-ray scattering, and Mössbauer spectroscopy. The structure and particle geometry of synthetic Fe-phyllosilicate is similar to natural nontronite, but with a lower degree of crystallinity and smaller average particle size. The Fe(II) content in the synthetic Fe-phyllosilicate is about 1-3% of total Fe and free of Fe-oxide impurities.

Integrated Isotope Studies of Geochemical Processes

PROGRAM SCOPE

Objectives are to better understand (1) molecular to micro-scale processes that control isotopic fractionation and trace element partitioning during mineral precipitation and transport in fluid phases and (2) behavior of isotopes and trace elements in large-scale hydro-geochemical systems. Molecular scale models are developed for mineral formation at both high and low temperatures, using isotopic and trace element fractionation effects as a guide to dynamical processes at the mineral surface. Isotopic fractionation during diffusion in liquids is also studied. Large scale system studies involve development of methods for characterizing transport and fluid-solid reactions rates using isotopes of solid radiogenic elements (Sr, Nd, Pb, Ca, U, etc.), light stable isotopes (O, C, H, Li, N, S, Ca, Mg, etc.), and noble gases (He, Ne, Ar, Kr, Xe). Molecular to micro-scale processes are addressed with experiments and measurements on natural systems focused on Ca, Mg, and O isotopic fractionation and trace metal incorporation during mineral precipitation, isotopic fractionation associated with diffusion of ions in aqueous solution, gases, and silicate liquids, and noble gas incorporation into biogenic and diagenetic minerals. Field scale research includes advancement of geochronological techniques focusing on U-Th-He and groundwater noble gases, studies of noble gases as gas phase partitioning tracers, investigation of S, H, C, and Fe isotopic fractionation during abiotic sulfide reduction, kinetic isotopic effects in pore fluids, sedimentary minerals, and plants, and modeling of isotopic effects due to fracture flow and inhomogeneous permeability in fluid-rock systems.

FY 2014 HIGHLIGHTS

The ion-by-ion growth model for calcite that predicts the variable Ca isotopic fractionation associated with non-equilibrium growth from oversaturated solutions has been extended to account for C and O isotopic fractionation, and also for clumped C-O isotopologues in calcite. The model is based on fits to new experimental data for the dependence of O isotopic fractionation in calcite on temperature, pH and growth rate, which incorporate the use of dissolved carbonic anhydrase in the precipitating solution to ensure isotopic equilibration of dissolved carbonate species. The resulting formulations represent the first comprehensive description of non-equilibrium Ca and O isotopic fractionation into calcite and have broad implications for the use of calcite as a paleoenvironmental proxy. Ca isotopes in calcite were also used to relate CO₂ loss to calcite precipitation during evolution of hydrothermal fluids in an active geothermal system. Experiments confirm models for the transport of noble gases during advection of CO₂ through porous media, and that Fe-oxyhydroxide nanoparticles are especially effective at adsorbing heavy noble gases while excluding light noble gases. Isotopic fractionation of K isotopes by diffusion has been shown with new experiments to be much smaller in methanol than in water, providing additional clues to mechanisms of ionic transport in these fluids.

PROGRAM SCOPE

Subsurface engineering endeavors, be they waste storage or resource extraction, rely on computational methods and characterization for prediction, risk and performance assessment. Central to these efforts are continuum constitutive models linked to first-principles conservation laws that are then represented in discretized numerical models of ever-increasing complexity. This project fills in knowledge gaps on multiphysics constitutive laws applicable to fluid pressured porous media, including pore-scale structures and topologies that define limits of applicability for traditional Darcy-type flow laws and influence percolation behavior, effective pressure laws that expand from typical Biot poroelastic treatments to include yielding and partially-drained effects, and stress-strain mechanical constitutive laws that move our understanding beyond ad-hoc non-associative elasto-plasticity or soil mechanics approaches. Specific tasks examine the coupling of mudstone mechanical, hydrological and chemical multiphysics as impacted by pore topology and structure, percolation methods that describe multiphase fluid invasion physics and capillary hysteresis, and thermodynamically-constrained mechanical laws validated by experiment. Novel imaging methods guide constitutive law development and include 3D

focused ion beam/SEM, optical and TEM confocal, SEM and TEM-EDS, CT scanning, and ultrasonic/acoustic methods.

FY 2014 HIGHLIGHTS

Central to FY 2014 efforts have been the successful submission of a renewal proposal in February titled “Shale Poromechanics: Heterogeneity, Flow, Failure, and Creep”; this is an outgrowth of this current project and was initiated in early FY 2015. Dewers and Heath along with Bill Carey from LANL received approval for AGU Fall Meeting session titled “Shale Science: Coupled Processes in Hydraulic Fracturing and CO₂ Sequestration.” Heath and Dewers (with A. Ilgen from Sandia) submitted a proposal to LANSCE titled “Deformation Partitioning in Shale Observed with in-situ Small Angle Neutron Scattering” to obtain beam time for clay deformation experiments and initiated novel experiments examining evolution of clay pore structures under *in situ* loading at the LANSCE facilities. Based on these results, Dewers and Heath worked with LANL staff in developing a new high pressure oedometric view cell for use in small angle neutron scattering. Ingraham *et al.* finished a test series on poroelastic effects. Dewers visited Zuleima Karpyn’s CT lab at Penn State and was given a tour and overview of their new micro-CT instrumentation and facility. A new student from NMT (Joseph Grigg) has begun work on nano-characterization and scale-dependence of shale mechanical properties. Ben Rosandick (NMT) successfully defended his thesis on the Mancos shale petrophysics in July.

Molecular Mechanisms of Interfacial Reactivity in Near Surface and Extreme Geochemical Environments

PROGRAM SCOPE

The Basic Energy Sciences (BES) Geosciences Research Program managed at PNNL is designed to advance our fundamental understanding of molecular and microscopic processes that control interfacial reactivity in near surface to extreme geochemical environments. Specific aspects of the research program are focused on 1) unraveling the dynamics of mineral interfacial reactions and the changes induced in mineral surface chemistry by electron conduction/transfer reactions, 2) determining the

molecular/microscopic mechanism resulting in mineral and water film nucleation and growth in geochemical environments including supercritical fluids and, 3) developing new computational approaches for interrogation of reaction mechanisms at mineral and nanoparticles interfaces. The research program provides a fundamental molecular-level understanding of macroscopic mineral-water and more complex rock-water interactions which are critical for accurately predicting the consequences of geologic disposal of the byproducts of energy production activities. Current activities focus on unraveling the influence of surface specific potentials of redox transformations of the iron oxides, understanding the local chemical environment of uranium substituted into iron oxide minerals, examining the role of interfacial strain in mineral nucleation and growth, providing new insights into transformation of metal silicate to metal carbonate minerals in low water high CO₂ fluids, and the development of new computational algorithms for evaluation of molecular mechanisms of reactivity at mineral surfaces which are applicable for use on petascale/exascale computer platforms.

FY 2014 HIGHLIGHTS

The program had many noteworthy accomplishments in FY14. In the area of redox transformations, we calculated electron mobilities in pure and impure goethite crystals using plane-wave DFT+U calculations, which revealed energetically favorable pathways along the double octahedral chains at nanosecond rates. We also published new experimental work on the incorporation of uranium in goethite, which showed that pentavalent uranium was the primary oxidation state of incorporated U, adding to the list of minerals in which pentavalent uranium is stabilized. Time-sequenced atomic force microscopy images of calcite reacted with cadmium chloride solution were used to quantify overlayer growth kinetics and showed that the heteroepitaxial growth of cadmium carbonate proceeds via three different mechanisms depending on the initial supersaturation: advancement of existing steps, nucleation and growth of three-dimensional islands, and nucleation and spread of two-dimensional nuclei. Crystallization of the overgrowth follows a non-classical pathway involving the formation of a surface precursor that is not fully crystalline, whereas high supersaturation favors the formation of crystalline nuclei. We studied the forsterite-wet supercritical CO₂ system using an innovative *in situ* method for infrared spectroscopic titrations of minerals with water in high-pressure fluids. We showed for the first time that Mg-carbonate surface complexes predominate below the threshold for continuous carbonation. The magnesite particles that form are hundreds of times larger than nanometer thicknesses of the adsorbed H₂O films that facilitate the transformation. First principles simulation analysis of x-ray scattering data were performed to identify solution structures of Ca²⁺ and Zn²⁺ as a first step in the development of molecular-level insight into the structure of the solute species. All areas of the program were productive in high-impact peer-reviewed journals.

Mineral-Fluid Interactions: Synchrotron Radiation Studies at the APS

Institution: Argonne National Laboratory

Principal Investigator: Paul Fenter
Sr. Investigator(s): Sang Soo Lee; Argonne National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$521,000 (2014)

PROGRAM SCOPE

We seek a fundamental molecular-scale understanding of mineral-water interface processes that control the geochemical transport and cycling of elements in Earth's near-surface environment. Processes of interest (including adsorption/desorption, growth/dissolution, and oxidation/reduction) play a critical role in controlling the bioavailability of nutrients and the sequestering or transport of toxins. This understanding is necessary for the development of robust predictive capabilities associated with the geological disposal of energy byproducts (e.g., sequestration of CO₂, spent nuclear fuel). The program strategy emphasizes direct molecular-scale observations of fundamental geochemical processes through *in situ* studies at ideal mineral-fluid interfaces. This is achieved using the unique characteristics of the Advanced Photon Source at Argonne National Laboratory (e.g., X-ray beam brilliance, flux, and tunability), allowing fundamentally new *in situ* experiments of mineral-fluid interfaces to be performed, including the ability to visualize the interfacial structures with sub-Å vertical resolution and <100 nm lateral resolution, with unique elemental and chemical sensitivities, and in real-time. These experiments will (1) help bridge the gap between the actual processes and the idealized conceptual models that are used to interpret field-scale observations, (2) further define kinetics and reaction mechanisms at the atomic scale in key mineral-fluid systems, and (3) provide results that can test computational studies of mineral-fluid interface processes through direct comparison to theoretical results. This approach will lead to an understanding of the interrelationships between structural, thermodynamic, and kinetic controls of interfacial processes that ultimately control the transport of elements through the near-surface environment.

FY 2014 HIGHLIGHTS

We have made multiple novel observations of mineral-water interfaces.

- The interaction of monovalent cations with the muscovite-water interface reveal the interrelationships between the adsorption structure and adsorbed ion distribution through a systematic study of alkali metal cations (Li⁺ through Cs⁺, along with H₃O⁺). Specifically, these studies revealed the significant differences in the adsorption energy due to differences in the cation adsorption speciation (i.e., the number of water layer separating the cation and the surface). Observations with Y³⁺ reveal that the large trivalent ion charge of Y leads to a phenomenon of cation “over-compensation” and a broad distribution indicative of multiple coexisting adsorption states.
- Pb²⁺ interaction with the calcite-water interface revealed a distinct interaction with carbonate surfaces. Our results revealed that Pb²⁺ does not interact with calcite by adsorbing on top of the surface, but instead by incorporating within the top 3-4 calcite layers, substituting for the Ca²⁺ ions. This observation was unexpected since the PbCO₃ adopts the aragonite structure in the bulk.
- The initial orthoclase (001) dissolution rates as a function of temperature and pH within the acidic regime (0 < pH < 3.4) was observed revealing two distinct regimes in its systematic variation with pH. Comparison of these results to predictions of transition states obtained by high level theory showed that this behavior could be explained as due to the presence of two distinct reaction sites (i.e., the Al-O-Si vs. the Si-O-Si sites) leading to a change in the rate limiting dissolution process near pH 0.5. We have also made advances in developing the X-ray reflection interface microscopy technique that was first demonstrated in this program. Recent advances include changes in optics that provide shorter imaging times as well as an improved spatial resolution of 70 nm.

Interconnections Between Dynamic Processes That Control the Formation, Evolution and Reactivity of Environmental Interfaces

Funding: \$230,000 (2014)

PROGRAM SCOPE

Unraveling the physics of an earthquake's source, reliable sequestration of CO₂, predicting wellbore breakout in oil and gas reservoirs, monitoring and imaging hydraulic fracture, monitoring thermal damage to rock in nuclear waste storage, and probing rock and cement integrity are all areas of research that require a new approach to material characterization and imaging. A material's elastic nonlinear response is extremely promising in this regard, and as far as we know, there is no more sensitive measure of material mechanical damage. A persistent problem in the application of nonlinear diagnostic imaging methods has been the direct relation between elastic nonlinearity and mechanical damage, because a physics-based theory does not yet exist; however, recent work has led to an experimental breakthrough in measuring material nonlinear response. The breakthrough, termed dynamic acousto-elasticity (DAE), has significant implications for the development of a physics based theory, and thus ultimately to our ability to quantitatively relate nonlinear response to material damage. In order to address the question of the origin of elastic nonlinearity in a material, we are developing DAE in conjunction with a new theoretical approach based on an extended Arrhenius model in combination with a numerical modeling approach based on local interactions. The outcome of this work will be a major advance in the domain of nonlinear mesoscopic elasticity research, and will have importance to OBES interests in wellbore collapse, near wellbore fracture conduits, CO₂-induced mechanical changes and general rock and cement integrity studies.

FY 2014 HIGHLIGHTS

During the past year we had a significant breakthrough in our understanding of the nonlinear elastic parameters that are measured applying Dynamic Acousto-Elasticity (DAE). We measure five different signatures of nonlinearity applying DAE; however we find that we need only measure two of them in order to fully characterize the nonlinearity (assuming a homogeneous, isotropic effect). This simplifies the experimental work and the theoretical approach considerably. This breakthrough is described an article that is currently in press in the Journal of Geophysical Research. We also had a breakthrough in application of DAE. We hypothesize that DAE can be applied to characterize the strong ground motion response of a site of interest. In this case we conducted an experiment in west Texas applying a large vibrator source to excite the nonlinear elasticity of the sediments, and we probe with accelerometers mounted in boreholes. We find that the site can be fully characterized in an advanced manner compared with other techniques and that the method holds great promise to future applications. This work was published in the Journal of Geophysical Research this year. A follow on experiment was conducted at Los Alamos this year as well applying a modified version of the experimental configuration. Analysis is in progress. The theoretical work that should provide the means to obtain the causal scale of

the features responsible for the nonlinear response is advancing as well, and it is a challenging problem. Initial results were published this past year by collaborators in Colorado and Russia. Our work involves collaboration with the University of Texas at Austin, with the Laboratory of Parametric Imaging, University of Paris VII [Sorbonne], with the Institute of Applied Physics, Nizhny Novgorod [Russia], and with the University of Colorado at Boulder.

²³⁰Th-²³⁸U Disequilibrium Measurements

Institution: Los Alamos National Laboratory

PROGRAM SCOPE

Uranium-series geochemistry and geochronology techniques have a wide range of applications in a number of fields including hydrology, paleoclimatology, paleoceanography, and volcanology. Our project aims to use well established bulk measurement techniques such as MC-TIMS and MC-ICPMS along with new high spatial resolution LA-MC-ICPMS techniques for U-series measurements. We then apply these techniques to better understand U-series environmental transport and develop/apply U-series chronometers in support of basic geoscience research for energy and waste concerns. Our project has contributed to a 'new wave' of analytical development within the isotope geochemistry community while providing new constraints on actinide mobility. We proposed to, 1) continue development of micro analysis methods for actinide studies, 2) use bulk measurement techniques such as MC-TIMS and MC-ICPMS along with new high spatial resolution femtosecond laser ablation techniques to measure U-series transport in U-rich fractures, 3) investigate near surface transport of anthropogenic and natural components in soil cores, and 4) demonstrate *in situ* methods for uranium-series geochronology of corals. Our work during this project has mainly focused on the first two goals. This work has contributed to our understanding of the geochemistry of mineral-water interactions and assessment of radioactive waste repositories, along with other hydrologic and geochemical processes. Development of high spatial resolution techniques also has applications to human evolution, plate tectonics, forensics and climate change. Finally, the new methods, new understanding, and newly trained researchers that result from this work have contributed to interests of other agencies such as environmental monitoring and threat reduction.

FY 2014 HIGHLIGHTS

Studies of U-series disequilibria near uranium deposits can provide valuable information on the timing of actinide mobility over a range of spatial and temporal scales. In our most recent work (Denton *et al.*, 2013), we characterized the geochemical evolution of the Nopal I uranium ore deposit (Sierra Peña Blanca, Chihuahua, Mexico) in terms of mineral-fluid interactions as well as the role that vertical fractures play in U transport and retention. The Nopal I deposit is a possible analog for actinide transport from a nuclear waste repository in fractured, unsaturated tuff and an arid climate. Samples were obtained from a vertical drill core (PB-1b) that extends to ~250 m depth below the surface. Our data show that uranium concentrations range from ~0.1- 0.8 wt. % and U/Th weight ratios range from ~50-700. The ore deposit contains ~0.57 wt. % U, therefore our results suggest that U has been mobile

up to 200 m depth in the past. $^{234}\text{U}/^{238}\text{U}$ activity ratios in the drill core samples range from 0.66 to 2.44 and illustrate a complex evolution consistent with interaction between groundwater enriched in ^{234}U and a tuff matrix that is depleted in ^{234}U due to recoil-related leaching. Closed-system U-Th model ages are generally >200 ka, and U-Th whole rock isochrons yield ages >200 ka with one exception. Although mineral-fluid interaction is ongoing and more complex open system models are possible, the most consistent interpretation of these data is that the drill core samples have generally remained closed with respect to U and Th mobility for >200 ka. These results confirm our prior U-series chronology studies of surface fractures at this site and provide one indicator of the effectiveness of natural barriers to actinide transport in this type of environment over long (10-100 ka) timescales. The results also provide a baseline for more detailed mineral work on actinide mobility and retention using LA-MC-ICPMS.

Geophysics - Detection and Monitoring of Fluids, Faults and Coupled Processes in the Earth's Crust

Institution: Lawrence Berkeley National Laboratory

Funding: \$1,152,000 (2014)

PROGRAM SCOPE

The problem we address is how to monitor fluid movement in the Earth using changing geophysical signals (time-lapse seismic and EM data) and to extract from the geophysical data 3D images of the evolving hydrogeological (permeability and porosity) and geomechanical (damage and rock-frame strength) fields. A host of subsurface energy and environmental priorities involve the injection or extraction of fluids from the Earth including CO₂ sequestration, geothermal energy generation and enhanced oil recovery. There is a critical need at present to have 3D time-lapse images of where the fluids go in the subsurface and what they do in terms of fracturing or changes to the rock properties. The work is divided into three focus areas: (1) Rock physics modeling that develops and experimentally tests new models for how changing fields related to fluid injection (fluid pressure, fluid saturation and fracture density) influence geophysical properties such as seismic velocities and electrical conductivity; these relations are the key that allow the evolving fluid invasion process to produce changes in geophysical signals (seismic and EM). (2) Hydrogeological and geomechanical forward modeling that develops novel ways to numerically simulate the complex processes of immiscible fluid invasion and the arrival of cracks and fractures; the proper physical modeling of these processes remains ongoing fundamental research. (3) Inverse modeling that develops various approaches to obtain information about the evolving hydrogeological fields and geomechanical damage from time-lapse seismic and EM data, including seismicity (earthquake) recordings. In the initial time period of FY 2014-2016, the focus is on developing the needed theoretical and numerical modeling abilities to perform this inverse problem with the various components (rock physics and forward modeling) constrained by lab experiments. The initial focus is on applying the developed algorithms to synthetic data sets.

FY 2014 HIGHLIGHTS

We began with the problem of injecting a fluid having a different salinity than the ground water. The injected fluid causes changes to the rock properties through three effects: (1) direct fluid substitution (the injected fluid has a different bulk modulus, viscosity, density and electrical conductivity compared to the *in situ* fluid), (2) fluid pressure-induced changes to the rock frame (permeability, porosity and drained elastic moduli) and (3) the creation of any cracks and fracture damage. A novel finite-difference code was written from scratch that models the above processes with the exception of damage modeling. A novel damage-modeling algorithm was developed that is based on the conservation of energy; namely, new fractures arrive when the work expended in creating new surface area in rocks is just balanced by the reduction in stored elastic strain energy. In the forward modeling of an injected fluid having a different salinity than the *in situ* fluid, we addressed the nature of the fundamental laws controlling the diffusion and dispersion of the solute in porous media and discovered that the transport law for dispersion is not symmetric due to advection. We also developed a way to track the arrival times of a salinity front with the goal of ultimately performing tomographic inversion for the dispersion and permeability coefficients. In other work, we continued to develop an alternative damage model based on the fluid creating wing crack extensions from pre-existing flaws in the rocks. Novel inversion methods were also developed for obtaining seismic moment tensors (that characterize the displacement across slip surfaces) associated with fluid-induced earthquakes; the novelty is to model the entire seismic recording (amplitudes and arrival times) and invert not only for the moment tensor of each earthquake event but for the seismic velocities of the crust using techniques developed by the group for the full-waveform seismic inverse problem.

Mineral Transformations in Supercritical CO₂-Dominated Fluids: Impact on Caprock Integrity

Institution: Oak Ridge National Laboratory
Point of Contact: Phillip Britt
Email: brittpf@ornl.gov
Principal Investigator: Gernot Rother
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$77,000 (2014)

PROGRAM SCOPE

This project led by Pacific Northwest National Laboratory aims to understand the physical and chemical processes taking place at mineral surfaces in contact with carbon dioxide (CO₂) plus water mixtures and in hydrous carbonates. The project addresses fundamental science questions relevant to the long-term caprock integrity of carbon sequestration sites. The ORNL-led part of this project is focused on the study of the pristine and reacted minerals (e.g., olivine, muscovite) and the properties of sorption phase formed at the mineral grain surfaces. Neutron scattering experiments, primarily neutron diffraction, of minerals (i.e., phyllosilicates, orthosilicates, and hydrated carbonates) are carried out to resolve the structural details of mineral-CO₂ interactions. The second subtask studies the sorption from mixtures of CO₂ and water (D₂O) to pristine and reacted mineral surfaces. The goal of this small angle neutron scattering study is to measure the density and composition as well as the volume (thickness) of the sorption phase for different conditions of temperature and fluid mixture composition. The combined analysis of neutron scattering and sorption analysis data will feed into new models for quantitative description of the sorption behavior of binary mixtures at mineral surfaces. The third subtask studies the structure of hydrated carbonates using neutron diffraction techniques with isotope substitution. The

ORNL effort will be synergistically linked to the overall project, leading to a novel understanding of complex geo-fluids in natural environments.

FY 2014 HIGHLIGHTS

In this project, led by PNNL, neutron scattering, optical spectroscopy, and gravimetric excess sorption measurements are utilized to assess the chemical stability, adsorptive capacity and swelling/shrinking properties of clays upon exposure to CO₂ as a function of pressure, temperature, and water/brine saturation. Neutron diffraction data are currently being analyzed to understand the impact of cation identity on the interlayer spacing, CO₂ uptake, and carbonate formation in smectites and illite. We have performed a quasi-elastic neutron scattering study of the dynamic properties of water in the clay interlayers for different clay hydration states and pressures of CO₂. The observed changes in the water single molecule dynamics are tentatively attributed to mobilization of interlayer water by addition of CO₂. We speculate that the CO₂ may partially substitute for interlayer cation hydration waters, effectively liberating these water molecules from their binding sites. A related FTIR study carried out with researchers at Virginia Tech and NETL measured CO₂ and water accommodation in the clay interlayers at different CO₂ pressures and provided clear evidence against carbonate formation in the clay interlayers. Excess sorption measurements of light hydrocarbon adsorption to clays and shales are currently being performed using the new high-pressure Rubotherm apparatus. In an extension of our ongoing studies of aqueous CO₂ – rock interactions, we aim at identifying the loci of wet natural gas adsorption in shaley rocks. Finally, the properties of hydrated carbonates have been studied by a combination of neutron diffraction and computer modeling. In the first experiments, the atomic to nanoscale structure of deuterated dypingite was measured at the POWGEN diffractometer and combined analysis with high-resolution XRD data is currently underway. Additional studies of other hydrated carbonates are planned to understand the formation and stabilities of these complex minerals.

Geochemical Equilibria and Reaction Dynamics: Atomic- To Pore-Scale Processes

Institution:	Oak Ridge National Laboratory
Point of Contact:	Phillip Britt
Email:	brittpf@ornl.gov
Principal Investigator:	Dave Wesolowski
Sr. Investigator(s):	Lawrence M. Anovitz; Oak Ridge National Laboratory Ariel A. Chialvo; Oak Ridge National Laboratory Miroslav S. Gruszkiewicz; Oak Ridge National Laboratory Gernot Rother; Oak Ridge National Laboratory Andrew G. Stack; Oak Ridge National Laboratory

Funding:	\$1,544,000 (2014)

PROGRAM SCOPE

The long-range goal of this project is to attain a fundamental, quantitative, and ultimately predictive understanding of geofluid speciation, mineral-fluid interfacial equilibria and dynamics, mineral reactivity, and the effect of these properties on the evolution of porous geologic media over wide ranges of temperature, pressure, composition and spatio-temporal scales. There currently exists a major gap in the geochemical community's ability to apply insights gained from integrated experimental and computational breakthroughs at atomistic-molecular scales to pore- and reservoir-scale geochemical processes. In this project our focus is on building a bridge across this gap by developing chemically-

realistic and experimentally guided and validated conceptual and computational models of geochemical reactions and mineral-fluid equilibria, and testing their ability to explain and ultimately predict the complex processes controlling geofluid properties, sorption, mineral growth and dissolution, and the interplay of these phenomena with diffusive/advective transport and nanoconfinement in porous geologic media. We address our project goal in three highly interactive subtasks that will ultimately unleash the ever-expanding power of integrated experimental, computational and analytical methodologies to achieve fundamental and predictive understanding of: geochemical reaction equilibria (Subtask 1); rates of mineral growth and dissolution (Subtask 2); and the textural and mineralogical evolution of porous geologic media resulting from fluid-rock interactions (Subtask 3).

FY 2014 HIGHLIGHTS

Our CMD Gaussian Charge Polarizable Model of water has been expanded to include aqueous electrolytes and their interactions with minerals. We have developed “best practices” to calibrate and validate CMD force fields using geochemical data of thermodynamic, structural and kinetic properties. CMD simulation results were validated by quasielastic neutron scattering data for the diffusional dynamics of water sorbed on minerals. We have measured the structure and vibrational dynamics of the interfacial water on cassiterite nanoparticles using inelastic neutron scattering and neutron diffraction coupled with CMD and *ab initio* molecular dynamics (AIMD), demonstrating the importance of sorbed water in nanoparticle stabilization, aggregation and growth. We expanded the model developed for calcite precipitation to an isostructural mineral containing a cation of substantially slower solvent exchange rate, magnesite. The difference in cation resulted in changes in the relative rates of the crystallization beyond that of just the difference in the solvent exchange rates. We incorporated the number of reactive sites on the mineral surface into the model and predicted net crystal morphologies from measurements of the growth rates of individual crystal faces. We used AIMD to identify the likely surface reactions that limit dissolution of quartz, demonstrating that chloride and alkali cations can promote formation of intermediate species controlling the dissolution process, and validated the simulations with X-ray reflectivity. Neutron scattering was employed to characterize porosity and pore morphology changes due to precipitation in pores during basinal brine migration, weathering, and metamorphic or diagenetic maturation in representative geologic formations. In addition, we have compared the diagenetic evolution of pore structures in tight gas shales as a function of shale composition, and determined that nanoporosity not associated with organic maturation is significant.

Institutions Receiving Grants

Differentiating Between Lanthanides and Actinides

Institution: Florida State University
Point of Contact: Thomas Albrecht-Schmitt
Email: talbrechtschmitt@gmail.com
Principal Investigator: Thomas Albrecht-Schmitt
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$640,000 (2013-2016)

PROGRAM SCOPE

A break in periodicity occurs in the actinide series between plutonium and americium as the result of the localization of 5f electrons. The subsequent chemistry of later actinides is thought to closely parallel that of lanthanides in that bonding should be ionic and complexation should not substantially alter the electronic structure of the metal ions. Herein, we demonstrate that ligation of californium(III) by a pyridine derivative results in significant deviations in the properties of the resulting complex with respect to that predicted for the free ion. We expand on this by characterizing the americium and curium analogs for comparison. These phenomena are also probed using quantum chemical calculations that support the involvement of 5f, 6d, and 7s orbitals in bonding. We show that these pronounced effects result from a second transition in periodicity in the actinide series that occurs, in part, because of the stabilization of the divalent oxidation state.

FY 2014 HIGHLIGHTS

This work was highlighted as the top discovery of 2014 by the Royal Society of Chemistry

Polymer-Supported Complexants: Metal Ion Selectivity and the Variables of Rational Design

Institution: New York-Hunter College, City University of
Point of Contact: Spiro Alexandratos
Email: alexsd@hunter.cuny.edu
Principal Investigator: Spiro Alexandratos
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

Polymer-supported complexants are important to environmental remediation, catalysis, separations, and the energy-efficient purification of product streams in industrial processes. The scope of this research is to probe the parameters that lead to a rational design of polymer-supported complexants. Rational design is the *a priori* approach to preparing a complexant that has a high affinity for a targeted metal ion. The parameters most important to the design of polymer-supported complexants are characteristic of the ligand (polarizability and conformational rigidity), metal (polarizability, ionic radius

and geometry) and polymer (conformational rigidity and polarity). The emphasis is on polarity / polarizability since it is present in all three components. The polymer support is polystyrene; rigidity is varied by the crosslink level and polarity is varied with comonomers. A range of metal ions is studied based on differences in polarizability and includes the uranyl ion because of its importance to DOE. A new set of phosphorus-based ligands with ion-exchange and neutral coordinating sites are being prepared, including phosphates, aminoalkylphosphonates and phosphinates. The ligands have different polarizabilities at the binding site due to substituents on and around the phosphoryl group. Monoprotic phosphates bound to ligands capable of metal ion coordination are of interest due to the possibility of synergism. Distribution coefficients are determined and correlated with parameters of the ligand, ion, and polymer. Spectroscopic analysis will give a detailed analysis of ion-ligand interactions. Changes at the binding site before and after loading with metal ions are followed with FTIR and the magnitude of band shifts correlated with the ion – ligand interaction. The goal, then, is to use correlations to define a set of principles wherein it is possible to predict the structure of a ligand that will have the highest affinity for a targeted metal ion.

FY 2014 HIGHLIGHTS

- A new polymer with a high affinity for the uranyl ion was prepared by binding pentaerythritol (PE) to polystyrene. The hydroxyl groups were first converted to bromide to provide a handle on which an array of ligands can be bound. Diethylamine was bound to the PE; greater affinity of the aminated polymer for the uranyl ion is found relative to a polymer with amine ligands directly bound to polystyrene. (Alexandratos, S.D.; Zhu, X. *J. Appl. Polym. Sci.*, 2013, 127, 1758)
- The polarizabilities of four ligands on polystyrene (phosphorylated ethylene glycol, ethylene glycol, sulfonic acid, and dimethylamine) were evaluated with Au(III) and Eu(III). Interactions were followed by percent sorption, acid concentration effect and FTIR spectra. The phosphoryl oxygen, hydroxyl OH, and amine have an affinity of Au(III) > Eu(III) while the sulfonic acid shows Eu(III) > Au(III) indicating neutral oxygen is soft while anionic oxygen is hard. (Zhu, X.; Alexandratos, S.D. *React. Funct. Polym.* 2014, 81, 77)
- In an important advance for the purification of wet process phosphoric acid, polymer-bound monoprotic phosphate ligands were developed for sorption of U(VI) from 3M phosphoric acid. The ligands are new phosphorylated mono- and triethylene glycol esters. The binding mechanism was probed by comparing their results to analogous diethyl esters. U(VI) was sorbed more efficiently by the monoprotic ligand. (Zhu, X.; Alexandratos, S.D. *Chem. Eng. Sci.* in press)
- Hydroxyapatite (HAP) is an inexpensive inorganic polymer made from lime. Its functionalization with ion-selective ligands would provide a low-cost option for environmental remediation. Functionalization with an organic complexant was developed as was a method to determine the amount of organic and inorganic phosphorus in the modified HAP. An increase in organic P capacity and a decrease in inorganic P capacity with increasing reaction time was found. (Daniels, Y.; Zhu, X.; Alexandratos, S.D. *Microchemical J.* 2013, 110, 263)

Thermochemistry and Reactivity of Atomic and Molecular Actinides

Institution: Utah, University of
Point of Contact: Peter Armentrout
Email: armentrout@chem.utah.edu
Principal Investigator: Peter Armentrout
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$478,000 (2014-2016)

PROGRAM SCOPE

These studies will contribute to understanding the reactivity, thermochemistry, and electronic structure of actinides. Quantitative experimental thermodynamic information for a variety of molecules containing the 5f elements, thorium and uranium, will be obtained. Studies will include reactions of 5f elemental cations with atmospheric gases yielding the thermochemistry of small covalently-bound molecules (such as oxides, carbides, nitrides, and hydrides), as well as ligation enthalpies of the elemental ions and their oxides by water and other ligands. Such quantitative information will be directly useful in the fundamental understanding of the chemical and physical properties of these elements at high temperature and will allow evaluation of chemistries useful in separations technologies. These studies will also provide benchmark data against which advances in electronic structure calculations for these elements can be rigorously tested. Such comparisons will be provided both in house and by collaboration with Dr. Wibe (Bert) A. de Jong, Lawrence Berkeley National Laboratory, an expert on coupled cluster approaches (both single and multi-reference) with relativistic corrections. Guided ion beam tandem mass spectrometry will be used to examine the kinetic energy dependence of a variety of reactions involving 5f-electron metal, metal oxide, and metal fluoride cations. Reactions of these ions with typical atmospheric gases (N_2 , O_2 , CO_2 , and H_2O) and halide containing species will be investigated. Analysis of endothermic exchange reactions using well-developed methods will yield quantitative bond energies of covalently-bound ligands. Binding energies of ligands non-covalently bound to the f-electron metal ions and their oxides will be measured using energy resolved collision-induced dissociation. Ligands could include H_2O , alcohols, ethers, ketones, amines, and more complicated ligands.

FY 2014 HIGHLIGHTS

The reaction of Th^+ with CH_4 (CD_4) and the collision-induced dissociation (CID) of $ThCH_4^+$ with Xe have been studied using guided ion beam tandem mass spectrometry. At low energies, Th^+ reacts with methane to yield $ThCH_2^+ + H_2$ as the only product, with an energy dependence that inconsistent with a barrierless exothermic reaction, as concluded from previous experiments at thermal energies. At higher energies, ThH^+ is the dominant product with $ThCH_3^+$ having a similar threshold energy. The latter product decomposes at still higher energies to $ThCH^+$. CID of $ThCH_4^+$ yields atomic Th^+ as the exclusive product, which indicates this species has a $Th^+(CH_4)$ structure. All cross sections are modeled to provide 0 K bond dissociation energies (in eV) of $D_0(Th+-H) \geq 2.25 \pm 0.20$, $D_0(Th+-CH) = 6.19 \pm 0.16$, $D_0(Th^+-CH_2) \geq 4.54 \pm 0.09$, $D_0(Th^+-CH_3) = 2.60 \pm 0.30$, and $D_0(Th^+-CH_4) = 0.47 \pm 0.05$. Quantum chemical calculations at several levels of theory explore the potential energy surfaces for activation of methane by Th^+ and the effects of spin-orbit coupling are carefully considered. The barrier to the dehydrogenation reaction is thought to exist as a result of the mixed (4F,2D) electronic character of the Th^+ $J = 3/2$ ground level combined with extensive spin-orbit effects. Reactions of Th^+ with H_2 , D_2 , HD , D_2O , and CO have also been studied. Reactions with the isotopomers of dihydrogen yield $D_0(Th+ H) = 2.46 \pm 0.07$ eV. Reaction with D_2O forms ThO^+ (75%) and $ThOD^+$ (25%) with a 70% efficiency at low energies. ThD^+ is also formed at higher energies. The primary ThO^+ and $ThOD^+$ products undergo subsequent exothermic reactions to form both ThO_2^+ and ThO_2D^+ . Cleavage of the very strong CO bond, $D_0(C-O) = 11.1$ eV, can also be induced by Th^+ to form ThO^+ and ThC^+ . Preliminary analysis of these data suggest $D_0(Th+ O) = 8.4 \pm 0.3$ eV and $D_0(Th+ C) = 4.4 \pm 0.3$ eV. The former value lies within the combined experimental uncertainties of the literature value, 8.74 ± 0.26 eV.

Computational Studies of NMR and EPR Parameters for Molecules Containing d- and f-Elements

Institution: New York-Buffalo, State University of
Point of Contact: Jochen Autschbach
Email: jochena@buffalo.edu
Principal Investigator: Jochen Autschbach
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

Actinide (5f) and lanthanide (4f) complexes have fascinating chemical and physical properties but they are not understood sufficiently well. Since actinides constitute dangerous radioactive and toxic components in nuclear waste there is an urgent practical need to address this problem. Theory is an integral part of the solution to this problem. We investigate magnetic properties of 4f- and 5f-element compounds (lanthanides, actinides) by using quantum theory and quantum chemical calculations. The main objective is to learn how observable magnetic properties are related to the geometrical structure, chemical bonding, and the nature of the ground and excited electronic states, of molecules containing 4f and 5f elements. These magnetic properties can also be measured in the laboratory. Once we have established their relation to structure & bonding for well-characterized compounds it will be possible to characterize other compounds via measurements of their magnetic properties. We develop and apply state-of-the-art relativistic theoretical methods, for example for computing of magnetic resonance parameters (electron paramagnetic resonance = EPR, nuclear magnetic resonance = NMR) and magnetic susceptibilities of lanthanide and actinide complexes, and perform benchmark studies in comparison with well-characterized transition metal complexes. The project goals include developments of new relativistic quantum chemical methods in the open-source NWChem quantum chemistry package and other quantum chemistry programs, and the development of chemically intuitive analysis methods for the calculated molecular properties.

FY 2014 HIGHLIGHTS

Highlights of the 2014 fiscal year include several theoretical studies of a variety of uranium(V), uranium(IV), neptunium(VI), and plutonium(VI) compounds with unpaired electrons. Calculated magnetic properties were in good agreement with experimental data available in the literature. New methods were used in these studies allowing a description of chemical bonding and the distribution of the unpaired electrons and their magnetization in chemically intuitive terms. Further, connections of current state-of-the-art calculations with older much more approximate theoretical methods (chiefly: crystal field theory) were established. A new method to calculate hyperfine coupling constants for ligand atoms in f-element complexes within a multi-reference quantum chemical framework was developed and tested. These hyperfine constants probe the shape and spatial distribution of unpaired electron spins from the actinide or lanthanide f-shells. Going forward, this will allow us to interpret complicated nuclear magnetic resonance spectra of actinide complexes. A book chapter was written jointly with other developers of the NWChem program, highlighting its capabilities for predictive modeling of complex actinide systems. These capabilities include relativistic density functional methods for magnetic properties developed by us during previous budget periods.

Synthetic, Spectroscopic, and Computational Studies of Redox-Active Uranium Complexes for Fundamental Organometallic Reactions

Institution: Purdue University
Point of Contact: Suzanne Bart
Email: sbart@purdue.edu
Principal Investigator: Suzanne Bart
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The principal investigator's laboratory is studying the synthesis, characterization, and reactivity of reduced uranium complexes. We propose the study of two redox active ONO ligands, 9-hydroxyphenoxazin-1-one (ONOphen), which consists of a 3 ring framework, and the bisphenol amine, (ONOcat), which is composed of two phenolic rings linked by an amine. These ligands can be easily tuned sterically and electronically by using substituted phenols, and formation of strong uranium-oxygen bonds make this class of ligands an excellent candidate for supporting low-valent uranium centers. These ligands can accept two electrons into the energetically low-lying π^* orbitals, allowing them to shift between monoanionic or trianionic supporters. Our studies will focus on several themes: 1) the synthesis of low-valent uranium derivatives supported by these redox-active ligands, 2) reactivity of these species for organometallic reactions and catalytic applications, and 3) spectroscopic, magnetic, and computational studies. This is a multi-disciplinary study that will examine the electronic structure and bonding environment of uranium complexes capable of performing multi-electron chemistry. Our proposed studies contribute to the general fields of actinide chemistry and organometallics by expanding the understanding of the chemical potential and unique properties of uranium, as we plan to combine both synthetic and spectroscopic techniques to develop uranium species that perform reactions necessary for catalysis applications. Using redox-active ligands to store and transfer electrons in multi-electron steps has been rarely studied with uranium, thus our studies will provide valuable insight into the fundamental reactivity of uranium. Finally, using uranium to produce useful materials that have an impact on daily lives will help to promote the message that uranium is not just for destruction, but can be used for consumer products and as a valuable carbon neutral fuel.

FY 2014 HIGHLIGHTS

We are currently exploring a family of redox-active ONO ligands, [ONOcat] and [ONOphen] ([ONOcat] H_3 = N,N-bis(phenol)amine); [ONOphen] H_3 = 9-hydroxyphenoxazin-1-one), for their ability to support uranium in varying oxidation states. Both the ligands have been successfully synthesized and metallated, and derivatives are currently being fully characterized. Their organometallic derivatives, Cp*U(ONOcat) and Cp*U(ONOphen), which have transonic ligands supporting tetravalent uranium centers, have also been synthesized and characterized by X-ray crystallography. These studies have recently been submitted to the journal *Inorganic Chemistry*. We also began exploring pyridine(diimine) ligands as an alternative to the ONOphen system, due to the difficulty in synthesizing this class of ligands. A series of pyridine(diimine) uranium compounds were synthesized by sequential reductions with potassium graphite, generating highly reduced uranium coordination complexes with ligands storing one, two, three, or four electrons. Full characterization of these molecules, including collaborative work with Prof. Laura Gagliardi, Dr. Stosh Kozimor, and Prof. Eric Schelter, has recently been submitted to the *Journal of the American Chemical Society*. These species easily reduce organic azides, forming uranium mono-, bis-

, and unprecedented tris(imido) products. The latter class of compounds are unprecedented for actinide species, demonstrating that oxidation of uranium species bearing reduced redox-active ligands is an effective route to previously unobserved moieties. All reported species have been spectroscopically and structurally characterized in our laboratory, and additional studies have been performed by Prof. Gagliardi, Prof. Schelter, and Prof. Justin Walensky. This work has recently been published in Nature Chemistry.

Actinide Sorption and Reduction on Sulfides, Oxides and Clay Minerals

Institution: Michigan, University of
Point of Contact: Udo Becker
Email: ubecker@umich.edu
Principal Investigator: Udo Becker
Sr. Investigator(s): Rodney C. Ewing; Stanford University
Students: 4 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$100,000 (2014)

PROGRAM SCOPE

In five publications, the mechanism of uranium reductions on semiconducting sulfide and oxide mineral surfaces is investigated. These studies reveal that typically, U(VI) is first reduced to U(V) before being further reduced to U(IV) or disproportionated to U(IV) and U(VI). In addition, it was found under which conditions U(V) or U(V)-containing solids form at least metastable states. In these sub-projects, significant progress has been made in method-development of the powder microelectrode, the single-crystal mineral electrode, and in the use of electrochemical atomic force microscopy to study redox reaction mechanisms on mineral surfaces. Electrochemical AFM allows one to observe *in situ* the growth of reduced U adsorbates on mineral surfaces as a function of solution pH, chemistry, and set electrochemical potential. In addition, samples were analyzed using EXAFS and XANES and, as a spinoff, an *in situ* electrochemical reaction cell was developed that allows for real-time structural and oxidation states changes using x-ray absorption spectroscopy. Both techniques are now available for powder and single-crystal applications. In addition, eight more publications have resulted from this grant on the atomic and electronic structure of actinide-containing metal organic frameworks, the thermodynamics of actinyl incorporation into carbonate, sulfate, and oxide minerals, as well as uranyl alteration phases, the thermodynamics of the UO₂-HfO₂ solid solution to evaluate the role of burnable poisons on nuclear fuel performance, and the mechanism and rate of He diffusion as a result of α -radiation from U in minerals.

FY 2014 HIGHLIGHTS

To understand the atomistic mechanism and kinetics of actinyl redox processes, quantum-mechanical electron transfer calculations involving Marcus theory have been performed. Electron-transfer (ET) calculations on the first rate-limiting ET-step (the reduction of U(VI)aq to U(V)aq by Fe(II)aq) complement the experimental results. The homogeneous reduction of U(VI)aq to U(V)aq by Fe(II)aq is thermodynamically and kinetically favorable if an inner-sphere complex can be achieved. However, significant thermodynamic and kinetic barriers exist to proceed from an outer-sphere ET reaction to an inner-sphere ET reaction, a process that needs to overcome dehydration of the first solvation shell and hydrolysis of Fe(II)aq. One publication from this grant reviews, evaluates, and expands the theory behind the calculation of redox potentials in solution for species such as organic compounds, inorganic complexes, actinides, battery materials, and mineral surface-bound-species. Different computational

approaches to predict and determine redox potentials of electron transitions are discussed along with their respective pros and cons for the prediction of redox potentials. This article reviews the importance of computational parameters, such as basis sets, density functional theory (DFT) functionals, and relativistic approaches and the role that physicochemical processes play on the shift of redox potentials, such as hydration or spin orbit coupling. In a new line of research, we evaluate the thermodynamic, structural, electronic, optical, and catalytic properties of actinide-containing metal organic frameworks (An-MOFs) which may be used for the determination of the potential of An-MOFs for photo-enhanced catalytic processes. Metal organic frameworks (MOFs) are a relatively new class of hybrid crystalline materials composed of metal ions or metal-clusters and organic molecules as building blocks.

EARLY CAREER: Actinide N-Donor Thermodynamics: Expanding the f-element Covalency Dialogue

Institution: Colorado School of Mines
Point of Contact: Jenifer Braley
Email: jbraley@mines.edu
Principal Investigator: Jenifer Braley
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

Unraveling the fundamental chemistry of the heaviest elements remains a grand challenge of science. Challenges associated with studying the heaviest elements stem from their radiological hazards and lack of availability. Understanding this chemistry will only become more important as nations worldwide consider and develop peaceful nuclear technology to meet future energy demands. To address current knowledge gaps, this research will study the chemistry of the actinide elements uranium, neptunium, plutonium, americium, curium, berkelium, californium and einsteinium. While most of the elements to be studied have reasonable availability, the berkelium and einsteinium isotopes will be produced using U.S. Geological Survey's TRIGA[®] Reactor. The thermodynamics of the interactions of these elements with nitrogen donor complexants (nitrogen complexants that donate electrons) will be investigated to gain insight into how these elements share electrons with other elements or materials. The interaction of actinides with these complexants is particularly interesting as nitrogen has demonstrated some ability to share electrons (bind covalently) with actinides. Resolving this chemistry will allow for improved management of used nuclear fuel and provide the United States with key fundamental knowledge in this important area of technology. The data that will be gathered at the extreme edge of the periodic table will elucidate uncertain and suspected periodic trends.

FY 2014 HIGHLIGHTS

FY 2014 Highlights: I started receiving project funding September 1, 2014. During this time, I was able to hire a postdoctoral researcher for the project, recruit a graduate student and initiate a literature review for publication in FY15. The graduate student is currently being sponsored in a teaching assistantschips. Efforts were initiated in evaluating the thermodynamic data for americium complexation by acetate.

Topological Structural Relationships, Properties, and Nano-Structures of U(VI), Np(V), Pu(V) and Pu(IV) Materials

Institution: Notre Dame, University of
Point of Contact: Peter Burns

Email: pburns@nd.edu
Principal Investigator: Peter Burns
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

The structural chemistry of the actinides is extremely varied, complex and fascinating. Recent studies have clearly indicated that actinide structural chemistry, especially as it pertains to transuranic elements, is an underdeveloped field. Many important actinide materials await discovery that will provide novel insights into actinide solid state chemistry. The revolution in the understanding of the crystal chemistry of U(VI) that has occurred over the past dozen years provides the foundation for extension of such studies into the transuranic elements, especially Np(V). Ultimately, a detailed understanding of the structural chemistry of Np(V) that approaches the current state of knowledge for U(VI) will be achieved. The specific objectives of this program are as follows. (1) Continue to synthesize and determine the structures of a chemically diverse suite of Np(V) compounds, develop topological relationships within this group of structures and those of U(VI), and study the magnetic properties of well-characterized Np(V) compounds. (2) Synthesize and characterize a broad range of compounds containing highly unusual U(VI) cation-cation interactions, and delineate the conditions under which such interactions are favored, to understand the impact of U(VI) cation-cation interactions on structural stability. (3) Renew efforts to crystallize Th nano-scale clusters (polymers), guided by small-angle x-ray scattering studies of mother solutions and studies of the crystal-chemistry of Th. (4) Train two Ph.D. graduate students and one post-doc in solid state actinide chemistry. Through research assistantships and supervision, introduce six undergraduate students, over three years, to actinide research.

FY 2014 HIGHLIGHTS

We have made progress in answering longstanding questions about the origin of uranyl peroxide complexes following the sunlight photolysis of uranyl nitrate and uranyl acetate solutions in pyridine, demonstrating that they arise from photochemical oxidation of water.¹ We developed methods for ionothermal synthesis of novel uranyl compounds, and examined relationships between their structural units and interstitial complexes. The exclusion of water provides insights relative to typical uranyl minerals and compounds synthesized using the more common hydrothermal approach.²⁻⁴ Studies of cation-cation interactions in actinide solids resulted in the several novel examples.^{5,6} We synthesized and characterized uranyl diphosphonate and arsonate compounds with new structure topologies, including nanotubular and nanocage arrangements of building units.⁷⁻⁹ Studies revealed complex uranyl-based structure topologies.^{10,11}

Novel Uranyl Bearing Materials via Restricted $\text{UO}_2^{\text{n}+}$ Speciation Profiles and Supramolecular Assembly

Institution: George Washington University
 Point of Contact: Christopher Cahill
 Email: cahill@gwu.edu
 Principal Investigator: Christopher Cahill
 Sr. Investigator(s):
 Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
 Funding: \$105,000 (2014)

PROGRAM SCOPE

The uranyl ion is subject to hydrolysis in aqueous media, which in turn leads to a diverse speciation profile that complicates the assembly of extended crystalline networks. As such, we have explored synthesis strategies in low pH, high-halide or high thiocyanate containing media to produce restricted speciation profiles. For thiocyanate media, the $[\text{UO}_2(\text{NCS})_4(\text{H}_2\text{O})]^{2-}$ tecton forms almost exclusively and thus provides a reproducible building unit for assembly with various organic cations such as substituted pyridinium cations (4-XpyH (where X = CH_3 , NH_2 , $\text{N}(\text{CH}_3)_2$, Cl, Br, I, SCN) Moreover, cations that are capable of sustaining multiple non-covalent interactions have been explored to provide a platform for multiple assembly modes. This strategy has led to the synthesis novel families of compounds and has provided a forum for systematic study of the predominant supramolecular interactions (i.e. halogen and hydrogen bonding) with respect to acceptor donor pairing. As a consequence, we are able to explore and rank and relative strengths of such interactions.

FY 2014 HIGHLIGHTS

A relative scale of interaction strengths responsible for the self-assembly of the uranyl isothiocyanate tecton and pyridinium molecules was published in *CrystEngComm* (December 2013; <http://dx.doi.org/10.1039/c3ce42106f>) and featured as a cover article and as a 'Hot' article on the Royal Society of Chemistry Blog: <http://blogs.rsc.org/ce/category/hot-article/>

Origin of Actinide Ion Partitioning in Biphasic Systems

Institution: Washington State University
 Point of Contact: Aurora Clark
 Email: auclark@wsu.edu
 Principal Investigator: Aurora Clark
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
 Funding: \$160,000 (2014)

PROGRAM SCOPE

Liquid-liquid solvent extraction for the isolation of metals is an essential feature of many processes within the nuclear fuel cycle. It is used in mining of uranium ore, fuel manufacturing, fuel recycling and reprocessing, and in waste treatment and management. The success of extraction derives from solute-solvent interactions, aqueous complexation and complex-adduct formation, as well as long-range properties described by the activity factors of the solutes in the pure phases. Empirical theories that describe solvent extraction are known, however advances in computational methods provide impetus for new models that incorporate a fundamental understanding of the underlying multi-scale physical phenomena. For extraction processes to become economically feasible and to design new separations approaches for the next generation of nuclear reactors, we must go beyond empirical observations and understand the fundamental molecular forces and mechanisms that govern metal speciation, complexation, and transport across phase boundaries. The scope of the project is to utilize multiscale theoretical methods and novel data analyses to characterize model Purex raffinate solutions and extraction systems, where deviations from solution ideality and changes in actinide hydrophobicity form the fundamental driving forces for successful extraction. This will provide an improved understanding of how perturbations to the H-bonding network and dynamics of water influence actinide complexation reactions and transport across aqueous:organic phase boundaries. The project uses simultaneous density functional theory calculations and molecular dynamics simulations that provide electronic structure and ensemble correlations of molecular systems. Novel data analysis provides the key to achieving insight into the structural and dynamic effects that are imparted by high ion concentrations and the hydrophobic character of extracting ligands and of neutral metal-ligand complexes.

FY 2014 HIGHLIGHTS

Major progress has been made in 3 core research areas:

- 1) Decomposing Hydrogen Bond Dynamics into Multiscale Components for the Development of a Hydrophobic Scale. Two manuscripts were published that outline a new software program that can quantify at a very high level of detail the dynamics of hydrogen bonding in a wide variety of chemical environment. A new algorithm was developed that allowed for more accurate calculation of hydrogen bond lifetimes so that all analyses can be better correlated with ultra-fast experimental studies.
- 2) Quantification of Organization and Dynamics at Aqueous:Organic Interfaces - Understanding How Mesoscale Interfacial Properties are Related to Miscibility and Microsolvation Reactions. One manuscript was published and another submitted that examined a special class of chemical reactions that occur at oil:water phase boundaries, microsolvation reactions. Microsolvation is defined as the rare event where one solvent molecule temporarily penetrates the co-solvent phases and is fully solvated therein. These reactions are the underlying processes that lead to permeability of an interface and are, we believe, correlated to rates of transfer of solutes across an interface. Our research examined the how microsolvation reactions are altered by the shape and packing ability of the organic solvent, and also the presence of an amphiphilic solute.
- 3) Accurate Solution Phase Thermochemistry of Actinides Across Oxidation States. In a published manuscript we developed a new computational protocol for obtaining highly accurate solution phase thermodynamic values for actinides in solution phase conditions that mimic Purex raffinates. Of specific importance in this context is to have equally accurate values for a wide variety of oxidation states of the actinide ions such that thermodynamic properties can be compared on equal footing for different chemical reactions.

Expanding the Fundamental Chemistry of Actinide Complexes

Institution: California-Irvine, University of
Point of Contact: William Evans
Email: wevans@uci.edu
Principal Investigator: William Evans
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$430,000 (2013-2014)

PROGRAM SCOPE

The objective of this research is to expand actinide chemistry to provide information that may be useful in the development of advanced nuclear fuel cycles. This research also provides training of graduate students who will be the next generation of scientists skilled in the chemistry of the f orbital metals, the lanthanides and actinides. This project involves examination of areas of uranium and thorium chemistry that have high potential to broaden heavy element chemistry. One of the fundamental aspects of any metal, the range of accessible oxidation states, is being studied to look for new actinide metal oxidation states. Underdeveloped reaction types, such as gas/solid reactions and radical reactions, are being examined to expand their scope and applicability with actinides.

FY 2014 HIGHLIGHTS

The first crystallographically characterized example of a molecular complex containing uranium in the +2 formal oxidation state was prepared. The isolation and structural characterization of the tris(trimethylsilylcyclopentadienyl)uranium anion provides the first opportunity to examine the reaction chemistry of the +2 oxidation state of uranium. The complex is unusual in that the electron configuration appears to contain d orbital as well as f orbital components. Efforts to develop new options for reaction protocols for complexes of the actinide metals have led to the discovery that solid samples of organoactinide complexes will react with gaseous reagents at room temperature in the absence of solvent. Organoactinide reactions are traditionally conducted in solution since the starting materials are soluble and high temperatures used in solid-state reactions can be avoided. Now it is possible to accomplish hydrogenations using gaseous hydrogen and solid organouranium alkyl complexes to make organouranium hydride complexes in better yield than the solution hydrogenolyses reported over 30 years ago. Carbon dioxide is also a viable gaseous reactant with solid organoactinides. The radical reactivity of thorium metallocenes has been studied to get information about actinide radical reactions in well-defined molecular complexes. The reactions of actinide complexes with radicals are of general interest since nuclear waste stream remediation chemistry involves radiolytically generated radicals. Reactions of thorium metallocenes with 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) have revealed that TEMPO can bind to thorium as a neutral radical, can replace anionic ligands such as methyl, hydride, and bromide, and can replace polydentate pentamethylcyclopentadienyl ligands. The radical reactions are synthetically useful to change actinide coordination environments since reproducible reactions are observed with high yields in most cases.

Multiconfigurational Quantum Chemical Study of Actinides and Lanthanides Containing Systems

Institution: Minnesota, University of
Point of Contact: Laura Gagliardi
Email: gagliard@umn.edu
Principal Investigator: Laura Gagliardi

Sr. Investigator(s):

Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)

Funding: \$177,000 (2014)

PROGRAM SCOPE

We will develop and employ quantum chemical models in order to study the chemistry of systems containing actinides and lanthanides in the gas phase, in low temperature matrices, and in condensed phase. The proposed research involves a strong collaboration with several of the experimental groups funded within the BES Heavy Elements Program. More specifically we intend to address the following problems:

1) Structural and spectroscopic characterization of molecules containing actinides and lanthanides in the gas phase and matrices

We will study actinide carbide cluster cations of compositions $[An_mC_n]^+$, with $m = 1$, $n = 2-14$, and $m = 2$, $n = 2-18$. These species have recently been produced by laser desorption/ionization or laser ablation coupled with mass spectrometry in the laboratories of Dr. John Gibson and Dr. Lester Andrews. The structures of the larger species are uncertain and theoretical studies are of importance.

2) Reactivity and spectroscopy of inorganic and organometallic compounds containing actinides

Besides isolated species in the gas phase, we are interested in studying systems in a condensed phase that may be relevant for catalytic purposes in inorganic, organoactinide chemistry, or for the design of new materials. We will investigate oxidative addition and reductive elimination reactions with f elements. Actinides do not have the two-electron redox couples that facilitate such reactions, as occurs in transition metal chemistry.

3) The ground and excited states of actinide and lanthanide ions in solution

We will also investigate actinide chemistry in solution, which is related to the separation, transport in the environment and safety of nuclear waste disposal. We will study the capture of uranyl, by a recently engineered protein (Zhou *et al.* Nat. Chem. 2014, 6, 236) with high selectivity and femtomolar sensitivity and predict new proteins with even enhanced selectivity for uranyl.

FY 2014 HIGHLIGHTS

- 1) In collaboration with Paula Diaconescu we studied the electronic structure of the arene-bridged complex in relation to a variety of mononuclear uranium amide complexes. The syntheses, molecular, and corresponding spectroscopic and magnetic properties were measured and interpreted with reference to results of DFT and CASPT2 calculations performed on model compounds.
- 2) We characterized the electronic structure of several actinide-containing molecules recently measured by various experimental groups. In collaboration with John Gibson we investigated gas-phase molecular thorium and uranium carbide cluster cations of composition $An_mC_n^+$, with $m = 1$, $n = 2-14$, and $m = 2$, $n = 3-18$. DFT computations were performed to illuminate this distinction between the thorium and uranium species.
- 3) In collaboration with Suzanne Bart we showed that a redox-flexible pyridine(diimine) ligand can stabilize a series of highly reduced uranium coordination complexes by storing one, two or three electrons in the ligand. These species reduce organoazides easily to form uranium–nitrogen multiple bonds with the release of dinitrogen. Computational analyses of the uranium imido products probed their molecular and electronic structures, which facilitated a comparison between the bonding in the tris(imido) structure and its tris(oxo) analogue.

- 4) We studied the capture of uranyl, by a recently engineered protein with high selectivity and femtomolar sensitivity. We found that UO_2^{2+} is coordinated to five carboxylate oxygen atoms from four amino acid residues of the super uranyl binding protein (SUP). A network of hydrogen bonds between the amino acid residues coordinated to UO_2^{2+} and residues in its second coordination sphere also affects the protein's uranyl binding affinity. The results of our free-energy simulations confirmed the previously reported experimental results and allowed us to discover a mutant of SUP.

Exploring the Reactivity of the Uranyl Ion and Its Chalcogen Analogues: Expanding Our Understanding of Uranyl Reactivity and Behavior

Institution: California-Santa Barbara, University of
Point of Contact: Trevor Hayton
Email: hayton@chem.ucsb.edu
Principal Investigator: Trevor Hayton
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

In both the environment and in processed nuclear fuel uranium exists primarily as the uranyl ion (UO_2^{2+}). Understanding its bonding and reactivity is critical for understanding uranyl speciation, predicting redox behavior, and developing a proliferation-resistant fuel cycle that minimizes waste and consumes the transuranic elements found in spent fuel. To help achieve these requirements, the first goal of this project is to expand the oxo ligand functionalization chemistry of uranyl, and understand its influence on the reduction of the 6+ oxidation state to the 5+ and 4+ states. Improved understanding of the electronic interactions and structural properties that facilitate oxo functionalization will enable the design of better methodologies for actinide decontamination. To achieve this goal we will: (1) Study the reactions of electron-rich uranyl complexes with a variety of hydride sources, such as silanes (R_3SiH). (2) Develop Lewis acids capable of effecting the catalytic reduction of uranyl to UO_2 at ambient temperatures and pressures. These studies could have industrial significance, with potential applications in the processing of nuclear fuel. The second goal of this project is to synthesize and study new uranyl analogues, specifically the chalcogen analogues of uranyl, $[\text{E}=\text{U}=\text{E}]^{2+}$ ($\text{E} = \text{S}, \text{Se}, \text{Te}$). By synthesizing and characterizing new derivatives of uranyl we expect to achieve a greater understanding of its complicated electronic structure. Understanding this bonding picture is necessary for firming predictions of uranyl behavior in both the environment and in spent fuel. Additionally, we anticipate the discovery of new modes of reactivity, with potential applications to organic synthesis and small molecule activation. To achieve this goal we will: (1) Explore the synthesis and reactivity of new terminal uranium chalcogenide complexes. (2) Develop new chalcogen transfer reagents and apply these to the synthesis of the chalcogen analogues of uranyl.

FY 2014 HIGHLIGHTS

We recently reported the ability of KSCPh_3 to act as a convenient sulfur atom source. In particular, reaction of KSCPh_3 with $[\text{U}(\text{NR}_2)_3]$ resulted in formation of a terminal sulfide, $[\text{K}(18\text{-crown-6})][\text{U}(\text{S})(\text{NR}_2)_3]$ ($\text{R} = \text{SiMe}_3$), via spontaneous release of the trityl radical. No doubt, this mode of reactivity is enabled by the low C-S bond dissociation enthalpy in $[\text{SCPh}_3]$. The trityl elimination strategy can also be applied to the synthesis of a terminal oxo complex. Specifically, reduction of $[\text{U}(\text{OCPH}_3)(\text{NR}_2)_3]$ with 2 equiv of KC_8 ,

in the presence of 18-crown-6, results in the formation of $[K(18\text{-crown-6})][U(O)(NR_2)_3]$ and $[K(18\text{-crown-6})(THF)_2][Ph_3C]$, which were isolated in 36% and 52% yield, respectively. To our knowledge, this is the first example of reductive deprotection of trityl to form an oxo ligand, and demonstrates that traditional organic deprotection protocols can be applied to inorganic synthesis. Importantly, this work also demonstrates that the trityl group can be cleaved from the heteroatom by two different mechanisms: either spontaneous loss of trityl radical or reductive cleavage of the trityl group or loss of the trityl anion.

Selective Recognition of Heavy Element by Protein Based Reagents

Institution: Chicago, University of
Point of Contact: Chuan He
Email: chuanhe@uchicago.edu
Principal Investigator: Chuan He
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$209,000 (2014)

PROGRAM SCOPE

The objective of this project is to engineer protein-based reagents that can selectively bind heavy elements in aqueous solutions. In fiscal year 2014, our work on the development of a uranyl-selective binding protein that binds uranyl with high affinity and selectivity was completed and published. Through collaboration with Professor Laura Gagliardi, we further improved the current uranyl-binding protein based on computational analysis. This result was just accepted for publication. We are in the process of setting up a potential high-throughput screen strategy that would enable us to perform direct evolution in order to select proteins that may bind uranyl with even higher affinity. During our initial research on uranyl-binding proteins, a program called URATEIN was created to search for possible uranyl-binding sites in protein scaffolds. We initiated a new research direction by modifying this program to search for proteins that may contain the necessary octo-coordination sites to chelate lanthanide and actinide ions. Over a hundred different proteins were identified after searching through more than 34,000 PDB entries, and of these six were identified through manual selection for expression based on structure and anticipated ease of expression. All genes were subcloned into pet28a for expression in the BL21 strain of *E. coli*. We are developing binding assays and testing binding affinities of these selected candidates.

FY 2014 HIGHLIGHTS

Uranyl is present in the ocean at a concentration of ~ 13.7 nM. We have engineered a thermally stable protein that binds uranyl tightly (K_d of 7.4 femtomolar) and highly selectively ($>10,000$ -fold selective over other metal ions). This protein can repeatedly sequester 30-60% of the uranyl in synthetic sea water. This system could find broad applications in uranyl sequestration, bioremediation, and other biotechnology applications.

Zhou, L.; Bosscher, M.; Zhang, C.; Ozcubukcu, S.; Zhang, L.; Zhang, W.; Li, C. J.; Jensen, M.; Lai, L.; He, C. *Nat. Chem.* 6, 236 (2014).

Spectroscopic Studies of Prototypical Actinide Compounds

Institution: Emory University
Point of Contact: Michael Heaven
Email: heaven@euch4e.chem.emory.edu
Principal Investigator: Michael Heaven
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

This program investigates actinide bonding mechanisms and electronic structure via high-resolution electronic spectroscopy. To obtain data that are best suited for evaluation of theoretical models, small actinide-containing molecules (di- and tri-atomic) are studied in the gas phase. Laser excitation and dispersed fluorescence techniques are used to characterize the neutral molecules, while sequential two-photon excitation measurements are used to determine ionization energies and physical properties of molecular ions. High level theoretical calculations are carried out for comparison with the experimental results, in order to evaluate the predictive capabilities of current relativistic quantum chemistry models. Our most recent experiments have focused on the molecules ThN/ThN⁺, ThS/ThS⁺, ThF/ThF⁺, and UF/UF⁺

FY 2014 HIGHLIGHTS

The electronic spectrum of ThN, which is isoelectronic with ThO⁺, was recorded for the first time. Rotationally resolved spectra confirmed the ground state to be X²Σ⁺, derived from the Th(7s)N configuration. The characteristics of ground state ThN, including the spin-rotation constant, were found to be closely similar to those of HfN. Twenty vibronic bands of ThN were characterized in the 19800-21200 cm⁻¹ energy range. The ionization energy of ThN (6.3272(4) eV) and the molecular constants for ThN⁺ were determined using two-color photoionization. The ground state symmetry was found to be X¹Σ⁺, as expected for ionization by removal of the Th 7s electron. Relativistic quantum chemistry calculations yielded predictions that were in reasonably good agreement with the experimental results for both ThN and ThN⁺. High resolution Stark spectroscopy was used to measure the permanent dipole moment of ThS X¹Σ⁺ (collaboration with T. Steimle, Arizona State University). The value obtained, 4.58(10) D was used to evaluate the quality of single-reference and multi-reference quantum chemistry calculations. Despite indications that ThS should be treated using multi-reference techniques, it was found that the single-reference methods were successful if the reference determinant was suitably chosen. The preliminary indication from this study is that computationally inexpensive Density Functional Theory methods can be used to obtain reasonably good predictions for open-shell actinide species. New laser excitation spectra for the ThF⁺ ion were recorded to determine the symmetry of the ground state. Rotationally resolved data for a transition centered at 20506 cm⁻¹ were used to definitively identify the ground state as X¹Σ⁺. With a low-lying 3Δ1 state, this molecule is ideal for measurement of the electric dipole moment of the electron (eEDM). To facilitate the design of eEDM experiments we used high-level quantum chemistry calculations to predict the low-lying electronic states.

Accurate *Ab Initio* Thermochemistry and Spectroscopy of Molecules Containing f-block Elements

Institution: Washington State University
Point of Contact: Kirk Peterson
Email: kipeters@wsu.edu
Principal Investigator: Kirk Peterson

Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$125,000 (2014)

PROGRAM SCOPE

The primary goal of the present program is to develop and then implement the *ab initio* methodology required for chemically accurate thermochemical and spectroscopic investigations of atoms and molecules containing heavy elements, with particular emphasis on lanthanides and actinides. The accuracy goal for thermochemical quantities, e.g., bond dissociation energies, heats of formation, electron affinities, etc., is 1-3 kcal/mol. These studies are based on extensions to the Feller-Peterson-Dixon composite approach, which hinges on recovering all important contributions to thermochemical quantities as accurately as possible. Highly correlated wavefunction-based approaches are employed, like coupled cluster singles and doubles with perturbative triples, CCSD(T), or multireference configuration interaction (MRCI) and perturbation theory (CASPT2), with a series of correlation consistent basis sets that allow for reliable extrapolations to the complete basis set (CBS) limit. This methodology will then be applied to fundamental, gas phase actinide- and lanthanide-containing species to assist existing, as well as future, experimental studies.

FY 2014 HIGHLIGHTS

Two series of correlation consistent basis sets, one based on small-core energy consistent pseudopotentials and the other using the all-electron, 3rd-order Douglas-Kroll-Hess Hamiltonian, have been developed for both Th and U from double- through quadruple-zeta, including sets for recovering 5s5p5d correlation effects. These sets have been used in extrapolated CBS limit coupled cluster thermochemistry studies of ThF_n (n=2-4), ThO₂, UF_n (n=4-6), UO₂F₂, UO₃, and UO₂(OH)₂ that included contributions due to core correlation, spin-orbit coupling, and lamb shift effects. The all-electron approach yielded heats of formation that agreed to within the experimental uncertainties in nearly all cases (UO₃ was the slight exception) with some results predicted to be more accurate than the existing experimental values (e.g., UO₂(OH)₂). The pseudopotential approach became less accurate when the process involved a large change in oxidation state of the actinide.

Experimental Electron Density Distribution in Actinide Compounds - An Experimental Atoms in Molecules Approach

Institution: Toledo, University of
Point of Contact: Alan Pinkerton
Email: a.pinkerton@utoledo.edu
Principal Investigator: Alan Pinkerton
Sr. Investigator(s): Vladimir Zhurov; Toledo, University of
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014-2016)

PROGRAM SCOPE

Chemical and most physical properties of materials are dependent on the distribution of the valence electrons. This distribution is easily measurable for crystalline light atom containing materials using the tools of X-ray diffraction, but until recently was an intractable problem for compounds of heavy elements. Recent developments in hardware and software for X-ray diffraction in our laboratory allow

more ambitious experiments to be proposed than previously. We thus address a fundamental question in the chemistry of the actinides – the nature of the actinide-ligand bond, particularly with respect to the degree of covalence. We are now able to measure the valence electron density distribution in compounds of elements as heavy as thorium or uranium using the technique of cryo-crystallography, followed by the fitting of a multipole model of the electron density to the X-ray diffraction data. The systems proposed for study are selected compounds of Th^{4+} , U^{4+} and of the uranyl ion. We will determine the electron density distribution and its topology in order to examine the characteristics of the strong uranyl $\text{U} \equiv \text{O}$ bond, as well as the weaker bonds between the actinide metals and other ligands of varying hardness. This challenging project will provide significant insight into the chemical bonds to actinide ions, as well as provide benchmark data to evaluate different theoretical methods. Given the current resurgence of interest in nuclear power generation, nuclear fuel processing, and the concern for the environmental impact, we will provide needed new understanding of the basic chemistry of these elements.

FY 2014 HIGHLIGHTS

Funding for this proposal only became available on August 26, 2014, hence accomplishments are limited. A high resolution x-ray diffraction experiment at 20K has been carried out on sodium uranyl acetate. Analysis of the data is incomplete.

Accurate Theoretical Approaches for Studying Actinides and Other Heavy Elements in Solid State

Institution: Rice University, William Marsh
Point of Contact: Gustavo Scuseria
Email: guscus@rice.edu
Principal Investigator: Gustavo Scuseria
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

Theoretically describing solids containing lanthanides or actinides is far from straightforward. This is because the f electrons can delocalize into a conduction band, form a chemical bond, or localize onto the lanthanide or actinide center. The potentially large number of localized electrons leads to a large number of potential magnetic structures. Methods which treat actinides or lanthanides must then be able to treat the various magnetic structures and the various possible behaviors of the f electrons on an equal footing. Actinide solids are crucial components of nuclear reactors. The actinide oxides focused on in this proposal are typical nuclear fuels; ideally, they would be replaced by actinide nitrides or carbides, which have superior refractory properties. Experimental characterization of actinide nitrides and carbides is fraught with difficulties, and theoretical investigations fare little better. This proposal seeks to continue the theoretical study of actinide oxides and to develop techniques capable of describing the actinide nitrides and carbides. Such theoretical investigations form an important counterpart for DOE-sponsored experimental research. This proposal seeks to develop sophisticated theoretical tools and apply them to the study of actinide materials. The theoretical techniques to be developed will fill an important void in the computational toolkit by combining low computational cost with an accurate description of strong correlations. The applications will enhance understanding of the magnetic behavior of actinide materials, as well as their behavior under extremes of pressure and temperature. In the long

term, they will provide a deeper understanding of actinide nitrides and carbides, which have the potential to be advanced nuclear fuels which will offer clean, carbon-neutral energy.

FY 2014 HIGHLIGHTS

These highlights correspond to the 2014 fiscal year. There were 5 publications acknowledging support from this grant during this period. Applications to actinide systems using density functional methods were carried out in collaboration with Xiadong Wen and Richard L. Martin from LANL. Applications to solid state actinide systems using the HSE functional developed in the PI's group are part of a long standing collaboration with Rich Martin's LANL research group. Methodological developments were carried out exclusively at Rice. Briefly, the most salient bullets have been: (1) A novel noncollinear density functional theory approach which is particularly important for heavy elements; (2) The implementation of full space symmetry group in our periodic boundary conditions code that will allow for much faster computations of crystalline solids; (3) The treatment of residual correlations not included by symmetry breaking and restoration (SB&R) techniques using a linearized Jastrow-type approach; (4) Development of a quantum embedding theory that will allow for accurate wavefunction calculations using Wannier functions on solids containing actinides; (5) Utilizing our SB&R wavefunction nodal surfaces in constrained-path quantum Monte Carlo calculations in collaboration with Zhiwei Zhang's group and partially supported by a CMCSN award.

Ion Pair Receptors: Fundamental Studies and Tests Involving Sulfate Anion and Thorium Cation Extraction

Institution: Texas-Austin, University of
Point of Contact: Jonathan Sessler
Email: sessler@cm.utexas.edu
Principal Investigator: Jonathan Sessler
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$495,000 (2014-2016)

PROGRAM SCOPE

As stated in the 2013 competitive renewal application, our goals during the current 3-year funding period are to continue our fundamental studies involving the development of ion pair receptors and their application to the recognition, sensing, and extraction of ions relevant to the DOE mission, including the uranyl (UO_2^{2+}), Th(IV), Cs^+ , and Li^+ cations, the chloride and sulfate anions, and various ion pairs derived therefrom. New work is designed to explore the possibilities of exploiting ion pair receptors as through-membrane transport agents with biomedical potential.

FY 2014 HIGHLIGHTS

We have made progress towards several of our stated project goals. Noteworthy was the synthesis of a new, bipyrrrole-strapped calixpyrrole receptor that was found to bind the sulfate anion and act as an effective extractant for this DOE mission-critical anion. This work was carried in conjunction with Dr. Bruce Moyer at Oak Ridge National Laboratory (ORNL) and members of his research team. Other work with strapped calixpyrroles led to the identification of the first systems wherein solid state self-assembly was promoted by ion pair recognition, as well as those wherein fluoride selectivity was engineered into the molecular structure. A particularly interesting finding made during the reporting period was the

discovery that one of our ion pair receptors, namely a pyridine diamide strapped calix[4]pyrrole, acted as an effective chloride transporter. As a consequence of this transport, apoptosis is induced in cancer cell lines. This work, which was carried out in conjunction with Profs. Philip A. Gale and Injae Shin, went “viral” on the internet after its publication in August of 2014 in Nature Chemistry. Apparently, the appeal to the broad, lay audience was the newly reported mode of action that basically involves the carrier-mediated transport of salt into cells. On the uranyl cation front, we completed our initial studies of cyclo[1]furan[1]pyridine[4]pyrrole (“F1P1P4”) and showed that this species not only complexed the uranyl cation well, but also assumed aromatic character as a result. A practical consequence of this change in electronic structure is that F1P1P4 acts as a highly effective sensor for the uranyl cation, with huge color changes being engendered as the result of cation complexation. To the extent the uranyl cation is a surrogate for the neptunyl and plutonyl cations, such a result may lead to improved detection protocols that could be applied in the event of untimely release of radioactive material.

Probing the Actinide-Ligand Binding and the Electronic Structure of Gaseous Actinide Molecules and Clusters Using Anion Photoelectron Spectroscopy

Institution: Brown University
Point of Contact: Lai-Sheng Wang
Email: Lai-Sheng_Wang@Brown.edu
Principal Investigator: Lai-Sheng Wang
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$270,000 (2014-2015)

PROGRAM SCOPE

This project focuses on the investigation of gaseous actinide-containing molecules using anion photoelectron spectroscopy. Three thrust areas are pursued: 1) probing the ligand-uranyl interactions in gaseous anionic complexes produced by electrospray ionization; 2) probing the electronic structure and chemical bonding of simple inorganic actinide compounds using electrospray and anion photoelectron spectroscopy; 3) probing the metal-metal bonding and size-dependent electronic structures in uranium oxide and fluoride clusters as a function of size and composition. Understanding the chemistry of the actinide elements, in particular, uranium, is of critical importance to the mission of DoE. The chemical properties of uranium are fundamental to the understanding of its speciation, transport, and eventual fate in the environment. Two state-of-the-art photoelectron spectroscopy apparatuses, one involving a laser vaporization cluster source and another involving an electrospray ionization source, are used in this project. Two new experimental capabilities, a temperature-controlled ion trap to create cold anions and a high resolution photoelectron imaging system, have also been developed and are used for this project. Photodetachment of anions involves removal of electrons from occupied molecular orbitals and probes directly the bonding properties of the underlying molecular species. Photoelectron spectroscopy of anions yields electron affinities, and low-lying electronic state and vibrational information for the corresponding neutral species. The application of anion photoelectron spectroscopy to actinide molecules has opened up new research opportunities and will yield a wealth of accurate and systematic electronic structure and spectroscopic information that can be used to verify computational methods and advance our understanding of the reactivity, structure, and bonding of actinide molecules.

FY 2014 HIGHLIGHTS

High Resolution Photoelectron Imaging of UO^- and UO_2^- and the Low-Lying Electronic States and Vibrational Frequencies of UO and UO_2 :

We have carried out a high resolution photoelectron imaging study to provide the electronic and vibrational information on two simple uranium oxide molecules: UO and UO_2 . The spectra for UO_2^- are consistent with, but much better resolved than our previous study using a magnetic-bottle photoelectron analyzer. The electron affinity (EA) of UO is obtained for the first time as 1.1407(7) eV, whereas a much more accurate EA is obtained for UO_2 as 1.1688(6) eV. The symmetric stretching modes for the neutral and anionic ground states, and two neutral excited states for UO_2 are observed, as well as the bending mode for the neutral ground state. The stretching vibrational modes for the ground state and one excited state are observed for UO . The current results for UO and UO_2 are compared with previous theoretical calculations including relativistic effects and spin-orbit coupling. The accurate experimental data reported here provide more stringent tests for future theoretical methods for actinide-containing species.

Observation of Gaseous UCl_6^- and UCl_6^{2-} Anions:

The Electronic Structures and Chemical Bonding of Uranium Hexachlorides We have produced two gaseous uranium chloride anions, UCl_6^- and UCl_6^{2-} and studied their electronic structure and chemical bonding using photoelectron spectroscopy and theoretical calculations. The EA of UCl_6 is measured for the first time as 5.3 eV and its second EA is measured to be 0.60 eV. We find that the one-electron molecular orbital picture and Koopmans' theorem break down for the strongly correlated U-5f2 valence shell of the tetravalent UCl_6^{2-} . Insight into the trend of the chemical bonding from $\text{U(VI)Cl}_6 \rightarrow \text{U(V)Cl}_6^- \rightarrow \text{U(IV)Cl}_6^{2-}$ is discussed.

DOE National Laboratories

EARLY CAREER: Harnessing f-Orbital Bonding through Precision Antenna Ligand Design for Actinide Complexation

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Rebecca J Abergel
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The needs to resolve the role of f-electrons in actinide bonding and to understand and design new molecular systems that control the chemical selectivity of actinides constitute two scientific grand challenges in the development of improved materials and processes for nuclear applications. Controlling the selectivity of actinide-binding species in complex environments necessitates the ability to understand and predict fundamental coordination properties of actinide-specific ligands. The objective of this work is to enable selective tuning of spectroscopic and thermodynamic properties of specific actinide complexes through precision ligand design and molecular recognition. The actinide sensitization efficiency of selective chromophore-containing ligands through the antenna effect will be explored, to establish a library of functionalized ligands with specific actinide-binding properties and spectroscopic features. Systematic and iterative characterization of the designed species will be used to harness the

influence of f-orbital bonding on the differences in actinide complex energetic and coordination features, including kinetic, thermodynamic and optical properties. Understanding the fundamental bonding interactions of selective actinide ligands presents a rich set of scientific challenges and is critical to the development of highly efficient separation reagents. The approach taken in this project paves the way to fulfill this difficult task by combining the precision ligand design, sensitive luminescence characterization, and theoretical modeling. The information gained from this effort will not only provide molecular signatures for the designed actinide coordination systems, it will yield fundamental knowledge of the role of f-electrons in actinide bonding and spectroscopic properties and will lay the foundations for further spectroscopic and synthetic work and discovery related to nuclear energy applications such as separation and waste storage processes.

FY 2014 HIGHLIGHTS

This project was successfully started in the last quarter of FY2014, with significant progress in the spectroscopic and thermodynamic characterization of actinide species. The first americium luminescence sensitization experiments were carried out using established ligands containing several hydroxypyridinonate and catecholate metal-binding isomers: complex formation between Am(III) and the octa-, hexa-, and tetradentate ligands 3,4,3-LI(1,2-HOPO), enterobactin, and 5-LIO(Me-3,2-HOPO), respectively, was probed in aqueous solution. Upon excitation of all three ligand pi-pi* transitions, structured emission patterns were observed and attributed to the Am(III) transition 5D_0 to 7F_1 (with fluorescence quantum yields of the order of 0.01 %). A series of Am(III) sensitizers was therefore identified for the first time and will be used to build functionalized ligand platforms with tuned actinide sensitization properties. These luminescence properties were also used to determine complex formation constants, demonstrating higher stability for Am(III) complexes in comparison to the corresponding Eu(III) complexes, but lower stability than Cm(III) complexes. These data will be used for building empirical trends in bonding and coordination within the 5f element series, which will in turn be correlated with theoretical predictions. In addition, a new experimental setup for multi-photon absorption spectroscopy with radioactive actinide complexes was implemented, using a tunable laser as an excitation source. Both hydroxypyridinonate ligands mentioned above were found to act as two-photon probes for the sensitization of several trivalent lanthanide cations and of Cm(III). This is the first example and characterization of two-photon antenna sensitization of a transuranic actinide ion in solution, which paves the way for the detailed mapping of intermediate energy levels in 5f metal complexes.

Influence of Solution Phase and Interfacial Structure on Stability of Actinide Oxidation States: A Computational Approach

Institution: Pacific Northwest National Laboratory
Point of Contact: Bruce Garrett
Email: bruce.garrett@pnl.gov
Principal Investigator: Eric Bylaska
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$49,000 (2014)

PROGRAM SCOPE

Knowledge of the oxidation states and reduction/oxidation (redox) chemistry of actinide elements in these complex environments, as well as the ability to predict, control, or manipulate them, is critical to

virtually all aspects of environmental actinide chemistry, waste processing, and separations. Comprehending the chemical behavior and properties of actinides as a function of structure and geometry of mineral/water interfaces at the molecular level is critical to a mechanistic understanding that can be propagated into field scale and of subsurface contaminant behavior and transport. With the availability of high-performance parallel computational resources and scalable software, computational chemistry can now be used to study the redox chemistry of actinides at experimentally relevant geochemical interfaces and in the presence of a mixture of interacting ligands in solution. This program focuses on the influence of dynamical local molecular environments on complex formation, redox mechanisms, preferred oxidation states, and the role of spin-orbit coupling, as well as the role of 5f electrons in the bonding of actinides in geochemically relevant solution environments and at complex solution/solid interfaces. We will use our highly scalable capabilities in Gaussian and plane-wave density functional theory (DFT), including the essential relativistic scalar and spin-orbit effects, and properly account for the influence of the local molecular environment.

FY 2014 HIGHLIGHTS

In FY14, *ab initio* molecular dynamics (AIMD) simulations were used to examine the hydration structures, coordination energetics, and the first hydrolysis constants of Pu^{3+} , Pu^{4+} , PuO_2^{2+} , and PuO_2^{2+} ions in aqueous solution at 300 K. The coordination numbers and structural properties of the first shell of these ions are in good agreement with available experimental estimates. The hexavalent PuO_2^{2+} species is coordinated to five aquo ligands while the pentavalent PuO^{2+} complex is coordinated to four aquo ligands. The Pu^{3+} and Pu^{4+} ions are both coordinated to eight water molecules. The first hydrolysis constants obtained for Pu^{3+} and PuO_2^{2+} are 6.65 and 5.70, respectively, all within 0.3 pH unit of the experimental values (6.90 and 5.50, respectively). The hydrolysis constant of Pu^{4+} , 0.17, disagrees with the value of -0.60 in the most recent update of the NEA Thermochemical Database but supports recent experimental findings. The hydrolysis constant of PuO^{2+} , 9.51, supports the experimental results of Bennett *et al.* [Radiochim. Acta 1992, 56, 15].

Since the project is being closed out we have made every effort in the last year to make our developments accessible to other actinide and lanthanide researchers. In FY14, we have completely re-implemented our localized basis projected augmented wave (PAW) AIMD codes so that they are faster, more parallel, and easier to use. This development is important for the far right lanthanides and actinides. These atoms have very stiff pseudopotentials, requiring very small AIMD time steps. As a result, simulations using our non-PAW AIMD codes take an order of magnitude longer to carry out than for other lanthanides and actinides. This important new development has less stiff pseudopotentials that makes AIMD simulations of systems containing the far right lanthanides assessable to actinide researchers (e.g., P. Yang (LANL), W. DeJong (LBNL), R. Atta-Fynn (UT Arlington)) and lanthanide researchers (H. Simka (Intel)).

NMR Spectroscopy of Plutonium Systems

Institution:	Pacific Northwest National Laboratory
Point of Contact:	Bruce Garrett
Email:	bruce.garrett@pnl.gov
Principal Investigator:	Herman Cho
Sr. Investigator(s):	David Clark; Los Alamos National Laboratory Eric Bauer; Los Alamos National Laboratory
Students:	0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding:	\$638,000 (2014)

PROGRAM SCOPE

This project will evaluate magnetic resonance spectroscopy, ^{239}Pu nuclear magnetic resonance (NMR) especially, as a probe for Pu materials. By virtue of its place between the heavy actinides, whose electrons occupy atom-like states, and the light actinides, whose electrons delocalize into covalent or band-like states, plutonium is the pivotal element to investigate for insights into the extraordinarily rich electronic properties of the actinide series. Despite its potential for elucidating electronic structure and the favorable magnetic properties of the ^{239}Pu isotope, NMR spectroscopy has seldom been used for the study of Pu systems. With NMR instruments now available in radiological facilities at the Pacific Northwest National Laboratory (PNNL) and Los Alamos National Laboratory (LANL), and Pu samples of high quality at hand, we are in an unprecedented position to initiate NMR experiments of Pu-containing compounds of relevance to DOE missions. The primary objective is to measure ^{239}Pu and ^{17}O shielding and electric field gradient tensors and relaxation times in selected plutonium oxides. These parameters will enable us to visualize structures at defect sites and develop explanations for the complex behavior of nonstoichiometric PuO_2 . Recent work at LANL and PNNL suggests that the promise of ^{239}Pu NMR spectroscopy is within reach after 50 years of unsuccessful previous attempts. This multi-institution collaboration brings together the world's leading experts in the specialized procedures required for the synthesis and spectroscopic analysis of Pu materials.

FY 2014 HIGHLIGHTS

PuO₂ experiments. NMR spectra of PuO_2 have been collected in piecewise fashion over a 200,000 ppm range. Several resonances, probably originating from ^{239}Pu centers in a variety of crystalline and defect sites, have been observed, and are being investigated for assignments to putative microscopic environments.

Spectra of $(\text{Me}_4\text{N})_2\text{PuCl}_6$. An array of low temperature spectra has been acquired using the swept field NMR instrument at LANL. Like PuO_2 , $(\text{Me}_4\text{N})_2\text{PuCl}_6$ has a Pu(IV) center in a cubic environment, and is expected to have a singlet ground state that is favorable for ^{239}Pu NMR. A model assuming cubic symmetry, low magnetism, and small electric field gradients is being examined, and the interpretation of spectral features is in progress.

Theory development. In collaboration with Prof. Jochen Autschbach (University of Buffalo), who is a world leader in the computation of NMR parameters of heavy element systems, we seek to predict NMR parameters of Pu-containing systems. Knowledge of the shielding tensors of Pu and surrounding atoms is essential for the search of NMR lines and their interpretation in terms of the electronic environment. Also of interest is the energy and identity of the first excited state of cubic Pu^{4+} systems, which are critical to understanding the magnetic behavior of $5f^4$ systems.

Novel instrumentation and methods. Substantial effort has been devoted to management of the challenges of experimentation with Pu. Tubes and rotors designed by us are currently used to contain hazardous solid samples, but more recently we have pursued an alternative, superior approach that uses a sealed probe for radiological containment (Cho, *et al.*, U.S. patent pending). In addition, we have developed a process for making monolithic pellet-shaped samples that facilitate safe handling. Pellets made from PuO_2 synthesized by us have been created for current experiments. Technical Work Documents that codify our procedures have been prepared and approved.

An Integrated Basic Research Program for Advanced Nuclear Energy Separations Systems based on Ionic Liquids

Institution: Oak Ridge National Laboratory
Point of Contact: Phillip Britt
Email: brittpf@ornl.gov
Principal Investigator: Sheng Dai
Sr. Investigator(s): Huimin Luo; Oak Ridge National Laboratory
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$206,000 (2014)

PROGRAM SCOPE

Future advanced nuclear energy systems will require significant changes in the way nuclear fuel is processed, in order to achieve the increases in efficiency and reductions in waste sent to repositories that are necessary if nuclear power is to have a major role in serving the world's growing energy needs. Ionic liquids (ILs, salts that melt at low temperatures) enable technologies to achieve these goals. ILs have unusual physical properties and process safety advantages compared to ordinary solvents. Their properties can be controlled by design to fit a given need. This project explores the application of ionic liquids to nuclear separations processes with particular concern for their performance under ionizing radiation as found in separations conditions. A multidisciplinary team has been assembled to study the fundamental radiation chemistry of ionic liquids, learn how that chemistry interferes with separations efficiency in ILs, seek to prevent or mitigate such interference through substitution of ionic liquid components, and design and create ILs for more efficient and radiolytically robust separations chemistry. The goal is to replace current technologies with ones that allow more efficient use of resources and smaller environmental impacts, bringing us close to a sustainable energy future. The research effort at ORNL is a part of a project led by Dr. James Wishart at BNL that lies in development of ionic-liquid systems for separation of fission products.

FY 2014 HIGHLIGHTS

Solvent extraction of La^{3+} and Ba^{2+} by an ionic liquid extractant in an imidazolium-based ionic liquid diluent was investigated. Seven protic ionic liquid (PIL) extractants were examined based on five organic superbases and either 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octadione (Hfod) or 1,1,1,5,5,5-hexafluoroacetylacetone (Hhfac) β -diketones as the anion. For these PIL extractants, the extraction efficiencies and separation factors were found to be concentration dependent. Five new functionalized ionic liquids (FILs), tetraethylammonium di(2-ethylhexyl)phosphate, tetraethylammonium bis(2,4,4-trimethylpentyl)phosphinite, tetraethylammonium bis(2,4,4-trimethylpentyl)dithiophosphinite, tetrahexylammonium di(2-ethylhexyl)phosphate, and tetraoctylammonium di(2-ethylhexyl)phosphate were synthesized and characterized. These ILs along with two previously synthesized FILs were used as ionic extractants and investigated for rare earth elements (REEs) separation in $[\text{C}_{10}\text{mim}][\text{NTf}_2]/[\text{BETI}]$. These FILs as ionic extractants were miscible with $[\text{C}_{10}\text{mim}][\text{NTf}_2]/[\text{BETI}]$. A novel solvent extraction process for trivalent lanthanides and yttrium from aqueous solutions into ILs, which is promoted by a hydrophilic 1-methylimidazole (1-MIM) or 2-methylimidazole (2-MIM), was investigated. Slope analysis confirmed that MIM in ILs formed a 1:1 complex with La^{3+} and Y^{3+} and a 1:4 complex with Eu^{3+} and Lu^{3+} , depending on the atomic number of the metal. The metal–ligand interactions have been characterized by FTIR spectroscopy and ESI-MS. The effect of nitrate concentration on the extraction of lanthanides with 1-MIM in ILs was analyzed indicating that nitrate anions were involved in the extraction process.

EARLY CAREER: Molecular Transuranic Discovery Science: Underpinning National Energy Security and Waste Remediation Needs

Institution: Los Alamos National Laboratory
Point of Contact: David Morris
Email: demorris@lanl.gov
Principal Investigator: Andrew Gaunt
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$2,500,000 (2010-2014)

PROGRAM SCOPE

The aims of this research are to advance knowledge and understanding of transuranic coordination chemistry, electronic structure, and bonding (primary focus is upon the transuranic elements of plutonium and neptunium). The relevance of this project to DOE is to provide the basic chemical bonding information in support of development of novel actinide separation schemes for advanced nuclear fuel cycle processes and understanding how to control actinide speciation/behavior over a wide range of chemical environments. A central goal is to decipher the extent to which covalent bonding interactions are important in actinide complexes, the capacity of valence 5f and 6d orbitals to participate in metal-ligand interactions, differences between actinide and lanthanide bonding, and trends across the actinide series. There are two principal approaches to elucidating transuranic covalency in molecular systems that are under investigation. The first is to compare actinide/lanthanide bonding with 'soft' donor ligands, such as nitrogen, sulfur, and selenium, in which evidence for subtle covalency differences can be uncovered. The second is to isolate unprecedented transuranic metal-ligand multiple bonds that contain inherent covalent bonding character. Acquiring such detailed bonding understanding will ultimately facilitate rational molecular design processes for novel chemical solutions to nuclear fuel cycle and waste remediation challenges.

FY 2014 HIGHLIGHTS

New neutral An(IV) starting materials were developed, and published, to facilitate Np(IV) and Pu(IV) synthetic chemistry under anhydrous inert atmospheric conditions. Their preparations are high-yielding with X-ray single-crystal structural determinations performed. These tetrachloride-dimethoxyethane adducts have opened up access routes to previously unattainable target molecules. Of particular note, the Np(IV) starting material has been utilized in the isolation and solid-state structural determination of the first example of transuranic-ligand multiple bond that is not a dioxo cation. Specifically, a linear Np(V) bis-imido moiety was the product of reaction between the new Np(IV)-tetrachloride-dimethoxyethane adduct and an amide in the presence of bipyridine, a process during which Np(IV) is oxidized to Np(V), with the resultant product containing two Np=N bonds. The result demonstrates that the 5f and 6d orbitals are still accessible to engage in covalent multiple bonding interactions with 'soft' donors further across the actinide series than uranium, and also informs upon the redox stability of neptunium which is often problematic to control in processes. In a different system, a Np(IV) complex has been isolated and structurally characterized in which a tetradentate tris(amido) 'TREN' supporting scaffold has been installed onto the actinide metal center. This result now provides a platform to attempt to access a whole series of other metal-ligand multiple bonds, such as a terminal monoxo and chalcogenido groups, that can be used to develop covalency trends in comparison to uranium. In addition, characterization has been completed on a plutonium complex with a polydentate nitrogen

donor actinide selective extractant, in which it was demonstrated the Pu(IV) is unexpectedly reduced to Pu(III) upon complexation.

Heavy Element Chemistry

Institution: Los Alamos National Laboratory
Point of Contact: David Morris
Email: demorris@lanl.gov
Principal Investigator: Stosh Kozimor
Sr. Investigator(s): Enrique Batista; Los Alamos National Laboratory
James Boncella; Los Alamos National Laboratory
David Clark; Los Alamos National Laboratory
Steve Conradson; Los Alamos National Laboratory
Jaqueline Kiplinger; Los Alamos National Laboratory
Richard Martin; Los Alamos National Laboratory
David Morris; Los Alamos National Laboratory
Marianne Wilkerson; Los Alamos National Laboratory
Students: 8 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$1,286,000 (2014)

PROGRAM SCOPE

The central goal of the Los Alamos Heavy Element Chemistry program is to advance the understanding of unexpected covalency and electron correlation and their impacts on emergent phenomena in molecular and solid-state actinide materials. The purpose of this program is to understand f-element electronic structure and bonding and how it manifests itself in molecular and solid state structure and through its influence on spectroscopic and thermodynamic properties. Studies are directed at understanding 5f and 6d covalent mixing in metal-ligand bonding in light actinide complexes through a combination of synthetic chemistry, spectroscopic characterization, and theory and modeling to understand and predict the chemical and physical properties of actinide materials. Further studies are being undertaken to characterize collective and cooperative behavior within nanoscale domains with local compositions that deviate strongly from the average. The latter studies are primarily performed at OBES supported synchrotron or neutron sources. This multidisciplinary approach provides the scientific means to formulate rational approaches to solve complex actinide problems in a wide variety of environments to meet the next generation of needs in actinide science within the DOE complex. The systems under study are actinide species in aqueous and nonaqueous solutions, and solids.

FY 2014 HIGHLIGHTS

In FY14 the Los Alamos Heavy Element Chemistry (LANL HEC) program continued expanding understanding of unexpected covalency and electron correlation in actinide molecular science and in solid-state actinide materials. The success of the program in FY14 is demonstrated by the metrics summarized here. First and foremost are the LANL HEC quality manuscripts (over 20) that were published in high impact journals. Additionally, members of the LANL HEC team were invited to participate and organize international conferences in actinide science. LANL HEC has historically been a leader in the field of actinide chemistry, and consistent with this reputation members of the team were acknowledged within the community. This included Kiplinger's selection as the 2015 recipient of the F. Albert Cotton Award in Synthetic Inorganic Chemistry, Conradson named as an AAAS fellow, Kozimor being elected as the vice-chair of the Inorganic Gordon Conference, Martin honored with the 2nd Annual

Burris Cunningham Actinide Science award at LBNL, and Boncella's appointment as the chair of the ACS-Division of Inorganic Chemistry. The LANL-HEC program was also acknowledged by recruitment of its outstanding post-doctoral researchers into leadership roles at other institutions. For example, Neil Tompson accepted a position as an assistant professor at the Univ. of Penn., former post-doc Scott Daly was recruited to the Univ. of Iowa, Stefan Minasian was hired as a staff member at Lawrence Berkeley National Laboratory (LBNL), Matthias Löble was hired at Karlsruhe Institute of technology (KIT), and Angela Olson was converted to staff at LANL. Finally, the proximity of the team to programmatic efforts in national security facilitates transitioning LANL-HEC fundamental breakthroughs into operational capabilities. As testament, Kiplinger was honored in FY14 as a new Laboratory Fellow and Kozimor was recognized in the Los Alamos Award Program for outstanding contributions to the WIPP Investigation Project.

John Arnold; Lawrence Berkeley National Laboratory
Corwin Booth; Lawrence Berkeley National Laboratory
John K. Gibson; Lawrence Berkeley National Laboratory
Students: 7 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$3,117,000 (2014)

PROGRAM SCOPE

Berkeley Lab actinide research supports the role of the U.S. DOE as a key provider of fundamental science, science-driven solutions, and trained personnel to meet present and future national needs in actinide and nuclear chemistry. Objectives include understanding heavy element chemistry and physics at the atomic and molecular levels, and using this knowledge to address contemporary issues in actinide science. A central theme is 5f-orbital bonding and its impact on actinide chemistry and physics. Collaborative research ranges from exploring gas-phase actinide chemistry and synthesizing new actinide materials, to investigating 5f-element bonding, to elucidating electronic, magnetic, and reactivity characteristics of actinide molecules. Specific topics, including actinide complexation, solution chemistry, thermodynamics, and the chemical control of troublesome radionuclides, are pursued to overcome barriers to the advancement of nuclear energy. The research programs develop custom instrumentation for use with radioactive materials, including mass spectrometry, fluorimetry and calorimetry, and make intensive use of U.S. DOE synchrotron radiation light sources. Nuclear chemistry research explores chemical and nuclear properties of the heaviest elements. The comprehensive integrated approach to understanding actinide chemistry, as well as the emphasis on student involvement, make the program a unique effort in meeting the needs of the U.S. DOE in actinide science.

FY 2014 HIGHLIGHTS

The Berkeley Lab Heavy Element Chemistry research program has furthered fundamental understanding of the electronic structure, coordination chemistry, bonding and reactivity of f-electron materials,

spanning gas-phase to solution to solid state species. The first recognition of multiple sequential intramolecular energy transfer processes, leading to actinide luminescence sensitization by siderophore-like ligands forming macromolecular matrices, was established by single crystal X-ray diffraction and opens possibilities for new separations and sensors. Resonant hard X-ray spectroscopy provided the first evidence that details of f-orbital distribution, in addition to total f-orbital occupancy, dictate differences in Pu-based superconductors. These results indicate that differences in f-configuration fractions indeed exist, yet average to a similar total f-occupancy. Fragmentation of gas-phase complexes of Th⁴⁺, U⁴⁺, Np⁴⁺ and Pu⁴⁺ reflected variations in condensed phase redox chemistry across the actinide series and was shown to be a novel approach to explore actinide redox directly related to solution chemistry. The electronic structures of a new class of diamond-core U₅⁺²(U-O)₂ complexes, exhibiting strong exchange coupling between the U⁵⁺ centers, was unraveled in detail, clarifying the role of f-orbitals in magnetism and bonding of the actinides. Differences in f-element complexation were determined from the interactions of bis(2,4,4-trimethylpentyl)dithiophosphinate with Nd³⁺ and Cm³⁺ by a comparative study of thermodynamics and coordination modes. Unexpected bonding interactions were found by soft X-ray spectroscopy in two actinide sandwich molecules that have been at the center of debates regarding actinide covalency since the 1960s. The results show how f-element metal-carbon bonding can profoundly affect the reactivity and physical properties of organometallic molecules. A seaborgium carbonyl complex was synthesized and detected as part of a worldwide effort.

Richard Wilson; Argonne National Laboratory
Students: 5 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$2,539,000 (2014)

PROGRAM SCOPE

This program is providing fundamental knowledge of chemistry necessary for a predictive understanding of actinide behavior under environmental conditions and in basic separations scenarios of relevance to advanced technologies. The program has two primary foci, fundamental aspects of the chemical separation of actinides from fission products and the synthesis and characterization of new transuranic compounds. Our efforts are expressed in integrated and complementary projects centered on electronic properties, actinide-ligand interactions, structured phases, and solution interfaces. Within this context is an ongoing effort to develop the use of new-generation synchrotron radiation in support of actinide programmatic research. Our overall program is integrated through an emphasis on interactions that range from the atomic to the collective. We explore the structural correlations in solution and relate them to crystalline materials to understand the physical influences on bonding behaviors and energy partitioning. Single-ion properties such as formal potentials, optical behavior, and magnetic response

are quantified in detail. Complementing these studies are our efforts to understand molecular-level organization and aggregation of f-ion solutes in solution and the structures of solid phases that precipitate. On intermediate-length scales, we are characterizing solute and solvent organizations of supramolecular or nanoscale aggregates that can have a marked impact on solvent extraction systems. This effort is centered on structured solutions and deals largely with hydrophobic phases and aqueous/organic interfaces. Molecular dynamics calculations are coupled with X-ray scattering experiments from liquid-liquid interfaces to gain insight into molecular processes occurring at the interface during ion transfer between two immiscible liquids. These studies are providing insight into how to model and use molecular organization in targeted syntheses and separations.

FY 2014 HIGHLIGHTS

Novel results center on solution speciation, in which correlations were characterized that extend from the atomic through to the mesoscopic, probed in aqueous and organic phases as well as at liquid interfaces. Highlighting these efforts was the demonstration that solvent extraction, a common method for metal-ion separations, can be described using universality theories generally applicable to phase transitions in vastly different systems, from boiling liquids to traffic jams. Analyses of X-ray scattering data revealed how the complex structure and interactions in a solvent-extraction organic phase are modified as a function of extracted ion-pairs and temperature. Interactions between nanoscale aggregates change with temperature or solute concentration according to a simple universal critical function. This result considered as a foundational stone to a predictive solvent-extraction model that will improve the safety and efficiency of metal-ion separations from rare-earth refining to nuclear fuel reprocessing. Using a very different experimental approach, synchrotron X-rays were scattered from an interface designed to mimic a simple solvent-extraction system. We were able to demonstrate that a temperature-driven adsorption transition can turn an extraction on and off by controlling adsorption and desorption of extractant molecules at the interface. Lowering the temperature through this transition immobilizes the supramolecular complex at the interface. Under the conditions of our experiments, these complexes condense into a two-dimensional inverted bilayer, which was characterized with subnanometer spatial resolution. Raising the temperature above the transition leads to extraction as a result of desorption of the complexes from the interface into the bulk organic phase. This molecular-scale phenomenon has not previously been associated with solvent extraction and may have a fundamental role in the efficacy of this widely-used method of chemical separations.

EARLY CAREER: Periodicity and the Role of the 5f-Electrons at Protactinium

Institution: Argonne National Laboratory
Point of Contact: Emilio Bunel
Email: ebunel@anl.gov
Principal Investigator: Richard Wilson
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The scope of this program is understanding the fundamental chemistry of protactinium in order to gain a quantitative, predictive knowledge of the periodic properties of early actinide chemistry and how it may be applied to separations chemistry fundamental to advanced nuclear fuel cycles. Our approach and hypotheses are inspired by the important interplay between the 5f and 6d electronic states in the

bonding of the early actinides, particularly the progressive periodic stabilization of the atomic 5f orbitals relative to the 6d orbitals moving from Th to heavier actinides, and the role it has on their chemistry. The overarching theme that drives this study is that at protactinium, the 5f and 6d orbitals are nearly degenerate in energy making Pa the first actinide where significant contributions from both these orbitals are made to the molecular bonding. Therefore, the relative contributions of the 5f and 6d electronic states to the bonding in Pa complexes depends on the chemistry of the Pa-ligand interaction and can be tuned between d- and f-character. Using prior experimental and theoretical observations of Pa chemistry, in addition to the periodic chemical properties and trends established across the periodic table to guide this investigation, we propose to study the chemistry of Pa coupling synthesis of model inorganic Pa compounds with solid- and solution-state structural characterization, and spectroscopic studies in order to quantify how the unique electronic structure of Pa manifests itself in its chemistry. It is expected that the results from the study proposed here will serve to inspire and lead new theoretical treatment of actinide electronic structure as it relates to the interplay of the f and d states in the early actinides.

FY 2014 HIGHLIGHTS

Efforts this year have focused on the preparation and investigation of a series of fluoride and peroxide complexes of protactinium(V). Synthetic campaigns have resulted in the preparation of a series of alkali metal and alkyl ammonium bearing fluoroprotactinate complexes, and a heretofore never reported species of protactinium peroxide. These complexes were subsequently used as model systems in our investigation of the solution speciation and structure of protactinium in aqueous hydrofluoric acid and hydrogen peroxide solutions using X-ray absorption spectroscopy performed at the Advanced Photon Source at Argonne National Laboratory, and laboratory based vibrational spectroscopy. Because we are interested in observing the influence that the participation of the d- and f-orbitals have on the chemistry of protactinium, we studied its transition metal homologues, niobium and tantalum, in a parallel and complementary set of experiments. The results from these experimental efforts have highlighted both similarities and differences among the chemistry of protactinium, the other early actinide elements, and the transition metals. These results have garnered attention from other chemists interested in quantifying the electronic properties and reactivity of these compounds both computationally and experimentally.

An Integrated Basic Research Program for Advanced Nuclear Energy Separations Systems Based on Ionic Liquids

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: James Wishart
Sr. Investigator(s): Sheng Dai; Oak Ridge National Laboratory
Mark Dietz; Wisconsin-Milwaukee, University of
Huimin Luo; Oak Ridge National Laboratory
Ilya Shkrob; Argonne National Laboratory
Students: 2 Postdoctoral Fellow(s), 4 Graduate(s), 2 Undergraduate(s)
Funding: \$424,000 (2014)

PROGRAM SCOPE

Future advanced nuclear energy systems will require significant changes in the way nuclear fuel is processed to achieve greater efficiency and reductions in waste sent to repositories, which are necessary for sustainable nuclear power generation. We expect that ionic liquids (ILs, or low-melting salts) will enable technologies to achieve these goals. ILs have unusual physical properties and process safety advantages compared to ordinary solvents. Their properties can be controlled by design as needed. This project explores the use of ionic liquids for nuclear separations processes with particular concern for their performance under ionizing radiation as found under operating conditions. A multidisciplinary team has been assembled to study the fundamental radiation chemistry of ionic liquids, to determine how that chemistry interferes with separations efficiency in ILs, to seek to prevent or mitigate such interference through substitution of ionic liquid components, and to design and create IL-based systems for more efficient and radiolytically-robust separations chemistry. Some of these systems may operate in novel ways that take advantage of unique IL properties. The goal is to replace current technologies with ones that allow more efficient use of resources and smaller environmental impacts, bringing us closer to a sustainable energy future.

FY 2014 HIGHLIGHTS

- We studied the radiation chemistry of ionic liquids (ILs) made with functionalized cations from cheap, readily available sources: choline, betaine and carnitine. They are the focus of separations schemes that exploit their upper critical solution phase behavior with water. Our EPR studies on choline salts explained the mechanism of “radiation hypersensitivity” of choline chloride, a controversial subject since Calvin’s 1953 discovery. In a first-of-its-kind experiment, the BNL LEAF facility’s mid-IR transient absorption system was used to observe the formation kinetics and yields of the choline radiolysis products vinyl alcohol and acetaldehyde, using their characteristic C=C and C=O stretching frequencies. (DOI: 10.1021/jp5049716)
- We showed that 1-benzylpyridinium cations and related derivatives are highly radiation-resistant cations due to charge delocalization in both the reduced and oxidized forms of the ILs. Pulse radiolysis and EPR data show that the excess electron and hole are stabilized in these ILs by formation of pi-electron sandwich dimers, similar to dimer radical cations of aromatic molecules. The charge delocalization dramatically reduces the yield of fragmentation by deprotonation and the loss of benzyl arms, thereby providing a path to radiation resistant ILs suitable for nuclear fuel processing. (DOI: 10.1021/jp408242b)
- We are exploring alternative IL-based systems for group separation of lanthanides from minor actinides, analogous to the TALSPEAK process but taking advantage of the unique features of ILs. In one case, the role of water was replaced by the IL betainium NTf₂. The complexant DTPA was incorporated into the IL by esterification with choline cation. Extractions against HDEHP in cumene showed excellent group separations for Ln over An. In another study, good rare earth separation was achieved when dialkylphosphate ILs were used as extractants in a process where hydrophobic IL replaced the hydrocarbon phase in TALSPEAK. (DOIs: 10.1021/ie4036719)

Sr. Investigator(s): Harry Frank; Connecticut, University of
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

This project employs two-dimensional (2D) electronic spectroscopy and transient-grating spectroscopy with optical heterodyne detection to determine the structural and physical mechanisms that control and optimize the excitation energy transfer processes involved in photosynthetic light-harvesting. The research focuses on how carotenoids serve as mid-visible antenna chromophores that are capable of efficiently transferring excitation energy to chlorophyll molecules. The initial focus is on the question of how intramolecular charge-transfer (ICT) character develops upon optical preparation of carotenoid excited states. This issue is central to the mechanism for energy transfer from the dark carotenoid S_1 (2^1Ag^-) state to the chlorophyll Q_y state because the latter formally lacks any transition dipole strength. The research plan compares the photophysics of two carotenoids in solution, β -carotene and peridinin, to that of peridinin in the structurally well-characterized peridinin–chlorophyll a protein (PCP), a light-harvesting protein from marine dinoflagellates. This protein features energy-transfer pathways between four peridinin chromophores and one chlorophyll a chromophore in each of the two subunit domains of the protein. This work is intended to determine how the protein binding sites for peridinin optimize the rate of energy transfer to the chlorophyll acceptors by preparing excited-state conformations that favor the formation of ICT character. Optical heterodyne detection in transient-grating experiments provides the means to detect the formation and decay of the dark intermediate electronic states that are populated on an ultrafast timescale in carotenoids after optical preparation of the bright S_2 (1^1Bu^+) state. 2D spectroscopy allows the pathways of energy transfer and the sequence of intermediate states to be determined specifically.

FY 2014 HIGHLIGHTS

We have completed transient-grating experiments on β -carotene and peridinin in solution in parallel with studies of the peridinin-chlorophyll a protein (PCP). The experimental results have been analyzed with the aid of full simulations of the nonlinear optical response functions that contribute to the signals. Our findings support a new model for the nonradiative decay pathways of carotenoids in solution that includes ultrafast motions along torsional coordinates of the conjugated polyene backbone. Our model identifies the S_x intermediate state detected in previous work as a twisted structure, most likely with intramolecular charge-transfer (ICT) character. This state serves as the energy-transfer donor to the Q_x state of (bacterio)chlorophylls in light-harvesting proteins. Further, the energy-transfer donor to the Q_y state of (bacterio)chlorophylls is assigned to a S_1 state having a twisted and probably bent conformation with an enhanced ICT character; this structure may account for the S^* state detected in previous work.

The transient-grating studies of peridinin in different solvents show that nonradiative decay from the S_1 state obtains a conformationally displaced S_0 structure that exhibits a strongly solvent-dependent relaxation rate to the originally excited, ground-state conformation. This part of the work required observations of the dispersion component of the third-order nonlinear optical signal with optical heterodyne detection. In PCP, the results indicate that the binding site for peridinin optimizes the energy transfer yield to the chlorophyll a acceptor by favoring conformations of the conjugated polyene with twisted and bent conformations. These conformations promptly assume excited-states with ICT character after optical excitation.

Regulation of Thylakoid Lipid Biosynthesis in Plants

Institution: Michigan State University
Point of Contact: Christoph Benning
Email: benning@msu.edu
Principal Investigator: Christoph Benning
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$185,000 (2014)

PROGRAM SCOPE

Photosynthesis provides feed, food, and fuels through the conversion of sunlight into chemical energy. At the core of the light reactions of photosynthesis is an extensive membrane system inside plant chloroplasts into which the photosynthetic protein/pigment complexes are embedded. The long term goal is to gain a mechanistic understanding of the assembly and maintenance of the photosynthetic membrane in plants with a primary focus on its lipid constituents. The galactoglycerolipids mono- and digalactosyldiacylglycerol, MGDG and DGDG respectively, are the main polar lipid constituents of the photosynthetic membrane. Of these two, MGDG is only found in plastids. Establishment and maintenance of the photosynthetic membrane is a dynamic process throughout the life cycle of the plant and involves finely tuned mechanisms to adjust synthesis and breakdown of polar lipids, particularly in response to conditions adverse to growth. The turnover of the principal membrane lipid of the photosynthetic membrane, MGDG, is explored. Two biochemical processes are investigated that involve the recently discovered enzymes SENSITIVE TO FREEZING2 (SFR2) and PLASTID GALACTOLIPID DEGRADATION 1 (PGD1), which catalyze the recycling of MGDG derived diacylglycerol or acyl moieties, respectively, into triacylglycerol following the exposure to abiotic stresses. SFR2 is required for survival of freeze stress in *Arabidopsis* and PGD1 plays a role in the accumulation of triacylglycerols in the microalga *Chlamydomonas* following nutrient deprivation, but the function of its plant orthologs remain to be determined. The specific aims are (1) to determine the activation mechanism of SFR2 during freeze stress, (2) to explore the function of SFR2 in lipid remodeling in response to different abiotic stresses, and (3) to determine the function of plant PGD1-like lipases in lipid remodeling and abiotic stress responses.

FY 2014 HIGHLIGHTS

A detailed homology model of *Arabidopsis* SFR2 provided the basis for an in-depth structure-function analysis delineating the active site, the reaction mechanism and processivity. SFR2 is a novel type of processive galactosyltransferase using MGDG as a substrate and produces oligogalactolipids with up to six galactosyl residues. It is classified as a hydrolase but cannot hydrolyze any substrates tested. SFR2 is constitutively present in the cytosolic leaflet of the outer envelope membrane of chloroplasts but not

active under normal growth conditions. Experiments with isolated chloroplasts ruled out several possible factors, but identified a decrease in the pH and an increase in the concentration of magnesium ions as activating factors. It is hypothesized that freezing leads to a decrease of the cytosolic pH and an increase in the cytosolic magnesium concentration as the plastid envelope membranes are disrupted activating SFR2 and allowing it to repair and adjust the lipid composition of the envelope membranes. SFR2 is present in all plants. Inactivating SFR2 in cold sensitive tomatoes enhanced the sensitivity to salt and drought stress expanding the range of possible physiological roles of SFR2. The *Arabidopsis* genome encodes three PDG1 orthologs designated PDGL1-3. All three localize to the plastid, likely to different membranes: the inner and the outer envelope membranes and the thylakoid membrane. Active recombinant PGDL3 was produced and shown to have lipase activity removing unsaturated acyl-chains from the sn-1 position of specific chloroplast glycerolipid molecular species, e.g. phosphatidylglycerol with a 16:1 delta-3-trans acyl-chain in the sn-2 position. Double mutant combinations showed enhanced sensitivity to abscisic acid and a reduction in seed triacylglycerol content. It is hypothesized that PGDL lipases allows channeling of chloroplast lipid derived acyl groups into triacylglycerols under stress conditions that are currently being explored.

Molecular Mechanism of Action of the Cyanobacterial Orange Carotenoid Protein

Institution: Washington University, St. Louis
Point of Contact: Robert Blankenship
Email: blankenship@wustl.edu
Principal Investigator: Robert Blankenship
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$370,000 (2014-2015)

PROGRAM SCOPE

All photosynthetic organisms contain a light-harvesting antenna system, which is how the organism absorbs sunlight so that the energy is stored ultimately in reduced carbon of biomass. Photosynthetic antenna systems are extremely diverse, in terms of structural organization and type of pigment utilized. In addition to the light absorption function of the antenna, it is essential for all photosynthetic organisms to have regulatory mechanisms that serve to protect them against excess light. This project centers on the Orange Carotenoid Protein that is found in photosynthetic cyanobacteria and serves to regulate energy collection in the major antenna complex, which is known as the phycobilisome. The Orange Carotenoid Protein binds a carotenoid molecule as the pigment. Research proposed here includes a variety of mechanistic studies on the isolated Orange Carotenoid Protein derived from genetically modified strains. We propose to develop a mutagenesis system for the Orange Carotenoid Protein and some subunits of the phycobilisome and analyze a series of mutants to better understand how the protein environment of the phycobilisome contributes to the energy regulation process. We also plan to examine the Orange Carotenoid Protein photoactivation and deactivation pathway. The results of this research project should give us a much improved understanding of the photoactivation mechanism of this important photoprotection process at the molecular level and also improve our understanding of its physiological roles in cyanobacterial adaptation to changing environmental conditions.

FY 2014 HIGHLIGHTS

This is a new project initiated in 2014 so results are just beginning to be obtained. We are in the process of testing our mechanism of action of the orange carotenoid protein that involves a light-induced dimer to monomer transition. Chemical labeling mass spectrometry results support this mechanism, but more testing is underway.

Photosystem II: Structure and Assembly

Institution: Louisiana State University
Point of Contact: Terry Bricker
Email: btbric@lsu.edu
Principal Investigator: Terry Bricker
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$555,000 (2014-2016)

PROGRAM SCOPE

Elucidation of the functional properties and structural organization of membrane protein complexes is one of the central objectives of current biochemical investigation. One of the most intriguing aspects of membrane function is its role in the mediation of energy transduction in photosynthetic organisms. Light energy, which is the product of a most violent physical process, fusion, is transformed into biological energy equivalents utilized by the photosynthetic cell. This photosynthetic process provides both the carbohydrate that lies at the base of virtually all food chains and, as a byproduct, all of the atmospheric oxygen utilized by heterotrophic organisms. One factor which limits photosynthetic productivity is photoinhibition. The production of reactive oxygen species by Photosystem II is inherently damaging to the photosystem. The sites of production of the reactive oxygen species which specifically damage Photosystem II, however, have not been determined. Our first goal in this proposal is to elucidate the amino acid oxidative modifications which result from the reactive oxygen species produced by Photosystem II. In these studies we will use stable isotopic labeling with ^{18}O coupled with high-resolution mass spectrometry. Second, the Photosystem II of higher plants contains a different palette of extrinsic membrane protein components than does cyanobacterial Photosystem II. The locations of these components (a second copy of PsbO, as well as PsbP and PsbQ) within the higher plant photosystem have not been determined. In this proposal we will use a combination of radiolytic footprinting performed at the J. Bennett Johnston, Sr. Center for Advanced Microstructure & Devices synchrotron and *in vitro* protein crosslinking to elucidate the location and orientations of these important protein components of higher plant Photosystem II. Mass spectrometry also plays a vital role in these studies.

FY 2014 HIGHLIGHTS

Published Research: We published three papers during this time frame, with a fourth paper submitted (and subsequently published in PNAS). These are listed below.

1. Bricker, T.M., Bell, A.J., Tran, L., Frankel, L.K. and Theg, S.M. "Photoheterotrophic Growth of *Physcomitrella patens*". *Planta* 239, 605-613 (2014).
2. Roose, J.L., Frankel, L.K. and Bricker, T.M. "The PsbP-Domain Protein 1 Functions in the Assembly of Lumenal Domains in Photosystem I". *Journal of Biological Chemistry* 289, 23776-23785 (2014).

3. Zhang, P., Frankel, L.K. and Bricker, T.M., "Integration of apo- α -phycocyanin into phycobilisomes and its association with FNRL in the absence of the phycocyanin α -subunit lyase (CpcF) in *Synechocystis sp.* PCC 6803". Plos One 9, e105952 (2014).
4. Mummadisetti, M.P., Frankel, L.K., Bellamy, H., Sallans, L., Goettert, J.S., Brylinski, M., Limbach, P.A. and Bricker, T.M. "Use of Protein Crosslinking and Radiolytic Labeling to Elucidate PsbP and PsbQ Interactions within Photosystem II of Higher Plants." Proceedings of the National Academy of Sciences (USA), in Revision during the time period highlighted.

Unpublished Research:

1. We have made significant progress in isolating and characterizing protein cross linked products containing PsbO, PsbP and PsbQ. These have been identified using both the 0-length cross linker EDC and the bifunctional cross linker BS3 (span 11.4 Å). We are currently analyzing these with high resolution FTICR MS/MS.
2. Photoinhibition experiments with both red and white light have been performed in the presence of either ^{18}O -dioxygen or ^{18}O - H_2O . These samples will be analyzed by FTICR MS/MS to identify sites of oxidative modifications.
3. We have isolated a highly enriched PS I-LHC I -LHC II membrane fraction. The LHC II appears to be strongly energetically coupled to the PS I reaction center and the complex is isolated in very high yield (mgs of chlorophyll yields).

Multi-Frequency Pulsed EPR Studies of the Photosystem II Oxygen Evolving Complex

Institution: California-Davis, University of
 Point of Contact: R. David Britt
 Email: rdbritt@ucdavis.edu
 Principal Investigator: R. David Britt
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 3 Undergraduate(s)
 Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The primary goal of this grant is to better understand the catalytic mechanism of the Mn-Ca water oxidizing/oxygen evolving center of Photosystem II. This multimetal center carries out the four electron oxidation of two water molecules, producing bio-activated electrons and protons, with molecular oxygen released as a byproduct. Each of the four oxidation steps in the catalytic cycle is driven by photon induced electron transfer, which allows us to step through the successive intermediates of the "S-state" cycle using saturating laser flashes. We need to better understand the electronic structure of this complex metal cluster and its ligand environment as it advances through the cycle in order to understand how this unique natural catalyst carries out this crucial chemistry. We are using multifrequency pulsed electron paramagnetic resonance (EPR) spectroscopy as our experimental approach. EPR is a powerful tool for studying paramagnetic intermediates of enzymes that use metals or organic radicals in their reaction mechanisms, and the Mn cluster of the PSII OEC is a prime example, with S_0 and S_2 showing strong Mn EPR signals. The resolution of conventional continuous wave (CW) EPR is limited however, and non-linear pulsed echo methods have therefore been used to achieve resolution enhancement of two or three orders of magnitude. We carry out all the standard pulsed EPR techniques used to measure magnetic hyperfine interactions between electron spins and magnetic nuclei (such as ^{55}Mn , ^{13}C , ^{14}N , ^1H , and ^2H). These include electron spin echo envelope modulation methods in one and two dimensions (ESEEM and HYSCORE), pulsed electron nuclear double resonance (ENDOR), and their

variants. These methods give a direct probe of the electronic structure of the OEC as a function of S-state.

FY 2014 HIGHLIGHTS

Oyala, P. H., T. A. Stich, J. A. Stull, F. Yu, V. L. Pecoraro, and R. D. Britt. Pulse EPR Studies of the Interaction of Methanol with the S₂ state of the Mn₄CaO₅ cluster of Photosystem II. (2014) *Biochemistry*, 53:7914-7928. This 2014 paper uses pulsed EPR to study methanol binding (via ¹³C-labeled MeOH) in the S₂ state of the OEC. We conclude based on measurements on the OEC and related Mn model compounds that methanol does not bind directly to Mn, but is likely bound instead to the Ca of the OEC or possibly in one of several adjacent water sites.

Structure/Function Studies of Photosystem II

Institution: Yale University
Point of Contact: Gary Brudvig
Email: gary.brudvig@yale.edu

Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$230,000 (2014)

PROGRAM SCOPE

Despite significant recent progress, the mechanism of water oxidation in photosystem II (PSII) remains the least understood aspect of photosynthetic electron transport. The long-term objectives of this project are to develop an understanding at the molecular level of the structure and assembly of the active site of water oxidation, the catalytic mechanism of water oxidation, the electron-transfer properties of PSII, the damaging side reactions that occur in the process of water oxidation and the mechanisms by which the secondary electron-transfer reactions of PSII involving carotenoids moderate the damaging side reactions. The recent 1.9 Å resolution X-ray crystal structure of PSII provides a detailed architecture of the oxygen-evolving complex (OEC) and the surrounding amino acids. Building on the new structural information, this project uses biophysical studies in conjunction with manganese model chemistry to characterize the function of PSII. The specific aims of the current project are: (1) to characterize the redox functions of carotenoids and the secondary electron-transfer reactions in PSII by (a) studying site-directed mutants of PSII in which amino-acid residues predicted to perturb cofactors in the secondary electron-transfer pathways are changed, and (b) redirecting electron transfer on the acceptor side of PSII in order to utilize the electrons liberated from water oxidation by PSII for photoelectrochemical fuel formation; and (2) to carry out structure-based experiments on PSII to characterize the function of specific residues and the mechanism of the OEC by (a) investigating the function of chloride in oxygen evolution by studies of anion-substituted PSII and site-directed mutants of D2-Lys317 and (b) using oxygen isotope studies to gain insight into how the substrate waters are bound and activated for reaction in the OEC.

FY 2014 HIGHLIGHTS

To probe the side-path electron-transfer reactions of photosystem II (PSII) and their role in photoprotection (aim 1), site-directed mutations around the binding pocket of the D2 carotenoid (Car-D2) were made in *Synechocystis* sp. PCC 6803 in collaboration with Peter Nixon at Imperial College.

Studies of PSII core complexes by near IR and EPR spectroscopy show that oxidation of Car-D2 is the initial step in secondary electron transfer and analyses of mutant cell growth link this reaction to photoprotection. X-ray crystallography has revealed that chloride binds as an ion-pair with D2-K317 at a distance of 6-7 Å from the Mn₄Ca cluster in the O₂-evolving complex (OEC). To probe the role of chloride in PSII (aim 2), mutations at the D2-K317 site were made in *Synechocystis sp.* PCC 6803 in collaboration with Richard Debus at the University of California, Riverside. FT-IR and EPR spectroscopy, together with oxygen-evolution measurements, on PSII core complexes support our proposal that the function of chloride is to modulate proton transfer. Notably, the first chloride-independent water-oxidizing PSII was engineered by making the D2-K317A mutation. In addition, we completed a study on the inhibitory effect of nitrite on PSII. Nitrite has previously been reported to be a functional substitute for chloride, but this seems unusual owing to nitrite's chemical dissimilarity to chloride and its potential for redox activity. Our results show that nitrite is, in fact, an inhibitor of PSII. These results clarify the effect of nitrite and provide new information on the role of anions in photosynthetic water oxidation. We have also collaborated with the groups of Victor Batista (Yale University) and Marilyn Gunner (City College of New York) on computational modeling of PSII. Computational models have been developed and used to calculate pK_as and oxidation midpoint potentials of oxomanganese complexes that model the OEC and the structure of the S₀ state of the OEC.

Light Energy Transduction in Green Sulfur Bacteria

Institution: Pennsylvania State University
Point of Contact: Donald Bryant
Email: dab14@psu.edu
Principal Investigator: Donald Bryant
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$292,000 (2014)

PROGRAM SCOPE

Green bacteria characteristically occur in energy-limited environments that at extraordinarily low light intensities. Nevertheless these organisms often grow rapidly because they have exceptional light harvesting capabilities. This is because they use chlorosomes, the most efficient light-harvesting organelles known, for light harvesting. We are studying chlorosomes, and the reaction centers to which they are coupled in specific cases, in organisms that come from very different environmental niches, in order to understand specific adaptations to specific light conditions. An important recent achievement was the isolation of multiple axenic strains of *Chloracidobacterium thermophilum*, the first chlorophototrophic member of the phylum Acidobacteria. We are also continuing to characterize chlorosomes in *Chlorobaculum tepidum* and *Cba. limnaeum*, which employ different types of bacteriochlorophyll in their chlorosomes. To investigate the ecophysiology and metabolic capabilities of green bacteria, we employ genome sequencing, comparative bioinformatics and genomics, genetics, biochemistry, biophysics, and structural biology approaches. Comparisons of the properties of chlorosomes and homodimeric Type-1 RCs of organisms inhabiting anoxic (*Cba. tepidum* and *Cba. limnaeum*) and oxic (*Ca. C. thermophilum* and *T. aerophilum*) environments should reveal important adaptations to these two very different niches and will provide new information about the evolution of photosynthesis as well as the design principles for artificial photosynthesis.

FY 2014 HIGHLIGHTS

After finally obtaining an axenic isolate of *Chloracidobacterium thermophilum* in 2013, we spent most of the past year characterizing the physiology and metabolism of this novel chlorophototrophic bacterium. *Cab. thermophilum* requires all three branched chain amino acids, L-lysine, bicarbonate, vitamin B₁₂, and a reduced sulfur source (e.g., thioglycolate for growth). It is a microaerophile and grows best at about 50 micromolar oxygen. Once we understood the optimal growth conditions and requirements well, it has been possible to isolate additional isolates by direct plating from dilutions of mat samples. Characterization of these new isolates suggests that we have isolated either new species or at least ecological species of this organism. We have continued our structural studies on chlorosomes, and have characterized the chlorosomes of the *bchR* mutant of *Chlorobaculum tepidum* together with the group of Joergen Koehler. The results show that the bacteriochlorophylls (BChls) in this mutant have a different suprastructure than those in the wild type and other mutants we have characterized. We have produced mutants in genes encoding enzymes required for the synthesis of BChl e. Structural studies on uniformly ¹³C-labeled chlorosomes are in progress with collaborators in the laboratory of Dr. Huub de Groot. We also completed studies to characterize the photophysical properties of BChl e and BChl f. Finally, we have made some progress on our attempts to isolate an aerobic green sulfur bacterium, *Candidatus Thermochlorobacter aerophilum*, from microbial mats in Yellowstone National Park, WY.

Genetic and Metabolic Integration of the Carbon Concentrating Mechanism with the Light and Dark Reactions of Oxygenic Photosynthesis

Institution: Oklahoma State University
Point of Contact: Robert Burnap
Email: rob.burnap@okstate.edu
Principal Investigator: Robert Burnap
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$260,000 (2014-2015)

PROGRAM SCOPE

Cyanobacteria are considered as ideal vehicles for numerous bioengineering applications ranging from CO₂ mitigation to the production of biofuels and chemicals. The acquisition of inorganic carbon (CO₂, HCO₃⁻) very often limits photosynthetic performance in natural systems, including cyanobacteria. This limitation is likely to be even more acute in engineered systems that may have proportionally higher demands for inorganic carbon relative to other nutrients. To overcome this limitation, cyanobacteria possess a CO₂-concentrating mechanism (CCM) that is capable of utilizing cellular energy to acquire and concentrate CO₂ and bicarbonate from the environment. The overall objective is to better understand the cyanobacterial high affinity CCM and its integration with the reactions of oxygenic photosynthesis. Work is testing the general hypothesis that the genetic integration of the CCM with the light and dark reactions of photosynthesis is achieved mainly through physiological interactions involving metabolic intermediates that connect different photosynthetic processes. During the previous funding period, transcriptional control of inducible, high affinity, CCM genes was found to be modulated by key photosynthetic metabolites, including NADP⁺ and α-ketoglutarate. These metabolites, in turn, modify the DNA binding activity of regulatory proteins. These findings reveal a homeostatic regulatory mechanism that adjusts the CCM to changes in the demand for CO₂ based upon internal metabolic cues that themselves responding to changing environmental conditions, notably, inorganic carbon availability

and light intensity. Building on this progress, current experiments investigate the mechanisms of regulation and the unique CO₂ uptake enzymes that are being regulated.

FY 2014 HIGHLIGHTS

Molecular genetic and physiological analyses we applied to understand the fluctuations in the identified regulatory metabolites under changing light and Ci-availability. Analysis of cells experiencing Ci limitation reveals systematic changes associated with physiological adjustments and a trend towards the quinone and NADP pools becoming highly reduced. This was followed by a series of changes ranging from increased dissipation of the light energy to changes due to the induction of the high affinity CCM. The results are consistent with the proposed regulation of the CCM and provide new information on the nature of the Chl and NADPH fluorescence induction curves. The unique CO₂ uptake enzymology remains to be clarified, although it is known to involve variants of the Type-1 NAD(P)H dehydrogenase (NDH-1) complexes that have additional subunits. A mutagenesis system is being developed to probe the structure-function relationships of the NDH-1_{3/4} complexes for CO₂-hydration activity. This enhances the on-going effort to use synthetic techniques to manipulate the cyanobacterial CCM. An optimization computer model for autotrophic cyanobacterial growth, the autotrophic replicator model (ARM), was developed. The present model describes autotrophic growth in terms of the allocation of protein resources among core functional groups including the photosynthetic electron transport chain, light harvesting antennae, and the ribosome groups. This model will help us connect our molecular genetic and physiological analyses with the metabolomic studies of our NREL collaborators.

Investigations into Proteins Affecting Chloroplast Function

Institution: California-Davis, University of
Point of Contact: Judy Callis
Email: jcallis@ucdavis.edu
Principal Investigator: Judy Callis
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 4 Undergraduate(s)
Funding: \$75,000 (2014)

PROGRAM SCOPE

Capture of light energy into chemical energy and production of plant biomass for biofuels depend on the optimal development and functioning of the higher plant chloroplast and appropriate distribution and utilization of carbohydrates. We propose that these two functions require different members of the pfkB super-family of carbohydrate-like kinases, which are related to an *E. coli* phosphofructokinase. However, in plants this single gene has expanded consisting of 23 members in *Arabidopsis*. Functions for few are known. Seven have been either documented or postulated as kinases on adenosine (2), NAD, pyridoxal, thiamine, fructose or myo-inositol. Another was implicated in chloroplast function, but mechanism is unclear. Sixteen PfkB proteins remain uncharacterized. The long-term goals are to understand the function of these proteins through isolation and characterization of mutants, identification of subcellular localization and activity assays. Multiple PfkB proteins localize to chloroplasts. Chloroplasts capture light energy and convert it into chemical energy in the form of reduced carbon compounds. We previously focused on two PfkB proteins FLN1 and FLN2 found in chloroplast transcription complexes from proteomic analyses by other labs. No kinase activity has been demonstrated and their role in chloroplast transcription is enigmatic. Our analysis of loss-of-function mutants revealed their partially overlapping significant roles in chloroplast transcription and biogenesis.

This work was published with DOE support (Gilkerson *et al*, 2012). Fructokinase activity is thought responsible for fructose assimilation. However, the sum of fructokinase activities in a plant is unknown. Objectives of the current research are two-fold. One is to understand how FLN proteins regulate transcription of chloroplast photosynthetic genes. The other goal is to identify functions for the remaining PfkB proteins whose functions are unknown with an emphasis on putative fructokinase proteins.

FY 2014 HIGHLIGHTS

We conducted a phylogenetic analysis and identified six proteins that clade with active fructokinase. Another showed similarity to ribokinase. One is a pseudogene. We identified subcellular locale for all but 2. We isolated insertion mutants in 10 genes (2 have no insertions and another lab is studying 1). RNA analyses were performed and all suggest some loss of function. We are using Crispr system to knock-out function of two genes and to make multiple mutants in the fructokinase clade. One double mutant in fructokinase genes is made and under analysis. We focused on ribokinase. It has a putative transit peptide and we demonstrated that it localizes to chloroplasts. We determined that ribokinase mutant seedlings are hyper-sensitive to growth on ribose compared to wild-type. These data strongly indicate a biological function for ribokinase in phosphorylating ribose. We isolated *E. coli* ribokinase and demonstrated activity; however, we have not yet demonstrated activity with *Arabidopsis* ribokinase. We expressed several fructokinase proteins in *E. coli* and demonstrated activity for two. For our analysis of FLN proteins in chloroplast function, we made significant progress. We expressed FLN proteins in *E. coli* and are using recombinant protein for biochemical analyses. We discovered that FLN1 and FLN2 interact in an ATP-dependent manner, while FLN2 interacts independent of ATP. Most exciting is our observation that FLN1-FLN2 heteromers are preferred over FLN2 homomers in high ATP. This has led to our hypothesis that ATP controls assembly of the transcriptional complex. We expressed fluorescently tagged FLN proteins in tobacco and demonstrated that their interaction is ATP-dependent in the chloroplast. Thus, we are completing the final replicas and controls to prepare a manuscript on our findings.

Signal Transduction Pathways that Regulate CAB Gene Expression

Institution: Salk Institute for Biological Studies
Point of Contact: Joanne Chory
Email: chory@salk.edu
Principal Investigator: Joanne Chory
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Chloroplasts of higher plants contain about 3000 proteins of which more than 95% are encoded by nuclear genes. This necessitates a tight coordination of gene expression that involves two-way signaling between these spatially separated genomes. Thus, while plastid differentiation and development are largely under nuclear control, developmentally arrested or damaged plastids can regulate expression of a subset of nuclear genes via retrograde signaling pathways. Multiple retrograde signals have been proposed, but almost nothing is known of their signaling pathways. In previous years of this DOE-funded study, we performed a number of genetic screens that implicated the chloroplast-localized tetrapyrrole biosynthesis pathway as the source of both positive and stress-related retrograde signals. However, the

mechanisms by which tetrapyrrole intermediates or a secondary signal exit the plastid and the components by which this signal is relayed to promoters in the nucleus are mostly unknown. The goal of this proposal is to define the signal(s) and signaling pathways from chloroplasts that regulate nuclear gene transcription. The proposed studies will integrate genetic, genomic, molecular, and biochemical approaches in an effort to:

- (1) Test the hypothesis that GUN1, a chloroplast PPR protein, is a regulator of tetrapyrrole synthesis;
- (2) Further explore our finding that a specific pool of heme is the source of a positive signal that chloroplasts are functional;
- (3) Continue genetic and biochemical dissection of the signaling pathway(s) initiated from changes in photosynthetic electron transport redox state in response to excess light.

FY 2014 HIGHLIGHTS

- GUN1: GUN1 contains 10 PPRs and a second domain called the SMR (small MutS-related) domain. In bacteria, the SMR domain has endonuclease activity. We generated recombinant GUN1 protein and mutant proteins and showed that GUN1 contains nuclease activity. In plants, all 10 PPR domains and the nuclease activity are required for its function. Using whole genome RNA-sequencing analysis and genetic epistasis studies, we concluded that GUN1 acts in the same pathway as GUN2-6, but also acts in at least two other retrograde signaling pathways.
- High light stress screen: A distinct signaling pathway mediates signals derived from the reduction/oxidation (redox) state of the photosynthetic electron transfer chain (PET) and affects both photosynthesis-related and stress-related genes. Several studies have provided evidence for a role of the redox state of the PQ pool as a sensor of high light and a regulator of nuclear gene expression. We used a reporter gene fusion to identify mutants defective in the response to high light stress, and found genes involved in both early and late phases of the response. Early on, 3 heat shock factors (HSFs) of greater than 20 found in the genome play an important role in this process. For later responses, we are currently working through our mutant collection to clone genes. So far, we have identified mutations in 4 genes involved in later phases of light stress, including: cryptochrome, two RNA processing enzymes, and a co-activator. We want to order the genes into a regulatory network.
- A chloroplast quality control pathway. We identified a mutant that accumulates high levels of singlet oxygen—leading to selective chloroplast degradation and chloroplast-induced cell death. We performed a suppressor screen and cloned 8 genes, which when mutated suppress the cell death phenotype. One of these encodes an E3 ligase that marks chloroplasts with ubiquitin. We now want to know if these marked chloroplasts are selectively degraded.

Disruption of the CO₂ Concentrating Mechanisms in C₄ Plants: Implications for CO₂ Fixation and Photosynthetic Efficiency during C₄ Photosynthesis

Funding: \$170,000 (2014)

PROGRAM SCOPE

The specialized biochemistry and leaf anatomy of C₄ plants results in a high CO₂ concentration within the leaf, significantly increasing photosynthetic energy use efficiency compared with C₃ plants. However, the efficiency of the CO₂ concentrating mechanism in C₄ plants can be negatively affected by environmental conditions but it is not understood how C₄ photosynthesis responds to optimize photosynthetic efficiency. For example, changes in the activity of key C₃ and C₄ cycle enzymes and the cell wall properties may alter leakiness, defined as the ratio of CO₂ leak rate out of the bundle sheath to the rate of CO₂ supplied by the C₄ cycle, through changes in the C₃/C₄ cycle capacity and the permeability of CO₂ diffusion. Understanding how the coordination of the C₃ and C₄ cycles, and the diffusion of CO₂ from the bundle sheath cells influences the efficiency of the CO₂ concentrating mechanism in C₄ plants is critical for accurately modeling the yields of C₄ crops under future climatic conditions. Additionally, this information is important for optimizing the biochemical and structure features of potential C₄ plants for high photosynthetic efficiency while modifying cell wall properties to enhance processing for biofuel production. The research in this proposal is expected to increase our understanding of the photosynthetic conversion of solar energy into chemical energy, particularly how changes in the biochemical capacity and structural properties of the leaf influence the photosynthetic efficiency of CO₂ fixation in C₄ species. The overall objective of our research is to determine how changes in the capacity of the C₃ and C₄ cycles and bundle sheath cell wall properties determine the photosynthetic efficiency of the CO₂ concentrating mechanism in C₄ plants. Our central hypothesis is that the efficiency of the CO₂ concentrating mechanism in C₄ plants is optimized through balancing the activity of the C₃ and C₄ cycles with the structural properties of the bundle.

FY 2014 HIGHLIGHTS

Seven manuscripts were published in 2014 that acknowledge our BES funding. In 2014 we generated stable transgenic *Setaria viridis* that we are currently characterizing. Due to technical issues the development of these lines took longer than we anticipated; however, we are now position to finish up this research. Additionally, in 2014 we collected and analyzed data for four manuscripts on the temperature response of C₄ photosynthesis that are in preparation for submission in early 2015.

EARLY CAREER: Thylakoid Assembly and Folded Protein Transport by the Tat Pathway

Institution: Miami University
Point of Contact: Carole Dabney-Smith
Email: adabney@miamioh.edu
Principal Investigator: Carole Dabney-Smith
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The research objectives are to study the mechanisms of protein transport into the lumen of thylakoids by the chloroplast Twin Arginine Transport (cpTat) pathway by (1) identifying the cpTat component(s) that interact with the mature domain of the precursor during transport, (2) determining the organization of the cpTat translocon, and (3) comparing topology of cpTat component, Tha4, in thylakoids during active transport and at rest. This particular protein transport pathway is predicted to translocate ~50% of the lumen proteins. Understanding cpTat system mechanism in chloroplasts will lead to a better understanding of the biogenesis of photosynthetic membranes potentially providing a means to engineer photosynthetic complexes into synthetic membranes for energy production.

FY 2014 HIGHLIGHTS

Proteins destined for the thylakoid lumen of chloroplasts are nuclear-encoded, synthesized in the cytoplasm, and must cross three membranes en route to their final destination. The chloroplast Twin Arginine Translocation (cpTat) system facilitates transport of about half of all proteins that cross the thylakoid membrane in chloroplasts. Known mechanistic features of the cpTat system are drastically different from other known translocation systems, notably in its formation of a transient complex to transport fully folded proteins utilizing only the protonmotive force for energy. However, key details such as the structure and composition of the translocation pore are still unknown. Our aims were to identify the composition of the cpTat translocation complex as well as probe the topology of two of the membrane proteins, Tha4 and Hcf106, involved in the cpTat translocation apparatus. Previously, we identified points of contact between precursor and Tha4 and demonstrated topology of Tha4 in non-transport active thylakoid and in transport active thylakoid. Currently, we are determining the points of contact between Tha4 and the precursor as it transports. These data strongly implicate Tha4 as a major component in the translocation pore. We are also actively expanding our investigation of Tha4 during transport to get a complete picture of the changes the molecule undergoes during transport of precursor. We are addressing Hcf106 organization in the thylakoid and indirectly interaction with cpTatC. Further we are gaining insight into the general mechanism of spontaneous insertion of a protein into the membrane through biophysical studies of the Hcf106 protein and peptides. We would then apply this knowledge to the insertion of several thylakoid proteins, which also seem to follow a spontaneous insertion pathway.

Membrane-Attached Electron Carriers in Photosynthesis and Respiration

Institution: Pennsylvania, University of
Point of Contact: Fevzi Daldal

Principal Investigator: Fevzi Daldal
Sr. Investigator(s):

Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The long-term goal of our work is to define the nature, mechanism of function, and biogenesis of cytochromes (cyt). Cyts and cyt containing complexes are ubiquitous electron carriers in energy transduction pathways. They are essential for cellular processes for chemical energy production (ATP). We seek a mechanistic understanding of these energy transduction pathways that include photosynthesis (Ps) and respiration (Res). Understanding how cells make and maintain (maturation, assembly and repair) cyts c is a fundamental process with major significance for efficient biological energy conversion. Our experimental model for these studies is the facultative phototrophic *Rhodobacter* (*R.*) species. Our work investigates molecular organizations of “hard-wired” and “soft-wired” ET complexes in membranes, including biogenesis of c-type cyts. The overall process involves the attachment of a covalent heme cofactor to an apocyt c (cyt c maturation, Ccm) to yield a mature holocyt c, and the assembly of holocyts c into functional multi-subunit membrane complexes. The Ccm process is found virtually in all living organisms, and the specific Ccm (System I) that we study occurs in bacteria, archaea, mitochondria of plants and red algae. Our previous work uncovered the *R. capsulatus* CcmI, CcmE, CcdA components of Ccm, and the DsbA-DsbB components that interact with Ccm. Ongoing work is focused on deciphering the protein-protein interactions between the apocyt c and heme as substrates, and CcmI, CcmH, CcmG and CcmHFI complex as chaperones and catalysts of Ccm. We believe that these studies are relevant to energy biosciences and their applications. They are also of broad biological significance, as the biogenesis components are part of major cellular functions, including protein translocation, extra-cytoplasmic protein folding and degradation, redox homeostasis, metal trafficking and insertion into proteins. Their understanding is of utmost importance for our mastery of photosynthetic and respiratory electron transport.

FY 2014 HIGHLIGHTS

- Studies involving the interactions between heme and apocyt c2, apocyt c2 and chaperone CcmI as well as the substrate specificity of CcmI in respect to different c-type apocyts are being completed.
- Studies related to the role of the thiol oxidation-reduction loop that occurs during Ccm are being initiated.

FTIR Studies of Photosynthetic Oxygen Production

PROGRAM SCOPE

The project's scope is to characterize the dominant water access and proton egress pathways that link the oxygen-evolving Mn_4CaO_5 cluster in Photosystem II (PSII) with the thylakoid lumen. The Mn_4CaO_5 cluster provides nearly all atmospheric oxygen on Earth. The cluster accumulates oxidizing equivalents in

response to light-driven photochemical events within PSII and then oxidizes two molecules of water to oxygen in the final step of a five-step cycle. Water oxidation is an extremely difficult chemical reaction, both thermodynamically and kinetically. The Mn_4CaO_5 cluster catalyzes this reaction far more efficiently than any synthetic catalyst because its protein environment controls the cluster's reactivity at each step in the catalytic cycle. This control is accomplished by precise choreography of the proton and electron transfer reactions associated with water oxidation and by careful management of both substrate (water) access and proton egress. The project's overall goal is to identify the amino acid residues that are responsible for this control and to determine the role of each. The project's specific goals are (1) to further delineate the dominant water access and proton egress pathways that link the Mn_4CaO_5 cluster with the thylakoid lumen and (2) to characterize the influence of specific residues on the water molecules that serve as substrate or as participants in the networks of hydrogen bonds that make up these pathways. Proton egress through these pathways provides the thermodynamic driving force for oxidizing the Mn_4CaO_5 cluster in its higher oxidation states. The project's primary investigative tool is infrared (IR) spectroscopy. Both FTIR difference spectroscopy and time-resolved IR spectroscopy are being used to characterize mutant PSII core complexes containing single amino acid substitutions of residues identified crystallographically or computationally as potentially participating in these networks or otherwise interacting with the Mn_4CaO_5 cluster.

FY 2014 HIGHLIGHTS

There is growing evidence that D1-D61 is the initial residue of a dominant proton egress pathway linking the oxygen-evolving Mn_4CaO_5 cluster to the thylakoid lumen. This residue interacts directly with water molecules in the first and second coordination spheres of the Mn_4CaO_5 cluster. During FY 2014, we explored the influence of D1-D61 on the water reactions accompanying oxygen production by characterizing the FTIR properties of the D1-D61A mutant of the cyanobacterium, *Synechocystis sp.* PCC 6803. On the basis of mutation-induced changes to the carbonyl stretching region near 1747 cm^{-1} , we concluded that D1-D61 participates in the same extensive networks of hydrogen bonds that have been identified previously by FTIR studies. On the basis of mutation-induced changes to the weakly hydrogen-bonded O–H stretching region near 3600 cm^{-1} , we concluded that D1-D61 interacts with water molecules that are located near the chloride ion that is coordinated by D2-K317 ion and that deprotonate or participate in stronger hydrogen bonds as a result of oxidizing the Mn_4CaO_5 cluster to its S_2 and S_3 oxidation states. On the basis of the elimination of a broad feature between 3100 and 2600 cm^{-1} , we concluded that the highly polarizable network of hydrogen bonds whose polarizability or protonation state increases during the formation of the Mn_4CaO_5 cluster's S_2 oxidation state involves D1-D61. On the basis of the elimination of features in the D–O–D bending region near 1210 cm^{-1} , we concluded that D1-D61 forms a hydrogen bond to one of the H_2O molecules whose H–O–H bending mode changes in response to formation of S_2 oxidation state. The elimination of this H_2O molecule in the D1-D61A mutant provides one rationale for the decreased efficiency of the water oxidation in this mutant.

PROGRAM SCOPE

In the past year this grant provided support for one graduate student and partial support for one postdoctoral fellow. One PhD dissertation was published (David Vinyard). His dissertation has produced 5 manuscripts supported by BES, the last of which to be published is listed below. The training of a new first year graduate student, Colin M. Gates, began in January 2014. We report here results from one recently published manuscript and two other manuscripts currently in preparation. Since the inception of this project in June 2010 it has produced five refereed publications, seven national conference presentations, 9 regional or local conference presentations, one PhD dissertation, and one BS honors thesis.

Analysis of Ethylene-Regulated Growth Networks in *Arabidopsis*

Institution: Salk Institute for Biological Studies
Point of Contact: Joseph Ecker
Email: ecker@salk.edu
Principal Investigator: Joseph Ecker
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

Seedling growth and its response to changing environmental cues are governed by the collective action of plant hormones. In order to decipher these complex regulatory networks, precise knowledge about each individual plant hormone pathway is essential. The molecular composition of the ethylene signaling pathway is well-studied except for two essential components, EIN6 (ETHYLENE INSENSITIVITY6) and EEN (EIN6 ENHANCER). Recent identification of these genes in our laboratory revealed that both encode chromatin modifying enzymes. Interestingly, only the concomitant loss of both genes leads to a complete ethylene-insensitive phenotype. This insensitivity phenotype of *ein6een* mutant plants is caused by an aberrant localization of certain histone marks leading to a massive transcriptional down-regulation of key signaling components within the ethylene pathway. Thus, we propose a model where EEN and EIN6 cooperatively regulate the accurate deposition of particular histone modifications to control gene expression. A detailed functional characterization of the molecular connection between EIN6 and EEN is carried out in this study to ultimately address the question of how both factors shape the chromatin environment of essential plant growth regulators. This study will also lead to a better

understanding of how plants integrate changing environmental cues into their chromatin environment which is of fundamental importance for plant-based energy research.

FY 2014 HIGHLIGHTS

The *ein6een* double mutant was generated in a fast neutron bombardment mutagenesis screen in the Ler background that aimed to identify new regulatory components of the ethylene signaling pathway. The causal *ein6* mutation is a 7bp deletion in the fifth exon of EIN6. In contrast, the mutation of EEN is caused by a large genomic rearrangement leading to a chimeric gene that consists of EEN and another gene which is located 83kb further upstream. This rearrangement was initially discovered with TAIL-PCR. In addition, we performed structural variation analysis utilizing the Irys platform from BioNano Genomics which independently confirmed and visualized the genomic rearrangement leading to the mutation of EEN. We were also able to generate an *ein6een* mutant in the Col-0 background using T-DNA insertion lines. This new mutant shows almost similar molecular alterations of the chromatin landscape that are apparent in the Ler *ein6een* mutant. Moreover, we performed successful ChIP-seq experiments of EIN6 and EEN revealing a distinct binding pattern. Both factors predominantly bind in gene bodies, in contrast to classical transcription factors which mostly occur in promoter regions. Taken together, our study provides an ideal experimental framework for future studies of chromatin architecture in response to various stresses.

Biochemical and Biophysical Studies of the *E. coli* Aerobic Respiratory Chain

Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

Proton-coupled electron transfer reactions involving quinones are central to many of the enzymes in biological energy transduction. Understanding how Nature has solved the problem of efficiently converting chemical energy into electrical energy is clearly of importance. We will address aspects of several different, but related questions by examining two different respiratory oxygen reductases: 1) Cytochrome bo_3 from *Escherichia coli*, and 2) cytochrome aa3-600 from *Bacillus subtilis*. Both of these enzymes are members of the A-family of heme-copper oxygen reductases. They are closely related to each other by sequence homology, but they contain different heme prosthetic groups and use different quinols as substrates. Cytochrome bo_3 oxidizes ubiquinol-8 whereas cytochrome aa3-600 utilizes menaquinol-7. These enzymes are proton pumps and couple the redox chemistry of the reduction of O_2 (to water) to the generation of a transmembrane voltage (proton motive force). The mechanism by which these enzymes generate a proton motive force is of primary interest in biological energy transduction. Cytochrome bo_3 is the best characterized of the quinol oxidases and offers practical advantages that facilitate a number of experimental approaches. The protein can be easily prepared from *E. coli* in any amount that is required, from 10 mg to several hundred mg. Importantly, the protein can be genetically manipulated to place either natural or non-natural amino acids at any location. In addition, we have made a series of auxotrophic strains that allow us to selectively label specific amino acids with stable isotopes, which is valuable for different spectroscopic methods.

FY 2014 HIGHLIGHTS

During the past year significant progress was made on several parts of this project.

1) The tyrosine free radical was observed upon reacting hydrogen peroxide with Cytochrome bo_3 . By site directed mutagenesis, this was localized to Y173, located near the active site. This is the equivalent position previously identified in the cytochrome c oxidase from *Paracoccus denitrificans*. We determined that this mutation has no influence on the activity of the enzyme with O_2 , but it does perturb the reaction with hydrogen peroxide. The reaction with O_2 does not generate a tyrosyl radical, consistent with what is observed with other heme-copper oxygen reductases.

2) Although the substitution of a phenylalanine at position 173 (Y173F) eliminates the previously described tyrosyl radical, a new tyrosyl radical is observed. Further site-directed mutagenesis located this mutation at position Y1184 (in subunit II). No tyrosyl radical is observed in the presence of hydrogen peroxide in the double mutant Y173F/Y1184F.

3) Examination of the Y1184F mutant showed that it has remarkable properties. This enzyme when isolated contains a tyrosyl radical with no requirement to add hydrogen peroxide. Upon reduction, the radical vanishes, as expected. The reaction of the reduce enzyme with oxygen, however, generates the tyrosyl radical at residue Y173. It takes minutes for the radical to form to its maximum extent and takes hours for it to dissipate. These properties suggest that the Y1184F mutation may prevent protons from dissociating and re-associating from Y173. Formation of the neutral radical requires removal of a proton, and this proton must be returned upon quenching of the radical. This hypothesis must be tested experimentally. This observation demonstrates that the active site retains a highly oxidized state after the reaction with oxygen, sufficient to oxidize Y173 to a radical.

Studies of Photosynthetic Reaction Centers and Biomimetic Systems

Institution: New York-City College, City University of
Point of Contact: Marilyn Gunner
Email: marilyn.gunner@gmail.com
Principal Investigator: Marilyn Gunner
Sr. Investigator(s): Victor Batista; Yale University
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$195,000 (2014)

PROGRAM SCOPE

Computational studies of structure/function relations in photosynthetic proteins aim to elucidate how the physico-chemical constraints of proton coupled electron transfer (PCET) in natural photosynthesis work within the protein and to provide guidelines for the design of artificial photosynthetic systems. The goal is to carry out fundamental studies of proton coupled electron transfer mechanisms in photosynthetic water-splitting in Photosystem II (PSII). The project brings together complementary simulation methods. Gunner (The City College of New York, USA) contributes Monte Carlo techniques for calculations of pK_a s and electrochemical midpoints (Ems). Batista (Yale University, USA) contributes expertise in quantum mechanics and QM/MM methods of PSII and biomimetic oxomanganese complexes. Bruce (Brock University, Canada) provides expertise in large-scale molecular dynamics of photosynthetic reaction centers. Brudvig (Yale University, USA) provides extensive experience in spectroscopic, structural and mechanistic studies of O_2 evolution and photoprotection in PSII. Density Functional Theory (DFT), Quantum Mechanics/Molecular Mechanics (QM/MM), Molecular Dynamics (MD) and Multiconformation Continuum Electrostatics (MCCE) will be applied to study PSII. The overall

aim will be to carry out detailed study of the Mn_4CaO_5 Oxygen Evolving Complex (OEC), a unique redox catalyst that generates oxygen and other redox cofactors in PSII in the context of the surrounding protein. Specific aims include:

- (1) Study of the structural and electronic changes of the Mn_4O_5Ca cluster and ligand cofactors through the S-state cycle.
- (2) Understanding how the surrounding protein influences the OEC redox chemistry and the coupling of oxidation to proton loss in PSII.
- (3) Water is a substrate for the OEC and protons a product. Pathways for water transfer to these active sites will be identified and the energy for transfer evaluated.

FY 2014 HIGHLIGHTS

The combination of experimental information from EXAFS and X-ray diffraction data and DFT QM/MM simulations allows for a significant level of structural refinement of the OEC structure. We have developed a refined QM/MM model of the OEC. A model is developed for the less characterized S_1 state. A hydrogen bonding network, linking the D1-D61 residue to a Mn-bound water molecule, is proposed to facilitate the PCET mechanism. The structural changes of the OEC during the S_1 to S_2 transition show changes in the position of Mn_4 and its coordination environment. Studies of the OEC with Ca^{2+} substituted by Sr^{2+} shows X-ray crystal structures with either Ca^{2+} or Sr^{2+} are most consistent with the S-2 state, with O_4 and O_5 protonated. Ca^{2+} to Sr^{2+} substitution results in elongation of the heterocation bonds and displaces terminal waters that may play a role in water oxidation. A computational model that combines DFT, MD and MC techniques has been used to study the thermodynamics of the OEC S-state cycle in the PSII protein. The model analyzes the entire protein, keeping all acidic and basic residues in equilibrium with the OEC. The S_0 to S_1 includes deprotonation of a μ -oxo bridge, the S_1 to S_2 transition includes deprotonation of terminal water and the S_2 to S_3 transition involves deprotonation of amino acid residue H337. However, within the protein the S_1 to S_2 transition transfers the proton to the adjacent D61 so there is less proton release observed. Water delivery and oxygen removal from the OEC, buried deep within PSII, are needed to facilitate the reaction and minimize reactive oxygen damage. All-atom molecular dynamics simulations of PSII characterized the distribution and permeation of both water and oxygen. Most channels in PSII are permeable to both oxygen and water. However individual channels exhibit different energetic barriers for the two solutes. Selectivity arises from hydrogen bonds between water and channel amino acids, and steric restraints.

Chloroplast Dynamics and Photosynthetic Efficiency

Institution: Cornell University
Point of Contact: Maureen Hanson
Email: mrh5@cornell.edu
Principal Investigator: Maureen Hanson
Sr. Investigator(s): Thomas Owens; Cornell University
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

We are investigating the mechanism by which chloroplasts position themselves to maximize solar energy utilization, to enhance gas exchange, to minimize environmental stress, and to promote efficient exchange of metabolites with other compartments within the plant cell. Chloroplasts move within leaf cells to optimize light levels, moving toward levels of light useful for photosynthesis while moving away

from excess light. Plastids sometimes extend their reach by sending out projections (stromules) that can connect anchor chloroplasts in position within the cell or provide close contacts with plasma membrane, mitochondria, peroxisomes, endoplasmic reticulum, and the nucleus. The intracellular location of chloroplasts in relation to other organelles with which they share biosynthetic pathways, such as peroxisomes and mitochondria in photorespiration, affects metabolite flow. Presently we have little knowledge of the mechanisms of organelle movement and anchoring in specific locations in plant cells. The receptors responsible for detection of light level have been identified, but how the signals ultimately result in chloroplast localization is not understood. We are examining the signal transduction pathway that begins with blue-light and ends with actin-mediated chloroplast movement. Expression of motor proteins and putative signaling intermediates will be disrupted by insertional mutagenesis, virus-induced gene silencing, and/or expression of defective proteins causing dominant negative effects. We will examine the effect of disrupted movement on measures of photosynthetic function. The project will contribute to our understanding of responses of plants to environmental conditions to optimize photosynthesis and minimize photodamage. Information about how plants specify and control chloroplast location will be relevant to attempts to engineer C_4 photosynthesis into C_3 plants as well as to engineering of improved photosynthetic efficiency in C_3 plants.

FY 2014 HIGHLIGHTS

We produced a methods paper describing how to label plastids with fluorescent proteins for observation of their movement and interactions with other subcellular organelles. While carrying out other experiments, we made the unexpected observation that certain types of green fluorescent protein can be photoconverted to a red fluorescent protein. We have submitted a manuscript describing this observation that also demonstrates its use in several different cell types. Using BiMolecular Fluorescence Complementation, we have observed interactions between 14-3-3 proteins and proteins involved in signal transduction for chloroplast avoidance and accumulation. We have found that silencing of a group of 14-3-3 proteins affects light-regulated chloroplast movement. Using mutants altered in their ability to move in response to light, we have observed that the function of chloroplast movement is not merely to avoid photodamage, but also to increase the efficiency of photosynthesis.

Protein Targeting to the Chloroplast Thylakoid Membrane: Structure and Function of a Targeting Complex

Institution: Arkansas, University of
Point of Contact: Ralph Henry
Email: rahenry@uark.edu
Principal Investigator: Ralph Henry
Sr. Investigator(s): Suresh Kumar; Arkansas, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Biogenesis of thylakoid membrane protein complexes relies on evolutionarily conserved protein sorting/insertion machinery to rout both nuclear and chloroplast encoded thylakoid proteins. Chloroplast signal recognition particle (cpSRP) and its receptor in the chloroplast stroma (cpSRP and cpFtsY, respectively) utilize a chloroplast-specific SRP subunit, cpSRP43, to localize nuclear encoded light-harvesting chlorophyll a/b-binding proteins (LHCPs). LHCPs bind 30-50% of the chlorophyll responsible for photosynthetic light capture in mature chloroplasts. It is well established that cpSRP43

participates in LHC binding to promote formation of an SRP-LHC targeting complex. Our recent studies show that cpSRP43s ability to interact with the LHC targeting substrate, with GTP hydrolyzing targeting components, and with a thylakoid protein insertase, is used to coordinate membrane events that represent the transition from LHC targeting to LHC insertion by the protein insertase Albino3 (Alb3). We hypothesized that cpSRP43-Alb3 interaction serves to coordinate the order and timing of targeting events at the membrane, first triggering structural changes in cpSRP43 that lead to release of LHC from cpSRP to Alb3 followed by cpSRP/cpFtsY mediated GTP hydrolysis, thereby stimulating recycling cpSRP from the thylakoid membrane for additional rounds of targeting. Completion of the proposed biochemical and biophysical studies will be used to establish the order and timing of membrane events needed for LHC targeting to Alb3. The proposed work will also have a general impact on understanding insertase activity of Alb3 homologues required for biogenesis of energy generating complexes in bacteria being used for biofuels production.

FY 2014 HIGHLIGHTS

We show that LHCP is released from cpSRP without the need for GTP hydrolysis; a non-hydrolyzable GTP analogue (GMP-PNP) is sufficient to support LHCP insertion into thylakoids. The use of GMP-PNP to support LHCP targeting/insertion in the absence of cpSRP recycling makes it possible to estimate the number of active Alb3 insertases per chloroplast. We have also found that when Alb3 access is limited, a stable cpSRP-LHCP-cpFtsY complex accumulates at the membrane in the presence of GMP-PNP. Together, these data support a model whereby LHCP remains stably associated with cpSRP at the thylakoid until an Alb3 insertase becomes available. This mechanism would prevent dead-end targeting that stems from premature release of LHCP from cpSRP in the absence of an available insertase. The role of GTP hydrolysis in LHCP localization appears restricted to recycling of cpSRP from its receptor for subsequent rounds of protein targeting. Single molecule Förster Resonance Energy Transfer (smFRET) was employed to understand how cpSRP54 binding to cpSRP43 influences the interdomain structural dynamics of cpSRP43. Careful placement of fluorescent labels at specific sites on cpSRP43 identified several structural features that contribute to cpSRP43 structural dynamics. Upon binding to cpSRP54, the localized flexibility of cpSRP43 is reduced, particularly between the Ank2-Ank4 and CD2-CD3 domains. This flexibility model derived from our experimental FRET data is supported by all-atom and coarse-grained molecular dynamics simulations, which identified 3 main conformations, “closed”, “open” and “extended”. Potential functional implications of these structural dynamics indicate that cpSRP54 binding to cpSRP43 promotes a structure of cpSRP43 that enhances its ability bind LHCP targeting substrates, which was supported by studies that examine the affinity of the cpSRP binding motif in LHCP for cpSRP43.

Targeting, Maturation and Quality Control of Photosynthetic Membrane Proteins

Institution: California-Davis, University of
Point of Contact: Kentaro Inoue

Principal Investigator: Kentaro Inoue
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$360,000 (2014-2016)

PROGRAM SCOPE

Thylakoids are internal membrane systems of chloroplasts of photosynthetic eukaryotes and cyanobacteria where light harvesting, electron transport and ATP synthesis occur. Molecular compositions and properties of thylakoids have been elucidated well. By contrast, our understanding of the mechanisms underlying the photosynthetic membrane development and dynamic regulation of photosynthetic activities is far from complete. The overall goal of the BES research project is to address this issue by answering several questions about a thylakoidal protein called plastidic type I signal peptidase 1 (Plsp1). Plsp1 is the major form of thylakoidal processing peptidase (TPP) in the model plant *Arabidopsis*. Protein targeting to the thylakoid lumen requires thylakoid-transfer sequence (TTS) in its N terminus, using ATP-dependent cpSEC pathway or proton motive force-dependent cpTAT pathway for membrane translocation. TPP cleaves off TTS in the lumen. Supported by the DOE grant since 2008, we have made the following discoveries about Plsp1. First, it is essential for proper maintenance of thylakoids thus autotrophic growth of plants. Second, it is located in both the envelope and thylakoid membranes, and its distribution appears to correlate with the development of thylakoids from the envelope. Third, it forms a complex with a protein that plays a role in regulation of cyclic electron flow around the Photosystem I (CEF) although the biological significance of this complex formation is unknown. These findings have generated new questions. In FY2014, we have focused on addressing the following two questions: 1. How does Plsp1 catalyze TTS removal? 2. What is the significance of protein maturation in thylakoids?

FY 2014 HIGHLIGHTS

We have demonstrated catalytic activity of bacterially produced *Arabidopsis* Plsp1 against various TPP substrates including those using cpSEC and cpTAT pathways for transport. We also found that Plsp1 orthologs in angiosperms contain two unique Cys residues located in the lumen. Results of processing assays suggested that these residues were redox active and formation of a disulfide bond between them was necessary for the activity of Plsp1 *in vitro*. Furthermore, Plsp1 in *Arabidopsis* and pea thylakoids migrated faster under non-reducing conditions than under reducing conditions on SDS-PAGE. These results underpin the notion that Plsp1 is a redox-dependent signal peptidase in the thylakoid lumen. We have also gained insights into the mechanism underlying the importance of protein maturation in thylakoid development. In plsp1-null plastids, two TPP substrates that use cpSEC pathway (plastocyanin and PsbO) were shown to be tightly associated with the membrane, while non-mature TPP substrate that uses cpTAT pathway (PsbP) was found in the stroma. The import assay revealed that inhibition of TTS removal did not disrupt cpSEC- and cpTAT-dependent translocation, but prevented release of proteins from the membrane. The non-mature form of plastocyanin was quickly degraded under light, while that of PsbO was found in a 440-kDa complex. The 440-kDa complex was dissociated under reducing conditions. These results indicate that the cpTAT pathway may be disrupted in the plsp1-null mutant, and that there are multiple mechanisms to control unprocessed luminal proteins in thylakoids. Taken together, our data suggest that there may be a mechanism to control the activity of Plsp1, either by redox or association with the CEF regulator, which may be needed to regulate the energy-dependent protein transport. Also, our findings indicate that Plsp1 may be the novel tool to define the mechanism and significance of redox-dependent regulatory pathway in the photosynthetic membrane.

High-Resolution Study of Photochemical and Nonphotochemical Processes in Biological Proteins Assembled with Photosynthetic Pigments

Institution: Kansas State University
Point of Contact: Ryszard Jankowiak
Email: ryszard@ksu.edu
Principal Investigator: Ryszard Jankowiak
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$260,000 (2014-2015)

PROGRAM SCOPE

The research objectives are to study excitonically coupled bacteriochlorophylls (BChls) that are ubiquitous in bacterial photosynthetic complexes. Hole-burning (HB) and delta fluorescence line-narrowing (FLNS) spectroscopies and modeling studies are used to provide additional insight into the excitonic structure, electron-phonon and vibronic couplings, and excitation energy transfer (EET)/electron transfer (ET) processes in: i) various model protein systems; ii) the Zn-reaction center (RC) and its mutants; iii) *Rb. sphaeroides* RC and its mutants; and iv) various FMO complexes, found in anoxygenic green sulfur bacteria. Deeper insight into the origin of hole-burned (HB) spectra will provide a better framework for probing the electronic structure of complex biological systems via HB/FLNS spectroscopies and theoretical calculations. Our approach will provide a more complete picture of the EET/ET processes in various photosynthetic systems.

FY 2014 HIGHLIGHTS

- I. During the FY2014 we showed that various optical spectra (including hole-burned (HB) spectra) for FMO complexes can be properly modeled taking into account uncorrelated excitation energy transfer (EET) between pigments contributing to the lowest-energy states of FMO monomers. A new insight was provided into the nature of the 825 nm exciton band.
Publications: J. Phys. Chem. B 2014, 118 (8), 2032; J. Phys. Chem. Lett. 2014, 5 (8), 1450; and Photosynth. Res. 2014, 120 (3), 323.
- II. We showed that the low-energy Chl a Q_y absorption band in LHCII of PSII have charge-transfer (CT) character as revealed via strong electron-phonon coupling.
Publications: J. Phys. Chem. B 2014, 118 (23), 6086 and PCCP (2014), 16, 20856.
- III. We use both frequency- and time-domain low-temperature spectroscopies to further elucidate the shape and spectral position of singlet minus triplet spectra in the reaction centers of PSII isolated from wild-type *Chlamydomonas (C.) reinhardtii* and spinach. We have shown that the previously observed difference in transient spectra between RCs from *C. reinhardtii* and spinach is not due to the sample origin but due to a partial destabilization of the D1 and D2 polypeptides.
Publications: J. Phys. Chem. B, 2014, dx.doi.org/10.1021/jp510049k and Photosynthesis Research, 2014, submitted.
- IV. Two book chapters are in press:
 - 1) Biophotonics of Photosynthesis, in: Biological and Medical Photonics, Spectroscopy and Microscopy, vol. 4; Ed.: D. Andrews, Publisher Wiley (2014); and
 - 2) Mechanism of Primary Charge Separation in Photosynthetic Reaction Centers, chap. 8 in The Biophysics of Photosynthesis, Springer, Eds. J. Golbeck and A. van der Est (2014). V. Studies of the recombinant water-soluble chlorophyll (Chl) binding proteins (WSCP) from *Lepidium*

virginicum have been completed. This work will be submitted J. Phys. Chem. B. We revealed the presence of uncorrelated EET between two Chl dimers.

Controlling Electron Transfer Pathways in Photosynthetic Reaction Centers

Institution: Washington University, St. Louis
Point of Contact: Christine Kirmaier
Email: kirmaier@wustl.edu
Principal Investigator: Christine Kirmaier
Sr. Investigator(s): Dewey Holten; Washington University, St. Louis
Philip Laible; Argonne National Laboratory
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 3 Undergraduate(s)
Funding: \$341,438 (2014)

PROGRAM SCOPE

Photosynthetic reaction centers (RCs) convert light energy into chemical energy in a series of extremely efficient electron transfer reactions that accomplish transmembrane charge separation. RCs have two symmetry-related branches (or sets) of cofactors called A and B that are functionally asymmetric; bacterial RCs use only the A cofactors for light-induced electron transfer. Prior to this project, site-specific mutagenesis efforts had elicited B-branch activity but with only a very low yield of charge separation (~12%). The hypothesis of this collaborative project is that it should be possible to generate an RC that uses the B-side cofactors preferentially and efficiently. The goal is to produce such a transformative RC via the integrated and iterative efforts of the Laible group at Argonne National Laboratory (ANL) and the Kirmaier/Holten group at Washington University in St. Louis (WU). Our primary experimental vehicle is the RC from the purple photosynthetic bacterium *Rhodobacter (R.) capsulatus*. RC mutagenesis and protein purification are conducted at ANL and mutant RCs are screened via a high-throughput time-resolved spectroscopic assay at WU. Promising mutants (“hits”) re-enter the pipeline for subsequent rounds of 1) mutation and screening (ANL and WU) and/or 2) natural selection seeking photosynthetic growth that uses the B-side cofactors only (ANL) and/or 3) further characterization of the rates and yields of RC electron transfer steps via ultrafast spectroscopy (WU). The ultimate goal is to discover and understand the architectural and energetic factors that will transform the B-side cofactors from a normally non-functional state into one of high functionality. The principles realized will be broadly applicable, such as aiding design of biomimetic systems that are competent in light-induced ET and that provide a long-lived charge-separated state that can be an energy source for downstream energy conversion and storage.

FY 2014 HIGHLIGHTS

Both technical and scientific advances were made in 2014. Regarding the former, efficiencies of RC mutant construction and RC protein purification processes at ANL continued to be improved via streamlining or eliminating some steps while preserving or even increasing the quality of the output. At WU, the sensitivity and signal-to-noise ratio of the millisecond-to-seconds high-throughput screening assay also continued to be optimized such that assays can now be performed with samples of about one-tenth the concentration used two years ago. Some highlights of our scientific findings are as follows:

- (1) About 100 new mutants were generated and screened with many displaying enhanced overall yield of B-side charge separation.

- (2) Ultrafast transient absorption studies on select mutants detailed the rates and yields of each of the step-wise B-branch electron transfer reactions. These analyses revealed specific mutations that in some cases improve the initial, primary photochemistry (electron transfer from the photoexcited primary donor to the intermediate electron carrier) or in other cases improve the secondary stage of the photochemistry (electron transfer from the intermediate to the terminal quinone).
- (3) Studies on mutant RCs from *R. sphaeroides* that complement work on *R. capsulatus* were conducted and revealed differential effects (for the same mutation) that may be exploited.
- (4) Efforts to use natural selection methods to discover mutations that result in photosynthetic competence from use of only the B-side cofactors are underway and showing promise.

Collectively, this work demonstrated significant progress toward understanding and engineering an efficient B-branch electron transfer pathway in the bacterial photosynthetic RC. Such knowledge is applicable to the design of artificial systems for solar energy conversion using inspiration from the native photosynthetic systems.

The Energy Budget of Steady State Photosynthesis

Institution: Michigan State University
 Point of Contact: David Kramer
 Email: kramerd8@msu.edu
 Principal Investigator: David Kramer
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
 Funding: \$230,000 (2014)

PROGRAM SCOPE

The work focuses on how photosynthesis balances its energy budget, matching the output of energy in NADPH and ATP to precisely meet biochemical demands, which is critical for efficient, robust photosynthesis. We are currently focusing on the mechanism and modes of regulation of cyclic electron transfer around photosystem I (CEF), which is important in balancing ATP/NADPH output.

FY 2014 HIGHLIGHTS

The work focuses on how photosynthesis balances its energy budget, matching the output of energy in NADPH and ATP to precisely meet biochemical demands, which is critical for efficient, robust photosynthesis. We have made important breakthroughs on all proposed aims, resulting over the past year in the publication of three papers citing support from this grant (1-3), two manuscripts are accepted for publication and are In Press (4, 5) and four additional manuscripts are in revisions. We have also made progress on characterization of (and appropriate controls for) CEF mutants (hcef4, hcef5 and hcef6). We are accordingly nearly ready to publish on two of these mutants. Most excitingly, our very recent work shows that the chloroplast NDH complex 1) is a proton pump; 2) the proton pumping capacity of NDH allows it to be driven 'in reverse' under conditions of high pmf; 3) NDH affects the ion permeability of the thylakoids, perhaps because it acts as a H⁺/Na⁺ antiporter as proposed for the bacterial and mitochondrial homologues (Complex I); 4) the NDH complex can be driven in reverse, oxidizing plastoquinol and reducing stromal electron carriers. Based on these results, we propose that the NDH complex may act as a regulatory system that senses the balance of energy stored in the pmf, redox carriers and ATP.

Photoreceptor Regulation and Optimization of Energy Harvesting in *Nostoc punctiforme*

Institution: California-Davis, University of
 Point of Contact: John Lagarias
 Email: jclagarias@ucdavis.edu
 Principal Investigator: John Lagarias
 Sr. Investigator(s): James Ames; California-Davis, University of
 R. David Britt; California-Davis, University of
 Delmar Larsen; California-Davis, University of
 John Meeks; California-Davis, University of
 Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
 Funding: \$739,000 (2014)

PROGRAM SCOPE

Sustainable bioenergy production relies on the ability of photosynthetic organisms to use solar power to convert atmospheric carbon dioxide into organic fuels such as biodiesel. While plants effectively harvest solar energy and accumulate biomass, plant growth for energy production requires extensive use of nitrogen fertilizers and competes with food production for arable land. Algal and bacterial photosynthesis provide powerful alternatives. Cyanobacteria are among the most versatile photosynthetic organisms known, frequently fixing their own nitrogen and readily growing in liquid culture or in swamplands. Nitrogen fixation produces hydrogen gas as a byproduct, and hydrogen production allows energy to be made without converting biomass into usable fuel. Our work addresses both basic science and applied science of these organisms, with a long-term goal of engineering cyanobacteria as a sustainable bioenergy source. Such engineering requires the development of inducible gene regulatory systems, allowing researchers or engineers to manipulate the metabolism of the organism for optimal energy production. Using photosensory systems for this purpose permits control over the level of induction (by varying the quantity and quality of light) and can avoid problems associated with other artificially controlled inducers, such as heat-shock systems or expensive synthetic chemicals. This project seeks to characterize all bilin-based photosensors in the cyanobacterium *Nostoc punctiforme*, to understand the molecular basis of their light sensing selectivity and signaling activity, and to apply them in synthetic photosensory circuits to regulate gene expression.

FY 2014 HIGHLIGHTS

Following completion of our survey of the phytochrome superfamily of bilin-based light sensors in *N. punctiforme*, we initiated detailed investigations of targeted subfamilies with distinct light-sensing selectivities. We characterized a widespread tuning mechanism used by many of these photosensors that relies on conserved phenylalanine residues. This work aids both engineering of new photocycles and prediction of cyanobacterial photobiology from genome sequence. Time resolved photodynamics of the cyanobacterial phytochrome Cph1 and two cyanobacteriochromes, NpF2164g3 and RcaE, on the

femtosecond to nanosecond timescale revealed heterogeneity to be the rule rather than the exception with these photosensors. Such heterogeneity accounts for variable quantum efficiency and photoproduct diversity observed within individual subfamilies. Room temperature NMR studies of NpF2164g3 in both photostates identified a conserved light-induced structural change, permitting construction of an explicit, testable model for signal-propagation by cyanobacteriochromes.

Elucidating the Principles that Control Proton-Coupled Electron Transfer Reaction in the Photosynthetic Protein, Photosystem II. A Model for Design of Bio-Inspired Photocatalytic Water-splitting

Institution: Rensselaer Polytechnic Inst.
Point of Contact: K.V. Lakshmi
Email: lakshk@rpi.edu
Principal Investigator: K.V. Lakshmi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

The solar water-splitting protein, photosystem II (PSII), catalyzes one of the most energetically demanding reactions in nature by using light energy to drive a catalyst capable of oxidizing water. Proton-coupled electron transfer (PCET) reactions, which are exquisitely tuned by smart protein matrix effects, are central to the water-splitting chemistry of PSII and elucidating the water-splitting chemistry of PSII is of major importance in designing bio-inspired catalytic systems for solar fuels production. Proton motion coupled to electron transfer is the basic mechanism of biological energy conversion. However, a major challenge is to develop methods to directly probe PCET processes to understand the structural requirements for minimizing the energetic penalty for multiple charge transfers. The overall objective of this project is to understand the tuning and regulation of the PCET reactions of PSII. The specific goals of this research are: a) To understand the primary factors that influence the tuning of PCET processes in the oxygen-evolving complex (OEC) and b) to elucidate the role of “smart” matrix effects of the protein in tuning the charge-transfer sites of PSII. In order to achieve these goals, we are (i) determining the structure of the S-state intermediates of the OEC in the water oxidation reaction, (b) using metal-ion substitution in conjunction with pulsed EPR spectroscopy to determine the role of the Ca^{2+} ion in the water oxidation reaction, (c) elucidating the mechanism of PCET at the redox-active tyrosine residues, YZ and YD and (d) developing methods to probe protein-cofactor interactions that govern the functional specificity of the quinone cofactors, Q_A and Q_B , of PSII.

FY 2014 HIGHLIGHTS

We had previously detailed the structure and location of the substrate water molecules that are directly coordinated to the Mn_4Ca -oxo cluster in the S_2 state of Ca^{2+} -substituted PSII. In a very exciting development, we have unambiguously identified the substrate water molecules that are coordinated to the catalytic Mn_4Sr -oxo cluster in the S_2 state of Sr^{2+} -substituted PSII. This provides, for the first time, a direct window into the role of Ca^{2+} in the solar water oxidation reaction of PSII. The Sr^{2+} -substituted PSII was prepared in collaboration with Prof. Shen (Okayama University). Previously, we had also demonstrated the presence of three nitrogen atoms that are magnetically interacting with the Mn_4Ca -oxo cluster in the S_2 state of PSII and we had confirmed the assignment of these hyperfine interactions in dimanganese di- μ -oxo model complexes. Recently, we have utilized two-dimensional ^1H , ^2H and ^{14}N hyperfine sublevel correlation (HYSCORE) spectroscopy to characterize the structure of the active site of

super-oxidized (Mn(III)Mn(IV)) manganese catalase. The (Mn(III)Mn(IV)) form of manganese catalase is an excellent proteinaceous model of the Mn₄Ca-oxo cluster of PSII. The super-oxidized (Mn(III)Mn(IV)) manganese catalase was prepared in collaboration with Prof. Whittaker (Oregon Health & Science University). In addition, we have detailed the individual steps of the highly efficient PCET reactions mediated by the redox-active tyrosine residues of PSII. This study provides a blueprint for biological PCET reactions in solar energy conversion. Currently, we are conducting multi-dimensional pulsed EPR spectroscopy studies of genetic variants with mutations in the primary quinone, Q_A, binding pocket of PSII. This provides insight on the factors that tune and control the function of the quinone electron acceptors in PSII. The genetic variants of PSII have been prepared in collaboration with Prof. Debus (UC, Riverside).

Membrane Bioenergetics of Salt Tolerant Organisms

Institution: California-Irvine, University of
Point of Contact: Janos Lanyi
Email: jklanyi@uci.edu
Principal Investigator: Janos Lanyi
Sr. Investigator(s): Sergei Balashov; California-Irvine, University of
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$75,000 (2014)

PROGRAM SCOPE

With the discovery of the globally significant abundance of retinal-based proton pumps, we focus on generalizing and extending the bacteriorhodopsin paradigm. There is abundant evidence now that the lessons to be learned from the rhodopsins are much broader than previously thought. Our earlier finding that in the *Exiguobacterium* rhodopsin a lysine, instead of an acidic group, is the proton donor to the retinal Schiff base raises the question whether the source of the proton is the lysine NH³⁺ itself or an associated water molecule (or water network). We will explore these alternatives with IR spectroscopy and mutagenesis of the region around the lysine. Increased hydration at a late step of the transport cycle, as in bacteriorhodopsin, would account for the fact that although the donor is unprotonated in the initial state, it becomes transiently protonated from the bulk before it reprotonates the Schiff base. In the *Exiguobacterium* rhodopsin at about the time the Schiff base becomes deprotonated, a proton is released before a second proton is taken up. We will study the origin of this proton, and whether it is a consequence of a pK_a change of some buried group in response to a protein conformational shift. It is intriguing that the conformational change at the time this proton is released should be on the extracellular rather than the cytoplasmic side, the latter having been more thoroughly investigated in the rhodopsins. *Hymenobacter* rhodopsin is novel and an unusual proton pump with the conventional carboxyl proton acceptor and donor replaced by asparagine and glutamine. An alternative acceptor might be an aspartate residue one helical turn removed from its expected location. It is unclear what the donor is. We will describe how this unusual pump functions. Unexpectedly, in the presence of Na⁺ this rhodopsin transports Na⁺ instead of protons. We will identify the site(s) where the switch between the two kinds of transport functions occurs.

FY 2014 HIGHLIGHTS

1. Nature of the proton donor in *Exiguobacterium sibiricum* rhodopsin (ESR) and mechanism of Schiff base reprotonation. Uniquely, ESR contains Lys instead of the conventional acidic group in the position of the proton donor to the retinal Schiff base. In the proposal, we asked: "...what will

happen if a carboxylic residue replaces Lys96, as in all other conventional proton pumps? Will it be able to perform as internal donor?" We have now obtained an affirmative answer to this question. In the wild type ESR reprotonation of the Schiff base (the decay of M intermediate, followed as the decrease of absorbance 410 nm) occurs in ca. 1 ms. In the K96E mutant reprotonation occurs with a rate only slightly slower than in the wild type, and in the K96D/A47T it is even faster than in wild type (0.7 ms vs. 1 ms). This indicates that a carboxylic residue in place of Lys96 will efficiently facilitate proton transfer from the bulk to the Schiff base. Other ionizable residues in place of Lys96 (Arg or His) were not able to do this.

- II. Proton release mechanisms in ESR: role of carboxylic and other groups. We examined the source of the proton that is released to the extracellular surface before uptake at the cytoplasmic surface. We mutated all carboxylic residues in ESR, found that only mutation of Glu214 in the extracellular domain eliminates fast proton release. It also affects the pK_a of the blue shift of absorption spectrum which was attributed to deprotonation of His. Mutation of Glu214 to Asn facilitates also rapid Schiff base deprotonation. These results suggest that a strong hydrogen bonding network at the Schiff base regulates Schiff base deprotonation and proton release.
- III. Proton transport in *Hymenobacter roseosalivarius* rhodopsin (HRR) with changed or absent internal proton acceptor and donor. We identified Asp102 as the principal counterion that interacts strongly with the Schiff base.

Immunophilins in the Assembly and Maintenance of Photosynthetic Electron Transport Chain in *Arabidopsis*

Institution: California-Berkeley, University of
Point of Contact: Sheng Luan
Email: sluan@berkeley.edu
Principal Investigator: Sheng Luan
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$75,000 (2014)

PROGRAM SCOPE

The proposed project is to understand the function of immunophilins in the assembly and maintenance of photosynthetic complexes in *Arabidopsis*. Our studies have identified critical functions for several immunophilins in the biogenesis and maintenance of photosynthetic electron transport chain. Among the four protein-based electron carriers in the thylakoid, three (PSII, Cyt bf, and PC) have been shown to require immunophilins for their assembly. Furthermore, function of 2/3 of the 16 immunophilins in the thylakoid lumen is yet to be assigned. It becomes increasingly apparent that immunophilins in the thylakoid may constitute an "assembly line" for photosynthetic machines. Our goal is to establish this emerging concept by systematically dissecting the functions of all immunophilins in the context of photosynthetic light reaction. The specific objectives for this funding period will focus on mechanistic analysis of two thylakoid lumen immunophilins, FKBP20-2 and CYP38, which are involved in the assembly and maintenance of PSII. At the same time, we will expand our effort into the functional analysis of another immunophilin (CYP37) that is required for the accumulation of Cyt b6f complex. The work on FKBP16-2 in PC assembly briefly described above (details in attached preprint) has been completed at a mechanistic level. No immediate work is planned on FKBP16-2 in this proposal because the further work on this immunophilin will heavily rely on chemistry and structural tools beyond our direct expertise. Collaborative research is currently being explored.

FY 2014 HIGHLIGHTS

We have identified and characterized the function of a new player in the thylakoid lumen that interact with immunophilins and that plays a critical role in plant growth under variable light intensities. The function of this protein is independent of the formation of PSII supercomplexes and state transition. This finding has been published in PNAS at the beginning of 2015.

Molecular Genetic Dissection of Chloroplast Iron Homeostasis

Institution: California-Los Angeles, University of
Point of Contact: Sabeeha Merchant
Email: merchant@chem.ucla.edu
Principal Investigator: Sabeeha Merchant
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

Iron nutrition limits life because of poor bioavailability. The long-term goal of this project is to understand iron-nutrition dependent programming of chloroplast and mitochondrial metabolism in photosynthetic eukaryotes. Recent studies have contributed to the appreciation that photosynthetic metabolism and output from the photosynthetic apparatus is dependent on resource (CO₂, light, mineral nutrients) availability and is also tightly connected to respiratory function. *Chlamydomonas reinhardtii* has served as a premier reference organism for discovering and understanding the regulatory circuits that connect carbon source, photon flux density and inorganic nutrients to the operation of the light and dark reactions of photosynthesis. In this context, the specific aims for the new project period are,

1. To compare the transcriptomes of iron-replete, -deficient and -limited cells during the transition from photoautotrophic to photoheterotrophic growth with the goal of identifying the factors involved in iron salvage from the photosynthetic apparatus and iron delivery to the respiratory chain and better understanding of the connection between C metabolism and Fe nutrition.
2. To describe the elemental profile of the proteomes of cells grown in iron-luxury vs. iron-economy mode to compare and document the distribution of iron.
3. To determine the function of CGLD27 and FEK1 by localizing them and determining the molecular phenotype of *cgld27* and *fek1 Arabidopsis* plants or *Chlamydomonas* strains with respect to iron nutrition.

FY 2014 HIGHLIGHTS

Aim 1. In the last project period, replicate photoautotrophic cultures were grown with iron supplied at 0.25, 1 and 20 μM, representing the limited, deficient and replete states, respectively. Acetate was added to cultures in log phase following which they were monitored for biomass and chlorophyll and sampled for isolation of RNA immediately after addition (0 h) or 1, 2, 4, 6, 8, 12 and 24 h later. Physiological measurements indicate that the iron-limited culture behaves distinctly different from the iron-deficient and -replete cultures with respect to growth and Chl content, supporting our previous findings of a different metabolic state. The reduction in Chl content to 50% is timed precisely between 4 to 6 h. This reduction cannot be explained by cell division because the cells do not divide until many hours later. We suspect that the program to degrade the photosynthetic apparatus is initiated during this window.

Aim 2. We had proposed to use elemental profiling of the proteome to ascertain the location of intracellular Fe. In the iron-excess situation, this would address the question of where iron is stored, since ferritin abundance actually decreases in the overload situation. In the case of deficiency, the profile would reveal other iron-containing proteins that are either prioritized or dispensable. The amount of iron that is associated with ferritin increases as cells transition from iron-limited to iron-deficient to iron-replete, but once the cells are iron-replete, the ferritin associated iron remains constant even though intracellular iron increases nearly 5-fold. The abundance of the polypeptide actually decreases 10-fold in iron-excess vs. iron-limited cells, which translates to over 100-fold increase in the iron content of the ferritin. Preliminary data suggest that the non-ferritin associated iron is in compartments that also contain calcium.

Enhancement of Photoassimilate Utilization by Manipulation of ADP-glucose Pyrophosphorylase and Phosphorylase

Institution: Washington State University
Point of Contact: Thomas Okita
Email: okita@wsu.edu
Principal Investigator: Thomas Okita
Sr. Investigator(s): Paul Hwang; Washington State University
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$90,000 (2014)

PROGRAM SCOPE

ADPglucose pyrophosphorylase (AGPase) and the plastidial starch phosphorylase1 (Pho1) are two regulatory enzymes whose catalytic activities are essential for starch granule synthesis. Conversion of the pre-starch granule to the mature form is dependent on AGPase, which produces ADPglucose, the substrate used by starch synthases. We had earlier demonstrated that the AGPase catalyzed reaction limits the amount of starch accumulation in developing rice seeds and that carbon flux into rice seed starch can be increased by expression of a cytoplasmic-localized, up-regulated bacterial AGPase enzyme form. Results of subsequent physiological and metabolite studies showed that the AGPase reaction is no longer limiting in the AGPase transgenic rice lines and that now one or more downstream processes prevent further increases in starch biosynthesis. A second phase of this project examines Pho1, the enzyme required during the initial phase of pre-starch granule formation and its maturation to a starch granule. Although Pho1 catalyzes a reversible reaction, our DoE supported studies clearly demonstrated that the kinetic properties of this enzyme strongly favor synthesis of starch and that these catalytic properties are independent of the L80 peptide, a structural domain that is absent in phosphorylases from other organisms. Current efforts are directed at elucidating the role of the L80 peptide in regulating Pho1. Overall, results from these biochemical and physiological studies will increase our fundamental understanding on how these important starch regulatory enzymes operate at the molecular level and *in planta*, which will collectively aid in efforts to increase the utilization of higher plants as a renewable source of energy.

FY 2014 HIGHLIGHTS

1. A study on the regulation of the rice AGPase was completed and published. Redox control of the partially purified native enzyme not only affected affinity to the activator 3-PGA but also k_{cat} whereas redox regulation only affected 3-PGA affinity of the recombinant enzyme.

2. The interactions of substrates to heterotetrameric (SWTLWT) and homotetrameric (L302N and SWT) forms of ADP-glucose pyrophosphorylase were investigated using isothermal titration calorimetry. Our results clearly demonstrated that wildtype SWTLWT possesses two distinct types of ATP binding sites with significantly increased affinity compared to L302N and SWT homotetrameric enzymes. Interestingly, binding to the other substrate, glucose-1-phosphate, was not observed suggesting that AGPase may not have a defined binding site for this sugar-phosphate.
3. RNAseq studies showed that RNAs for several starch biosynthetic enzymes were elevated or depressed several-fold in the starch over-producing transgenic rice line modified for elevated AGPase activity. The most conspicuous transcriptome change (4-12 fold increase) was for a starch binding domain protein, which has never been isolated and biochemically characterized. These changes at the RNA level were also evident at the protein level. This starch binding domain protein may limit starch granule synthesis by competing against the binding of starch biosynthetic enzymes to starch chains.
4. The interaction of Pho1 with disproportionating enzyme (Dpe1) to form a multi-enzyme complex was verified by using Dpe1 as bait, which readily captured native Pho1 from seed extracts.
5. Transgenic rice lines of the Pho1 mutant BMF136 expressing intact Pho1 and Pho1 Δ L80 genes were generated. Interestingly, the Pho1 Δ L80 transgenic lines grew faster and produced larger grains than transgenic lines expressing wildtype Pho1. These observations suggest that the L80 peptide is a negative regulatory structural domain of Pho1.

Control of Chloroplast Morphology in Plants: Mechanisms and Physiological Significance

Institution: Michigan State University
 Point of Contact: Katherine Osteryoung
 Email: osteryou@msu.edu
 Principal Investigator: Katherine Osteryoung
 Sr. Investigator(s):
 Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
 Funding: \$180,000 (2014)

PROGRAM SCOPE

The proliferation of chloroplasts in leaf mesophyll cells through the process of division increases chloroplast numbers and compartment size during leaf growth and development, and is therefore essential for achieving maximum photosynthetic productivity. A striking feature of the division process is that it is restricted to the middle of the chloroplast, producing a large population of small organelles of similar size and shape. The first contractile component of the chloroplast division machinery to assemble is the stromal FtsZ ring (Z ring), which determines the positioning of other contractile components of the division complex. The tight spatial regulation of division-site placement is regulated by a complex system of proteins that together inhibit Z-ring assembly everywhere but at the chloroplast midpoint. The proposed research is aimed at furthering our understanding of the mechanisms restricting Z-ring formation to the mid-plastid, exploring the physiological significance of chloroplast size and shape for photosynthetic performance, and exploiting genetic variation in *Arabidopsis* to identify genetic loci potentially involved in the control of chloroplast size, number and total compartment size.

FY 2014 HIGHLIGHTS

ARC3 and PARC6 contribute to regulating Z-ring positioning. We showed that ARC3 is a direct FtsZ assembly inhibitor, and previous data have suggested that PARC6 also inhibits Z-ring assembly. To

confirm this, we generated *Arabidopsis* plants overexpressing PARC6, which exhibit enlarged chloroplasts indicative of impaired division. Immunofluorescence staining in T1 transgenics showed that FtsZ localizes to small punctae instead of rings. To test our hypothesis that the inhibitory effect of PARC6 on Z-ring assembly results from its interaction with ARC3, we are generating plants that overexpress PARC6 in *arc3* mutants. We predict that multiple FtsZ rings or filaments will be observed in these plants. To explore the relationships between chloroplast morphology, chloroplast movement and photosynthesis, we collaborated with David Kramer to develop a platform for imaging chloroplast movements and chlorophyll fluorescence on whole plants in white light using dual CCD cameras. Reflectance of pulsed red light from leaf surfaces measures chloroplast movement. Image data are integrated over all exposed leaves. With this platform we measured chloroplast movement and photosynthetic responses to fluctuating light in *Arabidopsis arc6* and two *ftsZ* mutants, which bear 1-2 giant chloroplasts in their mesophyll cells, and compared their responses to those of phot mutants, which exhibit impaired movement but normal chloroplast morphologies. The data indicated reduced movement in all mutants, confirmed by confocal microscopy, and showed that reflectance accurately reports chloroplast movements. Large-chloroplast mutants showed lower PSII efficiency and recovery from high-light stress than wild type. These responses differed from those of phot mutants, suggesting that the altered photosynthetic responses in the *arc6* and *ftsZ* mutants are not due solely to their impaired movement responses. Other photosynthetic parameters (NPQ and photoinhibition) are being analyzed in these mutants.

Redox Factors in the Thylakoid Lumen for Protection and Repair of the Photosynthetic Apparatus

Institution: Washington University, St. Louis
Point of Contact: Himadri Pakrasi
Email: Pakrasi@wustl.edu
Principal Investigator: Himadri Pakrasi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$195,000 (2014)

PROGRAM SCOPE

Cyanobacteria are the largest and most diverse group of oxygenic photosynthetic prokaryotes that play major roles in bioenergy production and carbon sequestration on our planet. They are also the progenitors of chloroplasts in plants and eukaryotic algae. In these organisms, production of oxygen from water by the Photosystem II (PSII) pigment protein complex on the luminal side of the thylakoid membrane requires a very strong oxidant, whereas the electron transfer reactions in the Photosystem I (PSI) complex on the cytoplasmic side of the same membrane generates a strong reductant. The simultaneous presence of highly oxidizing as well as reducing environments during the normal photosynthetic electron transfer reactions in cyanobacteria inevitably leads to the production of reactive oxygen species (ROS) that can potentially damage the photosynthetic apparatus. To face this challenge, cyanobacteria have developed multiple protection and repair pathways. The central objective of this project is to determine the mechanisms of thylakoid lumen localized redox proteins in photoprotection and repair of the photosynthetic apparatus. During the current funding period of this project, there are four specific aims: (1) To develop a simple and rapid method for the isolation of functionally competent thylakoid membranes from cyanobacteria, followed by analysis of the proteome of the thylakoid lumen; (2) To generate comprehensive maps of the thylakoid and plasma membrane proteomes of cyanobacteria; (3) To dissect the Redox Proteome of cyanobacterial thylakoid lumen, and (4) To investigate the role of a thylakoid lumen-localized thioredoxin-like protein as a critical regulator of

photosystem stoichiometry. These comprehensive studies are expected to broaden our understanding of the important roles of the thylakoid lumen in the protection and repair of the photosynthetic apparatus.

FY 2014 HIGHLIGHTS

During this year, we investigated the global redox proteome of the cyanobacterium *Synechocystis* 6803, and developed a proteome-wide quantitative site-specific profile of *in vivo* dynamics of thiol oxidation in this organism. In photosynthetic organisms, reversible protein thiol oxidation is an essential regulatory mechanism for many physiological processes. During the current project period, we aimed at examining the redox states of all protein thiols in a cyanobacterial cell in the presence or absence of photosynthetic electron transport activity. Toward this goal, we first developed a novel global proteomic approach for selective enrichment of oxidized thiols with quantitative isobaric labeling to determine the extent of oxidation of individual thiols, as well as the redox dynamics of the thiol proteome under different conditions that modulate photosynthetic electron transport activities in the thylakoid membranes of *Synechocystis* 6803 cells. The proteomics results exhibited consistent increases in the levels of cysteine thiol oxidation in the dark compared to the light condition. In total, changes in Cys oxidation status were observed in ~2600 peptides from ~1000 proteins, implying broad light-dependent redox regulation in this organism. In particular, the level of thiol oxidation for many known redox proteins such as thioredoxin, PSI and PSII reaction center proteins, and various oxidoreductases were significantly modulated. These results are consistent with earlier findings that specific electron carriers in the photosynthetic electron transport chain are increasingly oxidized during dark incubation than under light, and that disruption of the electron flow alters the redox state of the electron carriers. Interestingly, the identified redox-sensitive proteins are broadly involved in various biological processes, including photosynthesis, carbon fixation, amino acid biosynthesis, glycolysis and respiration.

Biochemical Integration of Metabolic Networks Critical for Energy Transformation in *Chlamydomonas reinhardtii*

Institution: Colorado School of Mines
Point of Contact: Matthew Posewitz
Email: mposewit@mines.edu
Principal Investigator: Matthew Posewitz
Sr. Investigator(s): Arthur Grossman; Carnegie Institution of Washington
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$185,000 (2014)

PROGRAM SCOPE

We are exploring *Chlamydomonas* energetics, with an emphasis on proteins required in dark metabolism, and identifying dark-specific electron carriers, supramolecular metabolic complexes, alternative electron transport pathways, and how these pathways interface with photosynthetic processes, which dominate during the day. Basic and specific questions being addressed are:

Why is an acetate kinase mutant (*ack1*) unable to grow in the dark?;

What targets of ferredoxin 5 (FDX5) dependent reduction are absolutely required for dark growth?

Why is the bifunctional alcohol dehydrogenase (ADH1) the dominant enzyme for reoxidation of electron carriers when O₂ is unavailable, and how is ADH1 activity regulated with respect to the many other enzymes that also use acetyl-CoA as a substrate?;

What is the role of the oxyhydrogen reaction in nature and how are electrons from H₂ captured in the dark and used to generate ATP and reductant?; and

How do conditions associated with oxyhydrogen function (dark, H₂, low O₂) alter pigmentation and pathways of electron flow?

One of the largest undertakings that we have initiated involves elucidating interactions among proteins associated with major hubs in dark and fermentation metabolism. Metabolite 'guiding' likely involves the linking of specific enzymes for the efficient trafficking of metabolites as a consequence of multi-protein, mega-complex formation. The key enzymes used for the analyses of protein complex formation are ADH1, the [FeFe]-hydrogenases (HYDA1/2) and PAT/ACK (chloroplast and mitochondrial), as well as pyruvate ferredoxin oxidoreductase (PFR1) and pyruvate formate lyase (PFL). The linking of enzyme activities through physical interactions might not only lead to efficient channeling of metabolites, but also potentially introduce rapid and effective mechanisms for fine tuning the activities of individual components through the binding of reactants and products.

FY 2014 HIGHLIGHTS

Key findings include characterizing the roles of chloroplast and mitochondrion acetate kinase (ACK) and phosphate acetyltransferase (PAT) in fermentation and dark oxic metabolism, the requirement for a specific ferredoxin (FDX) for anabolic electron transfer and growth in the dark, the further characterization of mutants null for both hydrogenases (HYDA1 and HYDA2), and insights into the operation of the oxyhydrogen reaction in the generation of reductant and ATP from H₂. Some of our novel, and surprising results include: (i) chloroplast localized ACK1 is critical for growing *Chlamydomonas* in the dark with acetate as a fixed carbon source (likely required for entry of acetate into plastid metabolism); (ii) FDX5 is critical for growth of *Chlamydomonas* in the dark, and is also important for maintaining the proper stoichiometry of galactolipids in thylakoid membranes, which likely reflects its role in donating electrons to fatty acid desaturases; (iii) the oxyhydrogen reaction (utilization of H₂ for the generation of ATP and reductant in the dark concomitant with O₂/CO₂ uptake) can restore dark growth of the *fdx5* mutant, potentially because the H₂ can be used to reduce FDX1 (FDX1 would not be readily reduced in the dark by NADH, unlike FDX5); (iv) oxyhydrogen reaction conditions cause modifications in cell pigmentation (carotenoid composition appears to change), and the cells potentially experience alterations in the architecture of the photosynthetic apparatus. Overall, our results suggest the need to generate more basic information concerning functional and regulatory rules controlling metabolism in both the light and dark if we are to understand the energetics and ecology of algae and plants, and ultimately use our understanding of basic metabolism for generating bio-products from photosynthetic organisms.

The Type I Homodimeric Reaction Center in *Heliobacterium modesticaldium*

Institution: Arizona State University
Point of Contact: Kevin Redding
Email: Kevin.Redding@asu.edu
Principal Investigator: Kevin Redding
Sr. Investigator(s): Raimund Fromme; Arizona State University
John Golbeck; Pennsylvania State University
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 3 Undergraduate(s)
Funding: \$325,000 (2014)

PROGRAM SCOPE

Our understanding of the homodimeric Type I (Fe/S-cluster) reaction centers is primitive, partly due to the difficulties of working with the anaerobic organisms that use them. In the case of the heliobacterial reaction center (HbRC), the facile conversion of the BChl g pigments to a Chl a-like molecule in the presence of O₂ necessitates that all work be done in anoxic conditions. We have found that the HbRC is very different from Photosystem I in the past funding period. In this project, our goals are to:

- (1) Investigate the properties of the F_x cluster. We have evidence that the PshBI and PshBII polypeptides serve as electron acceptors, rather than as subunits of the HbRC, implying that the F_x cluster is the biologically relevant terminal electron acceptor. We will determine the midpoint potential of F_x and we will establish if the protein makes use of the [4Fe-4S]²⁺/ [4Fe-4S]¹⁺ and/or [4Fe-4S]¹⁺/ [4Fe-4S]⁰ redox couple(s).
- (2) Study soluble electron acceptor proteins. We will determine the midpoint potentials of the FA and FB clusters in PshBI and PshBII and we will measure transcript and protein levels of PshBI and PshBII. We will also determine whether the dicluster ferredoxins HM1_0860 and MM1_2505 and the bacterial [FeFe]-hydrogenase can accept electrons directly from F_x.
- (3) Uncover the physiological role of the quinone. We will continue to seek a role for the quinone as an intermediate cofactor but we are also expanding our search to include a possible role as an alternative terminal electron acceptor.
- (4) Develop a genetic transformation system for *H. modesticaldum*. We will develop of a system to integrate DNA into the genome of *H. modesticaldum*, which would open the door for new experiments.
- (5) Solve the 3-dimensional structures of the HbRC. We will crystallize the PshA2 homodimer and determine its structure by X-ray crystallography.

FY 2014 HIGHLIGHTS

We have made advances in all of the sub-projects listed in our Scope:

- (1) We have determined the midpoint potential of the interpolypeptide F_x [4Fe-4S] cluster to be -500 mV (vs. SHE), which is much more positive than the F_x cluster in Photosystem I (PSI). Also unlike PSI, the F_x cluster appears to be the terminal acceptor, and therefore donor to all RC acceptors, since the PshB polypeptide(s) no longer appears to be a subunit.
- (2) We have determined the midpoint potentials of the [4Fe-4S] clusters in the PshBI and PshBII polypeptides to be in the -450 to -500 mV range, providing a small driving force for them to serve as acceptors. The ferredoxin encoded by the HM1_2505 gene is in the same range. We have measured transcript levels of all of the ferredoxins using next-generation sequencing, and found that PshBI and PshBII are the most highly expressed.
- (3) We have confirmed that the embedded menaquinone (MQ) does not serve as an intermediate cofactor: HbRC having or lacking MQ behave identically in ultra-fast pump-probe experiments for electron transfer from P800 (ultimate donor) to F_x. Illumination of membranes results in reduction of the pool MQ to MQH₂ when soluble electron acceptors are lacking, and that there appears to be a cycle operating between the HbRC and cytochrome bc complex. This would make the HbRC intermediate in function between PSI and the type II RCs.
- (4) We are developing a system to integrate DNA into the genome of *H. modesticaldum*. We have cloned four DNA methyltransferases associated with restriction endonucleases in the genome and constructed an artificial operon with them in *E. coli* to methylate plasmids by the heliobacterial enzyme before conjugation into *H. modesticaldum*.

- (5) We have crystallized the PshA2 homodimer in several different forms. By the end of the fiscal period, we had obtained diffraction to $\sim 5.5\text{-\AA}$ resolution, which is the best we have ever obtained. Efforts continue to improve resolution.

Revealing Excitonic Structure and Charge Transfer in Photosynthetic Proteins by Time-resolved Circular Dichroism Spectroscopy

Institution: Purdue University
Point of Contact: Sergei Savikhin
Email: sergei@purdue.edu
Principal Investigator: Sergei Savikhin
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$330,000 (2014-2015)

PROGRAM SCOPE

The goal of the project is to shed light on intrinsic properties of photosynthetic proteins that are used in nature to capture the energy of sunlight and convert it to other forms of energy such as electronic current. Prior to September 2014, the main goal of the project was to evaluate novel unconventional photoprotection mechanisms in photosynthetic pigment-protein complexes, in particular the formation of triplet excitons in closely coupled systems, and possible tuning of the electronic properties of the pigments by the protein environment. Several artificial and native systems have been studied: chlorosomes, Fenna Matthews Olson (FMO) complex and artificial aggregates of pigments. Beginning from September 2014, the project is focused on the development and application of new experimental technique - the optical time-resolved circular dichroism (TRCD) spectroscopy - and its application to investigate the energy transfer/conversion mechanisms in the Fenna Matthews Olson (FMO) light-harvesting complex and photosystem I reaction center (PS I RC). The FMO complex contains 24 closely spaced bacteriochlorophylls (BChls), which leads to strong interaction between them and results in highly delocalized optical excitations (excitons). Combining optical dichroism spectra with femtosecond and nanosecond time resolution will allow us to follow both singlet exciton energy transfer and triplet excitation transfer in real time via their CD signatures, assign the individual pigment properties and test the power and capability of the TRCD. PS I is a key photosynthetic protein complex shared by all green plants, algae and several bacteria. In the proposed research the electron transfer dynamics will be accessed directly by the unique CD signature of the RC as it contains several strongly coupled pigments.

FY 2014 HIGHLIGHTS

Four papers and a book chapter were published based on the results of this research in FY 2013. Main achievements:

- 1) Triplet state energies and lifetimes of almost all natural (bacterio)chlorophylls have been characterized by means of ultrasensitive home-built time-gated phosphorescence spectrometer and supplemented by respective quantum mechanical calculations (J. Phys. Chem. B 2014, 118:7221-7232).
- 2) Oxygen concentration within a functioning photosynthetic cell was estimated by means of diffusion theory based on experiment data. This has both evolutionary importance as well as experimental importance for future research (Biophysical J. 2014, 106, p.1882-1889).
- 3) The heterogeneity of dielectric constant in an electron transfer protein cytochrome b6f has been demonstrated and its functional importance outlined (J. Phys. Chem. B, 2014, 118: 6614-6625).

- 4) The photosystem II reaction center complex was analyzed and it was shown that most of the groups in the past worked on a damaged system that questions the validity of several conclusions on electron transfer in this important complex (Phys. Chem. B 2014)
- 5) A review chapter on charge separation complexes was published in a book (Savikhin S, Jankowiak R, 'Mechanism of Primary Charge Separation in Photosynthetic Reaction Centers', in: 'The Biophysics of Photosynthesis', Eds. John Golbeck & van der Est, 2014)/
- 6) A work started on building the TRCD spectrometer: the pump laser and other necessary equipment was ordered for the 2014-2015 project

Improved Efficiency of Energy Capture and Conversion by Regulating the Interaction Between ATP Synthesis and End Product Synthesis

Institution: Michigan State University
 Point of Contact: Thomas Sharkey
 Email: tsharkey@msu.edu
 Principal Investigator: Thomas Sharkey
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 3 Undergraduate(s)
 Funding: \$170,000 (2014)

PROGRAM SCOPE

The last step of photosynthetic carbon fixation, the first production of starch and sucrose (“end products”), can regulate the overall rate of photosynthesis. This project makes use of genetically engineered plants and variations in measurement conditions (temperature, carbon dioxide etc.) to explore the regulation of photosynthesis that results in efficient energy capture and conversion. The goal is to learn how this regulation works and to determine opportunities for improving the regulation to better adapt plants to bioenergy production. In addition, the physical separation of the two main end product pathways (starch and sucrose synthesis) can be eliminated by expressing a glucose 6-phosphate (G6P) transporter (GPT2) with an unregulated promoter.

FY 2014 HIGHLIGHTS

The GPT2 antiporter was overexpressed in *Arabidopsis* by placing the cDNA of GPT2 behind a 35S promoter. Four transgenic lines as well as an empty vector control were generated and the line with the highest expression level was carried forward for physiological experiments. When daytime light levels were constant, growth of the GPT2 overexpressing line was similar to WT or empty vector controls, although the flowering is a week to two weeks delayed. However, when the amount of light given to the plant is increased by as little as $20 \mu\text{mol m}^{-2} \text{s}^{-1}$, the transgenic plants show a large reduction in growth. The GPT2 overexpressing lines accumulate large amounts of anthocyanins within five days of the change in light level and an immediate increase in starch synthesis and degradation. The increase in starch persists in these plants so that by flowering they have four to five times the amount of starch in the leaves as the empty vector controls. The high starch amounts in the GPT2 overexpressing lines have led us to hypothesize that G6P is being imported into the chloroplast during the day. The increased G6P concentration in the chloroplast as a result of import by GPT2 could be high enough to overcome the high K_m of G6PDH for G6P. This would cause a G6P shunt around the Calvin-Benson cycle and require additional input of ATP. We found that cyclic electron transport was higher in GPT2 overexpressing plants and was increased even further in plants transferred from growth at $70 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ to $190 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ at five weeks and measured three weeks after the shift. This finding caused us

to change priorities to pursue the importance of the G6P shunt around the Calvin-Benson cycle. We were able to get preliminary evidence that it may explain a number of anomalous observations reported in the past and that the G6P shunt plays an important role in stabilizing photosynthesis, especially in fluctuating light.

Structure/Function of the Novel Proteins LCIB and LCIC in the *Chlamydomonas* CCM

Institution: Iowa State University
Point of Contact: Martin Spalding
Email: mspaldin@iastate.edu
Principal Investigator: Martin Spalding
Sr. Investigator(s): Yingjun Wang; Iowa State University
Thomas Smith; Texas Medical Branch, University of
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

LCIB, a novel protein of unknown function, is an essential component of the CO₂-concentrating mechanism (CCM) required by microalgae to grow in environments where available CO₂ is at or below air equilibration levels. Microalgae, together with cyanobacteria, are responsible for approximately half of the earth's primary photosynthetic productivity, and because of their photosynthetic CO₂ assimilation efficiency and high productivity, microalgae are a viable, solar energy driven source for conversion of CO₂ to renewable biofuel and other renewable bioproducts. We have only a limited understanding of the biological function underlying these applications, especially regarding our understanding of the functional components and detailed mechanisms comprising the microalgal CCM – an essential system for photoautotrophic growth. Identification in *Chlamydomonas reinhardtii* (*Chlamydomonas*) of essential CCM components, including LCIB, has improved our knowledge of the microalgal CCM, but significant gaps in our understanding still exist. Because LCIB is a novel, soluble chloroplast stromal protein lacking any recognizable domains or any apparent homologs outside of the “green lineage” algae (e.g., green algae and diatoms), and a small number of cyanobacteria and bacteria, the specific nature of its critical role in the CCM still is somewhat unclear. However, the observation that LCIB homologs are found in all algae with both sequenced genomes and demonstrated CCMs, argues for an important role in algal CCMs in general, as well as in enhancing microalgal CCMs to enable sustainable, efficient microalgal production of biofuels and other renewable bioproducts. Our hypothesis is that a key CCM complex, formed from LCIB and the similar protein LCIC, participates in an active CO₂ accumulation pathway that acts through vectorial hydration of CO₂ to bicarbonate to capture and concentrate external CO₂ diffusing into the cell for enhanced CO₂ assimilation in low CO₂ conditions.

FY 2014 HIGHLIGHTS

We identified two mutants of LCIC, which forms a functional complex with LCIB. They reveal that LCIB can form a functional complex in the absence of LCIC but that LCIC is required for relocalization of the LCIB/LCIC complex under very low CO₂ conditions. LCIC mutants show moderate decreases in CO₂-dependent photosynthetic O₂ evolution but grow fairly well in low CO₂ and very-low CO₂. It appears that LCIC is not essential for CCM function but may enhance CO₂ assimilation in very low CO₂ conditions. LCIB mutants have an “air-dier” phenotype; they are able to grow in either 5% CO₂ or very-low-CO₂, but cannot survive air-level CO₂. We identified a mutant defective in LCIA, a putative bicarbonate transporter, which is unable to survive in very low CO₂ when combined with an LCIB mutation. This

suggests that both LCIA and LCIB are needed for very low CO₂ survival, although neither individual mutation caused very low CO₂ growth defects. Both are essential for very low CO₂ acclimation, but LCIB and LCIA appear to function in active CO₂ uptake and bicarbonate transport, respectively. Based on these contrasting and complementary roles of LCIA and LCIB, we proposed a mechanism to explain differential regulation of the CCM based on CO₂ inhibition of bicarbonate transporters in air-level CO₂ conditions. We also used novel gene activation technology (TALEs), to selectively activate expression of the putative bicarbonate transporter, HLA3. In high-CO₂, where it is normally repressed, HLA3 overexpression modestly increased photosynthetic CO₂ assimilation only at very low CO₂ concentrations, and combined overexpression of HLA3 and LCIA caused a more significant increase in photosynthetic CO₂ assimilation, suggesting synergistic function of HLA3 and LCIA. These results are consistent with our hypothesis that bicarbonate transporters play a significant role in the CCM only when CO₂ concentrations are too low to support LCIB-facilitated CCM activity.

Role of the Rubisco Small Subunit

Institution: Nebraska, University of
Point of Contact: Robert Spreitzer
Email: rspreitzer1@unl.edu
Principal Investigator: Robert Spreitzer
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) catalyzes the rate-limiting step of photosynthesis, but it is one of the slowest enzymes. O₂ also competes with CO₂ at the enzyme's active site, and oxygenation initiates the photorespiratory pathway that leads to the release of CO₂. If carboxylation could be increased or oxygenation decreased, an increase in net CO₂ fixation would be realized. There is much interest in engineering Rubisco to increase the production of food and renewable energy. However, it is difficult to engineer plant Rubisco because the polyploid chloroplast genome encodes the active-site large subunits, and a family of nuclear genes encodes the small subunits. All of these gene copies can be eliminated in the green alga *Chlamydomonas reinhardtii*, which is the only eukaryotic model system that allows genetic engineering of both subunits. The goal of this project is to understand the structure-function relationships of the eukaryotic small subunit as a means for ultimately improving Rubisco. Analysis of the variable betaA-betaB loop by genetic selection, directed mutagenesis, and construction of chimeras, has shown that the small subunit can influence CO₂/O₂ specificity and catalytic efficiency even though the active site resides in the large subunit. X-ray crystal structures of engineered chimeric-loop enzymes indicated that additional residues and regions of the small subunit may also contribute to Rubisco function. To identify such regions, the most-conserved small-subunit residues were analyzed by alanine-scanning mutagenesis. From that work, a structural pathway was discovered between the betaA-betaB loop and alpha-helix 8 of the large-subunit active site. Hybrid enzymes have also been created comprised of plant small subunits and *Chlamydomonas* large subunits, and these enzymes have increases in CO₂/O₂ specificity, further indicating that small subunits may be the key for ultimately engineering an improved Rubisco enzyme.

FY 2014 HIGHLIGHTS

The betaA-betaB loops from each of four small subunits at the top and bottom of the holoenzyme define the opening of a solvent channel that passes through the large-subunit core. To determine whether the central solvent channel may play a role in holoenzyme function, substitutions were made at Ile-58, which defines the narrowest diameter of the channel opening. Single substitutions had little or no effect, but, when three Trp residues were introduced in place of Ile-58 (introducing 12 Trp residues from four small subunits), CO₂/O₂ specificity and holoenzyme thermal stability were decreased. These results indicated that the small-subunit betaA-betaB loop might influence large-subunit catalysis by altering the conformational change in the holoenzyme that occurs during catalysis. However, because the mutant enzyme was found to be activated normally, it might instead be possible that the channel plays a role in diffusion of CO₂ and O₂ to the Rubisco active site. In a second area of study, Ala-scanning mutagenesis of the most conserved small-subunit residues identified Y32A as the only mutant substitution outside of the betaA-betaB loop that affects CO₂/O₂ specificity. Tyr-32 shields the carboxyl-terminal end of large-subunit alpha-helix 8 from solvent. Y32A, Y32D and Y32E substitutions decrease CO₂/O₂ specificity and holoenzyme thermal stability *in vivo* and *in vitro*, but Y32F and Y32R substitutions do not. It seems likely that either a phenolic ring or positive charge complements the partial negative charge at the carboxyl-terminal end of alpha-helix 8. This interaction may influence the position or amino-terminal charge of alpha-helix 8, which, in turn, may influence interactions between amino-terminal alpha-helix-8 residues and the carboxylation transition state. These results can explain how changes far from the active site affect catalytic efficiency.

RNA Quality Control in the Chloroplast

Institution: Boyce Thompson Institute
Point of Contact: David Stern
Email: ds28@cornell.edu
Principal Investigator: David Stern
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

RNA molecules serve either as templates for protein production, or function directly in the form of RNA. These so-called non-coding RNAs may influence gene expression by binding to chromosomes, activating RNA interference pathways, binding metabolites to regulate related operons, or pairing with messenger RNAs to activate or repress their translation into proteins. Our project focuses on the chloroplast, where photosynthesis occurs, and how these various RNA populations are created and managed. Functional RNAs must have the correct length and sequence composition. For example, intron-containing RNAs cannot be translated, and long antisense RNAs can have undesirable impacts on gene expression. RNA quality control is a term that describes the mechanisms by which organisms differentiate between functional and unwanted RNAs, and dispose selectively of the latter. Our approach is to analyze chloroplast RNA populations, and the enzymes that act on them, in different fractions of the chloroplast. Our hypothesis is that the spatial separation of ribonucleases within the chloroplast underpins quality control. Thus, quality control is proposed to be exerted as an RNA progresses along a pipeline from the site of transcription to the site of gene expression. To test this, we are using high-throughput RNA sequencing (RNA-seq) which identifies quantitatively and separately sense and antisense RNAs. We are also using mutants defective in particular RNases to verify their roles in quality control.

FY 2014 HIGHLIGHTS

Our major accomplishments fall into two categories: bioinformatics and RNA analysis. In the area of bioinformatics, we have developed a customized and user-friendly pipeline to analyze next-generation sequence data for chloroplast expression. The pipeline extracts chloroplast reads, aligns them to the chloroplast genome, and allows quantitative analysis of transcript abundance. Furthermore, efficiency of intron removal (splicing) and RNA editing can be routinely evaluated. Parallel use of the pipeline on multiple datasets allows comparative RNA analysis. We have used this capability to 1) compare RNA populations in different subfractions of the chloroplast; 2) compare RNA populations in plants deficient in specific chloroplast ribonucleases with their wild-type counterparts; and 3) extract data from published datasets where chloroplast reads had been disregarded. Our most complete analysis in 2014 was of a mutant lacking a double-strand-specific ribonuclease called mini-III. No organellar ribonuclease of this type had previously been described. We discovered that chloroplast Mini-III has multiple roles including ribosomal RNA maturation, intron recycling and regulation of at least one antisense RNA. Thus, to summarize, our accomplishments are highlighted by development of a generally useable chloroplast NGS pipeline, and its application to study the metabolism of double-stranded RNA in the chloroplast.

Structure-Function Relationships of Regulator Proteins That Control Photosynthetic Carbon Dioxide Fixation in Nonsulfur Purple Bacteria

Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$70,000 (2014)

PROGRAM SCOPE

The overall objective of this project is to determine the mechanism by which a transcriptional activator protein affects CO₂ fixation (*cbb*) gene expression in nonsulfur purple photosynthetic bacteria, with special emphasis to *Rhodobacter sphaeroides* and with comparison to *Rhodospseudomonas palustris*. In *Rb. sphaeroides*, CbbR and RegA (PrrA) are transcriptional regulators of the *cbb_I* and *cbb_{II}* (Calvin-Benson-Bassham) CO₂ fixation pathway operons. We find that both proteins interact specifically with promoter sequences of the *cbb* operons, a rather unique situation for unrelated regulator proteins. RegA has four DNA binding sites within the *cbb_I* promoter region, with the CbbR binding site and RegA binding site 1 overlapping each other. Previous results showed that these transcriptional regulators interacted to form a specific RegA-CbbR complex on the DNA and we established that CbbR must first bind to the DNA at its specific binding site before RegA could interact with the CbbR-DNA complex. Over the past year, we have completed studies to define the residues in RegA that are required for specific interactions with CbbR, which is bound to the DNA. Exhaustive mutational analysis has established that RegA and CbbR interact through their DNA binding domains (DBDs). Most DBDs are connected to their “effector” domains through rigid linker helices or small linkers that prevent interactions between domains. Commonly, DBDs are either at the N-terminus or C-terminus of the protein, as is the case with CbbR and RegA, located at the N-terminus and at the C-terminus, respectively. Mutational analysis of the DBD of RegA has identified many single amino acid mutations located in the helix-turn-helix region of RegA (α -helix 7, α -helix 8 and the small turn region between the two helices) that abolish or severely

reduce the interaction with CbbR. As with the mutations in the receiver domain, a loss of interaction with CbbR is accompanied with a reduction in DNA binding.

Energetics and Mechanisms of Protein Transport and Energy Transduction in Chloroplasts

Institution: California-Davis, University of
Point of Contact: Steven Theg
Email: smtheg@ucdavis.edu
Principal Investigator: Steven Theg
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$170,001 (2014)

PROGRAM SCOPE

The long-term goal of the research in my laboratory has been to understand the mechanisms through which protein targeting is accomplished in both prokaryotic and eukaryotic cells. We have often made use of bioenergetics as a window into these processes. This necessarily includes consideration of the manner in which energy is initially transduced and converted into biologically useful forms (i.e., proton motive force and ATP). The experiments of this proposal are aimed at quantitating the energy required by chloroplast protein targeting reactions and discovering the principles through which the energy input is controlled. To this end we proposed quantitating the amount of energy utilized by two pathways the transport proteins into or across the thylakoid membranes. Our experiments also address the question of the use of localized protons for photophosphorylation and for protein transport across the thylakoid membrane.

FY 2014 HIGHLIGHTS

For the fiscal year 2014 we made the most progress on the second of the two goals for the proposal. After many unsuccessful attempts to generate stable plants in which a pH-indicating GFP protein resides in the thylakoid lumen, we moved to examining the signal from this protein delivered by *in vitro* protein targeting techniques. After import of pH indicating GFP into the thylakoid lumen, these thylakoids were subsequently used to monitor light-induced pH changes taking place in the lumen space. We found the signal from the GFP responded to the lower pH caused by light in predictable ways, and recovered its original qualities after cessation of illumination. We continue to develop this technique as a reliable indicator of light-induced pH changes in the lumen. We also completed a project in which we asked whether thylakoids can divide independently of the chloroplast division machinery. By examining thylakoid structure in well-characterized chloroplast division mutants, we have shown the thylakoids do not appear to possess their own independent division machinery.

EARLY CAREER: Residue Specific Characterization of Electrostatics, Conformational Heterogeneity, and Dynamics of Electron Transfer Proteins with Linear and Nonlinear Infrared Spectroscopy

Institution: Indiana University
Point of Contact: Megan Thielges
Email: thielges@indiana.edu
Principal Investigator: Megan Thielges
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Electron transfer reactions are central to life as they underlie the harvesting, storage, and retrieval of the energy required to sustain it. Unlike electron transfer between small molecules, biological electron transfer occurs between redox centers imbedded within proteins with environments that are structurally and electrostatically heterogeneous and undergo fluctuations on a broad range of timescales. Furthermore, inter-protein electron transfer requires protein-protein binding that is transient to maintain rapid turnover, but sufficiently specific to precisely control electron flow. Unfortunately, the rigorous characterization of biological electron transfer has proven challenging with currently available techniques as they are incapable of resolving dynamics on a sufficiently fast timescale, and/or because they are incapable of specifically probing different parts of the electron transfer complexes. This project overcomes both of these challenges by 1) employing recent advances in the techniques of linear and nonlinear infrared spectroscopy that are uniquely capable of quantifying conformational heterogeneity and fast motion in proteins, and 2) employing recent advances in protein production that allow for the incorporation of nonperturbative local probes that will enable the spectroscopic studies to report on specific parts of a protein or protein complex. This approach is applied toward delineating the nature of the physiologically central complex between plastocyanin (Pc) and cytochrome f (cyt f), two key electron transport proteins of the photosynthetic apparatus. These studies will aim to develop a picture of the electrostatics, conformational heterogeneity, and dynamics of electron transfer proteins, and how they conspire to mediate the efficient and specific electron transfer.

FY 2014 HIGHLIGHTS

The Cu redox center of Pc has been characterized through the incorporation of carbon deuterium (C-D) bonds as site-specific, frequency-resolved probes of the protein. This past year, (methyl-d₃)-methionine was incorporated as an axial ligand to the Cu center using mutagenesis and expression in labeled media. FTIR spectroscopy of the stretching frequency of the C-D bond has shown that the probe is sensitive to cyt f binding, the redox state of the Cu, substitution of Cu for Zn, and displacement of histidine Cu ligands by changing pH, despite that the Met-Cu bond is considered very weak for type I Cu centers like found in Pc. For example, significant shifts to lower frequency were observed upon reduction of Pc, which is consistent with increased σ donation of the S centered orbitals of Met to the Cu, resulting in increased electron withdraw from the C-D bond. The C-D frequency showed greater dependence on changes to the redox center in comparison to cyt f binding, but suggested that upon binding cyt f the redox environment becomes more polar and less heterogeneous. In addition, the amber codon suppression method was used to incorporate p-cyanophenylalanine (CNPhe) as a probe of the binding surface of Pc with cyt f. Three residues located along the binding interface of Pc have been successfully

substituted with CNPhe. FTIR characterization of CNPhe labeled at Tyr89, which located in the “electrostatic patch” of Pc, displayed a reduction in linewidth upon binding to cyt f, suggesting a decrease in conformational heterogeneity. In addition, the incorporation of (phenyl-3,5-d₂)-tyrosine is being employed to provide completely non-perturbative characterization of the proteins and gauge the potential perturbation induced by the CN probes. Finally, 2D-IR experiments of the CNPhe-labeled Pc have been initiated to characterize the site-specific dynamics and how they might be impacted by the redox state and/or interaction with cyt f.

Thylakoid Membrane Biogenesis in Cyanobacteria

Institution: Arizona State University
Point of Contact: Wim Vermaas
Email: wim@asu.edu
Principal Investigator: Wim Vermaas
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

We have observed that upon extended dark-incubation followed by illumination of a cyanobacterial mutant that is unable to synthesize chlorophyll in darkness, thylakoids are synthesized rapidly upon illumination. Indeed, we have been able to capture images of biosynthesis intermediates in the process that suggest that thylakoid membranes can originate from large membrane-enclosed vesicles in the cells. Moreover, we have developed and refined an *in vivo*, stable-isotope labeling method to determine whether proteins and lipids are newly synthesized or are utilized from existing pools. We now are in an excellent position to stepwise follow thylakoid membrane biogenesis and to elucidate the nature of vesicles and protein components involved. The theme of the research is thylakoid biogenesis, with as secondary theme the integration of proteins into thylakoids. The research includes (1) identification of proteins and processes involved in thylakoid membrane formation upon illumination of the *chlL*- strain that is impaired in chlorophyll biosynthesis in darkness; and (2) determination of the role of the VIPP-1 protein and chaperones that it potentially interacts with (DnaK, DnaJ and Slr1641 (ClpB1)) in thylakoid membrane biosynthesis. The research utilizes a variety of experimental approaches, including overexpression of key proteins in *Synechocystis* and its mutant strains, determination of *de novo* biosynthesis by means of *in vivo* isotope labeling, and ultrastructural (electron microscopy) studies to follow membrane biogenesis processes.

FY 2014 HIGHLIGHTS

We followed the process of chlorophyll, lipid and protein biosynthesis and recovery of thylakoids and photosynthetic function in a strain of *Synechocystis* that cannot make chlorophyll in darkness and that had been grown in virtual darkness for two weeks before being exposed to continuous light. Shortly before exposure to light, ¹³C-glucose was added to the culture, and the amount of labeled (newly synthesized) vs. unlabeled (pre-existing) chlorophyll, proteins, and lipids was determined by removing samples from the culture at regular intervals after the start of illumination, and isolating the various components. Proteins were size-fractionated on a gel, and pieces of the gel were washed and treated with trypsin. Recovered protein fragments were separated by LC-MS, and the origin of prevalent fragments was identified. About 160 different soluble and membrane proteins have been identified in our labeling experiments. PS I core proteins initially are virtually absent because of the lack of

chlorophyll, and are then synthesized rapidly. In contrast, most PS II proteins are found in darkness but are rapidly degraded in the light and then new synthesis starts. However, lipids as well as many proteins unrelated to photosynthesis remained rather unlabeled for the first 4 hours and then were labeled to the degree expected from the growth of the culture, indicating that lipids already pre-existed in dark-grown cells even though there were not many membranes yet. Our hypothesis is that large lipophilic bodies found in dark-grown cells contain lipids that are used for thylakoid membrane biosynthesis.

Structure and Assembly of Rubisco Activase

Institution: Arizona State University
Point of Contact: Rebekka Wachter
Email: rwachter@asu.edu
Principal Investigator: Rebekka Wachter
Sr. Investigator(s): Marcia Levitus; Arizona State University
Students: 1 Postdoctoral Fellow(s), 5 Graduate(s), 2 Undergraduate(s)
Funding: \$195,000 (2014)

PROGRAM SCOPE

This project addresses the regulation of carbon fixation by Rubisco activase (Rca), a chemo-mechanical motor protein essential in maintaining Rubisco activity. The goal of this work is to elucidate three-dimensional structures of higher plant Rcas and to investigate their interaction with Rubisco. Long-term, we are interested in gaining a full understanding of the mechanism of Rubisco remodeling. The extremely abundant enzyme Rubisco catalyzes the incorporation of CO₂ into simple carbohydrates, thus generating the necessary precursors for hexose biosynthesis. *In vitro*, higher plant Rubisco activity decreases with time, in large part due to the turnover-dependent production of substrate mimics that function as tight-binding competitive inhibitors. In addition, decarbamylation of a catalytic lysine residue leads to the formation of inhibitory complexes with the substrate ribulose-1,5-bisphosphate. In many photosynthetic organisms, the ATPase activity of Rca stabilizes the open form of Rubisco, so that Rubisco sites become available for CO₂ fixation. Rca belongs to a group of P-loop ATPases that tend to operate in ring-like assemblies to conformationally remodel their partner proteins. Rca activity is thought to be regulated by the ambient ATP/ADP ratio in the chloroplast stroma, and in longer isoforms, by the stromal redox poise. Therefore, Rca embodies an important biological check point responsible for maintaining Rubisco turnover under stromal conditions of high energy charge, and for keeping Rubisco inactivated under less favorable conditions.

FY 2014 HIGHLIGHTS

Accomplishments for 2014:

Rubisco subunit assembly: ATP and magnesium promote cotton Rca hexamer formation at low micromolar concentrations. We have C-terminally labeled cotton Rca with an Alexa-Fluor dye, and have developed fluorescence correlation spectroscopic (FCS) methods to determine individual binding constants for the step-wise assembly of Rca subunits. We have applied these methods to study Rca assembly as a function of adenine nucleotide composition. Results obtained for wild-type cotton Rca were confirmed by comparison to the catalytically impaired substrate-trap mutant Walker B-D173N in the presence of Mg•ATP. Our data support the stabilization of biologically relevant closed-ring hexameric forms by ATP, whereas ADP facilitates a more continuous assembly pathway such as spirals. A titration with free magnesium ions provides evidence that hexameric forms are favored at high magnesium at the expense of supramolecular aggregates. These results suggest that a second

magnesium ion binding site with an equilibrium constant of 1-3 mM promotes subunit contacts critical for formation of toroidal assemblies.

Mechanistic enzymology of tobacco Rca: ADP inhibition, cooperativity and activation. To examine the regulation of Rca activity by the available ATP and ADP pool, we have developed a continuous enzyme-coupled ATPase assay that monitors phosphate production and tolerates moderate amounts of ADP in the reaction mixture. We have measured initial velocities as a function of ATP concentration for a variety of Rca preparations, and have fit the data to a steady state turnover kinetic model. In this way, we have determined turnover numbers, Michaelis constants, Hill coefficients, product inhibition constants and magnesium binding constants.

DOE National Laboratories

Functional Models of Photosynthetic Light Harvesting Systems Templated by Self-Assembling Proteins

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Matthew Francis
Sr. Investigator(s): Naomi Ginsberg; Lawrence Berkeley National Laboratory
Phillip Geissler; Lawrence Berkeley National Laboratory
Jeffrey Neaton; Lawrence Berkeley National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$582,000 (2014)

PROGRAM SCOPE

Photosynthetic organisms rely on a series of complex light harvesting systems to absorb broad spectrum light and transfer the resulting excitations to the reaction centers. Determining the key features that enable the unparalleled energy transduction efficiencies of these systems is paramount to our ability to harness and mimic them in the context of photocatalytic materials and optical sensors. The full and detailed theoretical understanding of photosynthetic light harvesting has remained elusive, however, due to our inability to determine the individual contributions of the many functional components that must work in concert to yield higher-level function. Additionally, the effects of protein dynamics and conformational disorder on the performance of these systems are poorly understood and often overlooked. This program is thoroughly examining these aspects by combining extended electronic structure calculations with dynamical simulations that span multiple time and length scales. The predictions of these models are then being validated spectroscopically using a well-defined experimental model in which chromophore arrays can be generated with readily specified distances, orientations, and interactions with the protein environment. The models and approaches developed through this program will inform the design of new artificial systems and also suggest the features responsible for the high quantum efficiencies exhibited in natural photosynthesis. This program will also yield a highly adaptable set of synthetic scaffolds that are accompanied by an unprecedented level of theoretical understanding. This combination will allow the design of future materials that integrate multiple types of interacting components into well-defined three-dimensional frameworks.

FY 2014 HIGHLIGHTS

1. Francis has generated two protein platforms for displaying multiple chromophores with defined distance relationships. They have also developed new methods to specify the numbers of

pigments. These efforts have provided some of the first available measurements of homogeneous and systematically varied chromophore arrays, allowing protein-pigment and pigment-pigment interactions to be evaluated on a separate basis.

2. Ginsberg has performed transient absorption studies of the Francis protein assemblies, which were sparsely labeled with dye molecules on their hydrated interiors. These studies showed that the environments of the chromophores can be tailored to reduce non-radiative decay pathways substantially.
3. The effects of rigidified linking groups have been elucidated by Francis using a new synthetic strategy for chromophore attachment. These studies have validated that the chromophore geometries can be altered to improve energy transfer performance.
4. Neaton has studied the electronic structures of unique chromophore monomers and dimers designed and synthesized by the Francis lab using TDDFT. They have shown that the ideal dipole and Heitler London approximations are not sufficient to describe the coupling between neighboring chromophores.
5. Neaton has explored the state manifold near strongly absorbing excited states on chromophores for which transient absorption spectra have been collected by the Ginsberg lab. They have shown that there are significant dipole changes between ground and excited states, implying that reorganization energies, and therefore environmental influences upon de-excitation pathways, may be significant.
6. Using molecular simulations of the double-layer protein disks prepared by Francis, Geissler has examined how the dynamical environment of a bound chromophore varies with its attachment site. Extensive comparisons were made with Ginsberg's measurements of these experimental systems.

Photobiological and Photobiohybrid Solar Fuels: Photobiological Component

Institution: National Renewable Energy Laboratory
Point of Contact: Bill Tumas

Principal Investigator: Maria Ghirardi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$437,000 (2014)

PROGRAM SCOPE

Photosynthetic systems are regulated by a number of mechanisms that act at different points during the process of light transduction into chemical energy. The goal of this project is to investigate the regulation of photosynthetic reductant partitioning between H₂ evolution, biomass accumulation, and the production of other storage molecules. We are interested in the mechanism of interaction between different signal/sensors, sensors/transducers, and the complex networks between those and the expression of specific genes of interest. This project consists of two subtasks addressing, respectively, (a) regulation of photosynthetic reductant partitioning between CO₂ fixation and hydrogenases under anaerobic conditions; and (b) regulation of reductant and carbon partitioning between biomass and carbon storage molecules under N and other stresses.

FY 2014 HIGHLIGHTS

We previously showed that a cyanobacterial mutant that is unable to store carbon as glycogen upon nitrogen deprivation secretes pyruvate and alpha-ketoglutarate (AKG), instead. Production of pyruvate releases additional ATP, while production of AKG releases additional NADH. When grown under different light intensities and then transferred to nutrient-depleted medium, the ratio of secreted pyruvate/AKG varied as a function of light intensity: high light, which activates cyclic electron flow and produces more ATP, resulted in lower pyruvate/AKG; conversely, under low light, the cells secreted a higher ratio of pyruvate/AKG. These results suggest that carbon partitioning is regulated by upstream photosynthetic activity, and that this regulation is possibly mediated by a pathway that senses the ATP/NAD(P)H intracellular ratio. Efforts are under way to actually determine the rates of cyclic and linear electron transfer in the mutant, and to measure ATP and NADPH *in vivo*, in collaboration with Graham Peers, Colorado State University and Rob Burnap, Oklahoma State University.

Photobiological and Photobiohybrid Solar Fuels: Photobiohybrid Project

Institution: National Renewable Energy Laboratory
Point of Contact: Bill Tumas
Email: bill.tumas@nrel.gov
Principal Investigator: Paul King
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$873,000 (2014)

PROGRAM SCOPE

Photosynthetic light-capture and conversion efficiencies in plant-type systems are constrained at ~12.5% photon-to-fuel due to narrow spectral bandwidth, low-light saturation kinetics and thermodynamic losses during energy transduction. Complex regulatory mechanisms provide additional elements of control via coupling between photosynthetic electron transport and downstream metabolic reactions. Simplifying the complexity of photosynthetic systems is one strategy toward improving conversion efficiencies. We have been investigating how semiconducting nanomaterials that exhibit wide spectral responses and high saturation intensities can be utilized to create molecular systems for artificial photosynthesis and production of reduced fuels. To create and control the essential charge-transfer interactions between synthetic chromophores and biocatalysts requires developing a broader understanding of energy transduction processes at molecular junctions. This project integrates fundamental research on structure-function mechanisms of enzymatic H₂ activation, with steady-state and ultrafast measurements of photochemical conversion in enzyme-nanoparticle biohybrids. The knowledge will help elucidate the physical, thermodynamic and kinetic parameters that control efficiencies of light-harvesting, charge-transfer and catalysis in molecular systems for solar hydrogen production.

FY 2014 HIGHLIGHTS

The *Chlamydomonas reinhardtii* [FeFe]-hydrogenase (CrHydA1) is a naturally minimized structure with only a catalytic H-cluster and is an ideal model to investigate mechanisms of H₂ activation by this class of hydrogenases. During this period we analyzed a proton-transfer mutant of CrHydA1 by EPR and FTIR spectroscopy under catalytic conditions. The H₂ binding and activation by the H-cluster involved a diferrous 2Fe subcluster and [4Fe-4S]¹⁺ subcluster, and formation of a terminal hydride (H) species with H/D isotope-sensitive IR signals. The results also show that H-cluster redox transitions are strongly coupled to proton-transfer. Mulder, D.W.; Ratzloff, M.W.; Bruschi, M.; Greco, C.; Koonce, E.; Peters, J.W.; and, King, P.W. 2014. J. Am. Chem. Soc. DOI: 10.1021/ja508629m.

The free energies along proton-transfer (PT) pathways in [FeFe]-hydrogenase were investigated using QM/MM and umbrella sampling techniques. Key residues including a conserved H-cluster proximal Cys were identified, and the pK_a values were estimated from a thermodynamics integration method, which together were used to model the PT profiles to the H-cluster. H. Long, P.W. King, C.H. Chang. 2014. J. Phys. Chem. B. 118:890.

The [FeFe]-hydrogenase from *Clostridium acetobutylicum* (CaI) self-assembles with semi-conducting nanoparticles (NP) to form photocatalytic complexes. NP light adsorption and charge-separation leads to interfacial electron-injection into the bound CaI at a surface localized [4Fe-4S]-cluster at rates of ~10⁷ s⁻¹. Changes in NP diameter control the internal charge recombination kinetics and the free-energy of interfacial electron-transfer, and we investigated how diameter affects k_{ET} and H₂ production. Surprisingly, the electron-transfer step was minimally affected by changes in free-energy. As a result, H₂ production rates were largely controlled by competition with NP internal recombination, which are slower in larger NPs to allow for higher quantum yields of H₂.

An Integrated, Super-Resolution Characterization of Natural Photosynthesis. Operating Principles, Structure, Regulation and Repair

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Krishna Niyogi
Sr. Investigator(s): Carlos Bustamante; Lawrence Berkeley National Laboratory
Graham Fleming; Lawrence Berkeley National Laboratory
Daniel Fletcher; Lawrence Berkeley National Laboratory
Naomi Ginsberg; Lawrence Berkeley National Laboratory
Eva Nogales; Lawrence Berkeley National Laboratory
Berend Smit; Lawrence Berkeley National Laboratory
Students: 7 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$902,000 (2014)

PROGRAM SCOPE

In plants and algae, a dynamic network of photosynthetic membranes forms inside chloroplasts, responds to changing light levels and spectral composition, regulates the balance of activities of the two photosystems, and repairs and replaces critical components as they are damaged by photo-oxidation. By integrating programs in plant genetics, biophysics, advanced imaging, ultrafast spectroscopy, engineering, and computational modeling, our goal is to obtain a detailed molecular description of the organization of the thylakoid membrane, the regulation of its composition, and the membrane dynamics occurring during its biogenesis, regulation and repair. We follow protein rearrangements in

photosynthetic membranes using a range of cutting-edge imaging techniques, which are ideally suited to reveal the complex structural dynamics of the membrane at different levels of spatio-temporal resolution. The imaging approaches are integrated with parallel modeling and theoretical efforts, which will provide new insights into the fundamental biophysical mechanisms governing protein interactions and the partitioning of protein complexes in the photosynthetic membrane.

FY 2014 HIGHLIGHTS

Atomic force microscopy (AFM) was used to visualize photosystem II (PSII) supercomplexes in grana membranes from *Arabidopsis*. We developed a statistical image analysis pipeline to discriminate disordered from crystalline particles in an unbiased fashion and classify crystalline arrays according to their unit cell properties. We found evidence that interactions among light-harvesting antenna complexes are altered in the *soq1* mutant, which affects regulation of light harvesting. Using a customized AFM with integrated fluorescence imaging, we directly characterized the dynamic changes in biophysical properties of the thylakoid membrane during a state transition. The elasticity (stiffness) of the thylakoid membranes increased immediately upon PSII-specific illumination, followed by a delayed height change. Electron microscopy was used to corroborate changes in membrane-to-membrane spacing. While the change in stiffness depended primarily on the transmembrane pH gradient, the height change required both a pH gradient and STN7-dependent phosphorylation. We are developing a novel near-field optical scanning microscopy that uses a cathodoluminescent film to combine the high spatial and temporal resolution of a scanning electron microscope with the non-invasiveness of light microscopy at length scales well below the diffraction limit. Fluorescence microscopy was used to identify *Chlamydomonas* mutants with altered formation or organization of the thylakoid network. Using a coarse-grained model of transmembrane alpha helices, we showed that hydrophobic mismatch between the membrane and the protein is the dominant factor determining transmembrane helix packing and the crossing-angle distribution of transmembrane helices.

Regulation of Photosynthesis

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Krishna Niyogi
Sr. Investigator(s): Graham Fleming; Lawrence Berkeley National Laboratory
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 3 Undergraduate(s)
Funding: \$582,000 (2014)

PROGRAM SCOPE

Photosynthetic light-harvesting systems are regulated, protected against photo-oxidative damage, self-assembled into supercomplexes, and rely on a subtle balance of electronic interactions to produce a highly robust system. In this project, we apply a multidisciplinary approach that combines genetic and biochemical techniques with ultrafast spectroscopy to understand the mechanisms by which oxygenic photosynthetic organisms regulate the efficiency of light harvesting in Photosystem II. In response to fluctuations in light intensity, nonphotochemical quenching (NPQ) mechanisms that regulate photosynthetic light harvesting are induced. In algae and plants, the qE type of NPQ is turned on and off rapidly by changes in thylakoid lumen pH, whereas the slower qI type downregulates PSII during long-term light stress. Our specific aims are (1) to investigate a novel type of violaxanthin de-epoxidase (VDE) enzyme in *Chlamydomonas*, (2) to identify the structural features that make LHCSR a qE-quenching

protein instead of a light-harvesting protein, (3) to assess the roles of LHCSR (and PsbS) in other algae, (4) to gain new insight into q1 in *Arabidopsis*, and (5) to develop predictive computational models of excitation energy transfer and NPQ.

FY 2014 HIGHLIGHTS

By complementing the *Arabidopsis npq1* mutation with the NPQ1 gene of *Chlamydomonas*, we showed that the NPQ1 protein is indeed a functional VDE. Furthermore, we were able to complement both the *Chlamydomonas* and *Arabidopsis npq1* mutations with a carboxyl-terminal epitope-tagged NPQ1 protein, and cellular fractionation experiments showed that, unlike the plant-type VDE, NPQ1 is a stromal protein associated with thylakoid membranes. By site-directed mutagenesis, we identified three lumen-facing, acidic residues in LHCSR3 that are necessary for its function in qE. Mutagenesis techniques were established for the green alga *Chromochloris zofingiensis*, which has an unusually high NPQ capacity, and for the heterokont alga *Nannochloropsis oceanica*, and npq mutants of both species were isolated. We identified suppressors of the soq1 mutation in *Arabidopsis*, which encodes a thioredoxin-like protein that is involved in a novel type of antenna q1. Using an apparatus for measuring fluorescence lifetime snapshots during induction of qE, we showed that PsbS changes the amount of quenching and the rate at which quenching turns on, but it does not affect the relaxation dynamics of excited chlorophyll during quenching. In contrast, the presence of VDE, which is necessary for the accumulation of zeaxanthin, affects the excited-state chlorophyll relaxation dynamics. We extended our structure-based model of the PSII supercomplex to membranes with differing ratios of PSII to LHCII, differing spatial segregations of PSII and LHCII and differing degrees of LHCII aggregation.

Fundamental Mechanisms for Solar Energy Conversion in Photosynthesis and Photosynthetic Hybrid Systems

Institution: Argonne National Laboratory

Funding: \$856,000 (2014)

PROGRAM SCOPE

Photosynthesis serves as a paradigm for solar photochemistry energy conversion within highly-tuned and chemically complex cofactor environments provided by protein frameworks. In this program photosynthetic hybrids are developed as model systems that allow fundamental mechanisms for photosynthetic energy conversion within protein environments to be investigated with a higher precision and greater variety of cofactors than can be achieved with native photosynthetic reaction center assemblies. Multiple cofactor protein 'wires' are investigated as prototype building blocks for the design of semi-synthetic architectures for solar fuels catalysis. In these concepts, the multiple cofactor

redox proteins serve as sources/sinks for electrons in fuels catalysis in hybrid assemblies constructed with photosensitizer-catalyst dyad assemblies. This program investigates fundamental processes of photosynthetic solar energy conversion that link transient, single electron excited-state on light-harvesting molecules with proton-coupled electron transfer, water oxidation and chemical energy conversion in photosynthetic protein environments. The goal of this program is to resolve fundamental mechanisms for light-harvesting and coupling of excited-state photochemistry to proton-coupled electron transfer, water oxidation, and chemical energy conversion in photosynthesis, and to test design concepts in semi-synthetic photosynthesis using photosynthetic hybrid systems. The program advances forefront time-resolved synchrotron x-ray, optical, and electron paramagnetic resonance (EPR) approaches for the resolution of fundamental mechanisms for solar energy conversion. This program will resolve fundamental mechanisms for photosynthetic solar energy conversion and provide concepts for the design of efficient natural and artificial photosynthetic systems based on biological host-guest chemistry with sustainable atomic compositions.

FY 2014 HIGHLIGHTS

This program investigated multi-heme cytochrome c7 'molecular wires' from *Geobacter sulfurreducens* as prototype frameworks for construction of semi-synthetic reaction center mimics for solar fuels catalysis. Strategies for introducing light harvesting and catalyst cofactors were investigated using the tri-heme domain, PpcA. Molecular recognition and electrostatic surface docking were investigated from NMR chemical shift perturbation measurements using anthraquinone-2,6-disulfonate (AQDS) as an electron donor substrate. The measurements found that the region around the PpcA heme IV interacts with AQDS through the formation of a reversible electron transfer complex with a K_d of 18 mM (BBA 2014, 1837: 750). The result identified a likely physiological entry point and pathway for intramolecular electron transfer in PpcA. Companion molecular recognition studies using tetrasulfonated porphyrins as anionic photosensitizers for electrostatic docking to the cationic PpcA was investigated using fluorescence quenching, small angle X-ray scattering, and all-atom molecular dynamics simulations (Biochem. 2014, 53: 5070). The results found that tetrasubstituted charged porphyrins serve as bridging ligands nucleating dimerization of the complementarily charged PpcA with sub-millimolar disassociation constants, while extensive multimerization beyond dimers were found for cyt. c and lysozyme cationic proteins. Models of the aggregation products suggest that multimerization involves a combination of electrostatic and hydrophobic interactions and demonstrate an overlooked complexity in the design of multifunctional ligands for protein surface recognition. Multimerization that self-limits to a dimer for PpcA is consistent with an association mechanism driven by a single ligand binding site on the protein surface. Cobaloxime catalyst incorporation via histidine coordination in heme deleted sites was investigated using myoglobin as a protein model (Inorg. Chem. 2014, 53: 8071).

Energy Conversion in Photosynthesis - Mechanism of Water Oxidation and Oxygen Evolution

Institution:	Lawrence Berkeley National Laboratory
Point of Contact:	Ali Belkacem
Email:	abelkacem@lbl.gov
Principal Investigator:	Vittal Yachandra
Sr. Investigator(s):	Junko Yano; Lawrence Berkeley National Laboratory
Students:	2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$991,000 (2014)

PROGRAM SCOPE

The objective of this proposal is to understand the mechanism by which water is oxidized to dioxygen at the Mn_4CaO_5 site. We propose to develop and utilize new methodologies of X-ray spectroscopy and crystallography in our investigations of photosynthetic water oxidation. The specific questions that are our focus and of the new methods being developed are: 1) What are the geometric and electronic structural changes of the Mn_4CaO_5 cluster of the photosynthetic OEC of Photosystem II? 2) How do the protein environment and the catalytic center interact with each other to carry out the sequential events during the four-electron water oxidation reaction, under ambient conditions? 3) Application of X-ray spectroscopic techniques to artificial photosynthetic systems. The present knowledge of the water oxidation reaction was accumulated primarily by studying cryo-trapped states with crystallography and various spectroscopic techniques. The question arises whether the information can be directly translated to the reaction that occurs under ambient conditions. More importantly, how the O-O bond formation, successive water substrate binding, and a rearrangement of the OEC occur through transient states between the S_3 to S_0 states? We plan to combine SR-based X-ray techniques and XFEL techniques to tackle these questions. A substantial part of this proposal is built upon our on-going development at XFEL facilities. While a large part of the current XFEL research is on crystallography, we also focus on the development of spectroscopic techniques for a seamless understanding of overall protein dynamics and chemical changes at the catalytic site; how the protein environment modulates the site for the catalytic reaction to occur through sequential events of photo-absorption, and electron and proton transfer reactions. We note that the methods we propose here will also be applicable to artificial photosynthesis research and catalysis research in general.

FY 2014 HIGHLIGHTS

Simultaneous Femtosecond X-ray Spectroscopy and Diffraction of Photosystem II at Room Temperature: The XES/XRD of PSII in various illuminated states was collected. We collected XES from PS II for the S_3 , S_0 and one intermediate time point at 250 μs in the transition between S_3 and S_0 , showing that the data for S_3 and S_0 match with previous data measured under cryogenic conditions at synchrotron sources and confirming that PS II is advanced through its catalytic cycle with our experimental conditions. In addition the XES signal measured at 250 μs after the S_3 state formation shows that within the 250 μs after the light excitation, no Mn-reduction has yet taken place, indicating that the peroxo-bond is not formed within this interval. We also collected XRD in the S_3 , S_0 and the time point of 250 μs after S_3 . The best spots were observed up to 4 \AA and complete datasets to $\sim 4.5\text{-}5.1$ \AA were obtained for each S-state. A strong anomalous signal from Mn was observed with its maximum centered in the middle of the Mn_4Ca cluster for all of the flash/S-states measured. The Ca atom is not within this density as expected. The result was published in Nature Comm 2014 (DOI: 10.1038/ncomms5371).

Hyperthermophilic Multiprotein Complexes and Pathways for Energy Conservation and Catalysis

Institution: Georgia, University of
Point of Contact: Michael Adams
Email: adams@bmb.uga.edu
Principal Investigator: Michael Adams
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

We are investigating the properties of energy transducing systems, the processes that regulate energy-relevant chemical reactions, the architecture of biopolymers, and the active site protein chemistry leading to efficient bio-inspired catalysts. The protein complexes under study have the remarkable property of being synthesized (self-assembling) at temperatures near 100°C in hyperthermophilic microorganisms. The complexes are involved in the conversion of low potential reducing equivalents into gaseous end products with the concomitant conservation of energy in the form of ion gradients. The model microorganism is *Pyrococcus furiosus* (Pf), which grows optimally at 100°C. Pf obtains energy for growth by fermenting carbohydrates and producing hydrogen gas and by reducing elemental sulfur (S°) to hydrogen sulfide. It has a respiratory metabolism in which it couples hydrogen gas production by a membrane-bound hydrogenase (MBH) to formation of a membrane potential that Pf utilizes to synthesize ATP. Pf also contains a cytoplasmic hydrogenase (SHI) that has the rare property of evolving hydrogen from NADPH, a reaction of utility in hydrogen production systems. Addition of S° to Pf prevents the synthesis of MBH and SHI, and induces synthesis of a membrane complex termed MBX. MBX is highly similar to MBH but is proposed to reduce S° and conserve energy by an as yet unknown mechanism. The specific aims of the proposed research are to characterize SHI, MBH, MBX and related respiratory complexes. The results of this research will provide a fundamental understanding of how the production of hydrogen sulfide and hydrogen lead to energy conservation. The goals will be achieved utilizing up to 800-liter fermentations of Pf, large-scale anaerobic enzyme purifications of cytoplasmic and membrane complexes, and various biochemical, genetic, spectroscopic and structural approaches.

FY 2014 HIGHLIGHTS

We have taken advantage of the recently developed genetic system in Pf to over-express an affinity-tagged version of SHI that can be purified by a one-step procedure. The pure protein has been used in *in vitro* enzyme pathways to produce H₂ and in collaborative studies for direct electrochemical and spectroscopic (FTIR) analyses. An affinity tagged-version of MBH was solubilized and purified from Pf membranes and was biochemically characterized. In a collaborative study the structural envelope of the soluble MBH complex was determined using small-angle X-ray scattering (SAXS). An extensive phylogenetic and bioinformatic analysis of MBH and MBX revealed that they are modular in nature and represent ancestral respiratory complexes. Two hyperthermophilic membrane complexes termed formate hydrogen lyase (encoded by 18 genes) and carbon monoxide dehydrogenase (16 genes) are closely-related to MBH and contain additional formate- and carbon monoxide-oxidizing modules. The

operons encoding these two complexes were each successfully expressed in Pf and these enabled the organism to convert formate or carbon monoxide to hydrogen gas and to use carbon monoxide as a source of energy for growth. In addition, by differential expression of the 14 genes within the operon encoding Pf MBH, an affinity-tagged, catalytically-active and soluble sub-complex of the enzyme containing five proteins was purified from Pf and biochemically-characterized.

Cellulose and the Control of Growth Anisotropy

Institution: Massachusetts, University of
Point of Contact: Tobias Baskin
Email: baskin@bio.umass.edu
Principal Investigator: Tobias Baskin
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 4 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Plant cell walls are tough and strong, characteristics that give plants mechanical integrity and give humanity durable and flexible wood and fiber. Cell walls owe much of their strength to cellulose microfibrils, long crystalline polymers of glucose, with strength rivaling steel. In a growing cell, microfibril strength, alignment, and interactions with the cell wall matrix allow expansion to be controlled, a control that is exerted not only on rate but also on direction. Expansion is anisotropic, and plants must control this anisotropy precisely to build organs with specific and functional shapes, i.e., for morphogenesis. Overall, this project aims to understand how the cell aligns cellulose microfibrils and how aligned microfibrils dictate the anisotropy of growth. The project uses the emerging model plant, *Brachypodium distachyon*. The objectives are to 1) Isolate and characterize root morphology mutants in *B. distachyon*; 2) Characterize variability in *B. distachyon* accessions for root morphology and cellulose synthesis rate; 3) Use reverse-genetic approaches to study the function of *B. distachyon* genes suspected to be important in cellulose synthesis; and 4) Develop methods for scanning electron microscopy to characterize cell wall architecture. The project uses a grass, a family of plants that have long sustained humanity with their nutritious seed and might soon be sustaining us as a source of liquid fuel. Grasses have a different kind of cell wall than other angiosperms, and one whose assembly is poorly understood. Recent research on grasses applies almost exclusively to the secondary cell wall; however, primary cell walls are responsible for the growth and shape of the plant body. Focusing on the primary cell wall, the results should increase our ability to understand and hence to optimally modify plant growth.

FY 2014 HIGHLIGHTS

We continue to verify phenotypes and inheritance of various morphological mutants pulled out of the forward genetic screen in *B. distachyon* and we have confirmed the existence of a mutant that initiates and fails to elongate root hairs. We have characterized root growth in *B. distachyon* using high resolution kinematics and conducted pilot runs to determine whether this can be used in a genome-wide association study to characterize the genetic structure of growth components. We have obtained an insertional mutant in one of the *B. distachyon* genes that synthesize cellulose for the primary cell wall. Currently, we are determining whether this can be fully complemented by the wild type gene, with or without a fluorescent protein tag. We have shown that, as a reverse genetics approach, gene silencing using hairpin constructs expressed constitutively fails because effects at the callus stage are

too severe for plant regeneration. As a consequence, we have placed silencing constructs under the control of an inducible promoter and these are currently being evaluated for expression and regeneration. Finally, for our high resolution studies of cell wall structure with scanning electron microscopy, we have shown that freeze drying from tert-butanol is a useful method and we succeeded in developing a protocol to identify specific structures with immuno-gold labeling. This method will be indispensable for understanding cell wall structure above the single polymer level.

Role of HydF in Hydrogenase Maturation

Institution: Montana State University
Point of Contact: Joan Broderick
Email: jbroderick@chemistry.montana.edu
Principal Investigator: Joan Broderick
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

The goal of the project is to elucidate the biosynthetic pathway for the [FeFe]-hydrogenase active site metallocluster, the H-cluster. The potential for harnessing biological hydrogen production as an energy solution cannot be fully realized without a complete fundamental understanding of how the complex metal clusters at the active sites of hydrogenases function and are synthesized. The hydrogenase H-cluster is an unusual iron-sulfur cluster assembly which exists as a [4Fe-4S] cluster cubane bridged to a 2-Fe cluster containing multiple inorganic (CO and CN⁻) ligands as well as an exogenous bridging dithiolate ligand. Three gene products, HydE, HydF, and HydG, have been implicated in the assembly and maturation of functional hydrogenase (HydA). Based on sequence analysis, two of these proteins (HydE and HydG) belong to the radical-SAM superfamily, proteins that utilize S-adenosylmethionine and a [4Fe-4S] cluster to initiate radical chemistry. The third (HydF) is a GTPase. Thus, assembly of the complex H-cluster of hydrogenase requires unique assembly machinery that is distinct from the standard host cell machinery like the Isc proteins involved in assembly of “standard” [2Fe-2S] and [4Fe-4S] clusters. Our research implicates HydF as a scaffold upon which the two radical SAM enzymes HydE and HydG act to synthesize and insert the unique non protein ligands through the modification of a [2Fe-2S] cluster precursor. The goals of this project are to develop a molecular-level understanding of the reactions catalyzed by HydE, HydF, and HydG by exploiting our preliminary results and using the HydF scaffold as a means to capture and characterize cluster synthesis intermediates. This work will reveal fundamentally unique biochemistry and help define valuable paradigms for complex metal cluster assembly in biology.

FY 2014 HIGHLIGHTS

We have made extensive progress in understanding the mechanism of HydG, and the roles of the two iron-sulfur clusters of HydG in this mechanism, as detailed in two publications during FY2014. We have shown that the N-terminal iron-sulfur cluster alone is required for reductive cleavage of SAM and subsequent tyrosine cleavage to produce p-cresol. The C-terminal iron-sulfur cluster is required for subsequent conversion of a tyrosine-derived intermediate to cyanide and CO. We have also shown that the H-atom abstraction initiated by HydG is a reversible process, with abstraction occurring at a solvent-exchangeable site. In our studies of HydE, we have utilized biochemical and bioinformatics approaches to provide considerable insight into the catalytic reaction catalyzed by HydE; we currently have a

manuscript in revision describing these results. In our efforts to characterize the scaffold HydF, we have employed spectroscopic and biochemical techniques to provide evidence for the active oligomeric state of HydF, and to demonstrate how the iron-sulfur cluster states of HydF vary with the oligomeric state of the protein. We have also successfully expressed *Thermatoga* HydF in a thermophilic *P. furiosus* host, and have used FTIR to demonstrate that this HydF contains the CO and cyanide ligands characteristic of the “loaded” form of the HydF scaffold.

The Role of Carbonic Anhydrase in C(4) Photosynthesis

Institution: Life Sciences Research Foundation
Point of Contact: Donald Brown
Email: brown@ciwemb.edu
Principal Investigator: Donald Brown
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$57,120 (2014)

PROGRAM SCOPE

Current pressures on the global food supply have accelerated the urgency for a second green revolution using novel and sustainable approaches to increase crop yield and efficiency. This proposal outlines experiments to address fundamental questions regarding the biology of C₄ photosynthesis, the method of carbon fixation utilized by the most productive food, feed and bioenergy crops. Carbonic anhydrase (CA) has been implicated in multiple cellular functions including nitrogen metabolism, water use efficiency, and photosynthesis. CA catalyzes the first dedicated step in C₄ photosynthesis, the hydration of CO₂ into bicarbonate, and is potentially rate limiting in C₄ grasses. Using insertional mutagenesis, we have generated CA mutants in maize, and propose the characterization of these mutants using phenotypic, physiological, and transcriptomic profiling to assay the plant’s response to altered CA activity. In addition, fluorescent protein tagging experiments will be employed to study the subcellular localization of CA paralogs, providing critical data for modeling carbon fixation in C₄ plants. Finally, I propose parallel experiments in *Setaria viridis* to explore its relevance as model C₄ grass. Using a multifaceted approach, this proposal addresses important questions in basic biology, as well as the need for translation research in response to looming global food challenges.

FY 2014 HIGHLIGHTS

An evolutionary genetics approach to studying C₄ photosynthesis relies on comparisons to C₃ species. Rice and brachypodium (members of the BEP clade) are the C₃ species currently used for comparisons with C₄ panicoid grasses such as maize, sorghum, setaria, switchgrass, and sugarcane, which are important for both biofuel and food production. The most recent common ancestor of these C₃ and C₄ grasses lived ~52 million years ago. Thus, there is a need to sequence a C₃ panicoid grass, which would give comparative studies more power to detect changes related to the evolution of C₄ photosynthesis. In an effort to identify a more informative C₃ species for evolutionary comparison, I initiated a collaboration with Dr. Elizabeth Kellogg. We identified *Dichanthelium oligoanthes* as a superior C₃ grass comparator because it shared a common ancestor with maize ~26 million years ago and it has a relatively small diploid genome of ~900 Mb. In addition, it has sister taxa that have evolved all three subtypes of C₄ photosynthesis, which indicates that *D. oligoanthes* might contain intermediate mutations on the evolutionary path to C₄ photosynthesis. Research funds from this fellowship have advanced this project, and currently we have a draft genome assembly (done in collaboration with Dr. James

Schnable). The genome of *D. oligoanthes* will not only provide a better C₃ in-group for comparisons with C₄ grasses, but it also will be a resource for the grass community as another model grass species. This work has also provided a proof of concept for a JGI funded CSP grant to sequence other grass transcriptomes. JGI has also agreed to do additional sequencing to improve the assembly of *D. oligoanthes*.

Jasmonate Hormone: Regulating Synthesis of Reduced Carbon Compounds in Plants

Institution: Washington State University
Point of Contact: John Browse
Email: jab@wsu.edu
Principal Investigator: John Browse
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Our original interest in understanding the role of jasmonate (JA) in regulating the final stages of stamen and pollen development led to our discovery of the JAZ repressors, and the molecular mechanism of JA action is now a second important focus of our research. The specific goals for this grant period are to:

1. Investigate the generation and clearance of the hormone with emphasis on the regulation of the OPR3 enzyme and the hydrolysis of JA-Ile.
2. Use dominant-negative and overexpression constructs to explore the role of the MYC5 transcription factor in initiating and regulating JA responses.
3. Investigate specific JAZ protein interactions that will help us to recognize and understand the extended network of processes, such as sulfur nutrition, that interface with JA signaling.

FY 2014 HIGHLIGHTS

The COI1 F-Box protein is a JA-Ile coreceptor and *coi1* mutant plants lack JA responses. We have tested the possibility that sites of JA action can be probed by using tissue-specific promoters to drive expression of a COI1-YFP fusion protein in *coi1* mutant plants deficient in stamen and pollen function. When we expressed COI1 behind a filament-specific promoter (from the DAD1 gene), filament elongation was restored but not anther dehiscence or pollen function. Three tapetum specific promoters, all failed to restore any of these three functions but, unexpectedly, a promoter active in the stomium and epidermal cells, restored both pollen function and anther dehiscence. Most importantly, our results demonstrate the power of promoter::COI1-YFP constructs in revealing the primary sites of JA-regulated gene expression that control developmental and other responses in neighboring tissues. We now plan to use this new tool to test current hypotheses about JA action in other organs of the plant. The MYC2, MYC3, and MYC4 proteins are the primary transcription factors initiating defense and root growth responses to JA signaling. However, transgenic plants overexpressing these proteins do not show any substantial reduction in shoot growth, even though they have increased expression of many JA-responsive genes. MYC5 is closely related to MYC2, MYC3, and MYC4 but has not previously been considered a candidate in JA signaling, in part because *myc5* mutants exhibit no overt phenotype. However, when we overexpressed the MYC5 protein in wild-type *Arabidopsis* we got a surprising result. Whereas plants overexpressing MYC2 were similar in size to wild type, as observed previously, MYC5-OE plants were much smaller. This is an exciting discovery because it indicates that growth responses to JA

may be controlled by a signaling pathway that is distinct from that pathway (or pathways) controlling secondary-product synthesis and defense.

N-Acylethanolamine metabolism and the acquisition of photoautotrophy during seedling establishment

Institution: North Texas, University of
Point of Contact: Kent Chapman
Email: chapman@unt.edu
Principal Investigator: Kent Chapman
Sr. Investigator(s): Elison Blancaflor; Samuel Roberts Noble Foundation
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014-2015)

PROGRAM SCOPE

Research in our labs has led to the discovery of a new lipid mediator pathway that influences phytohormone-mediated regulation of plant growth and development—the so-called N-acylethanolamine (NAE) regulatory pathway. This pathway in plants shares conserved metabolic machinery with the endocannabinoid signaling system of vertebrates that regulates a multitude of physiological and behavioral processes in mammals, suggesting that the metabolism of NAEs is an important regulatory feature of eukaryotic biology. Current evidence in plants points to interactions between NAE metabolism, abscisic acid (ABA) signaling and light signaling to modulate seedling establishment and the acquisition of photoautotrophic growth. Our main hypothesis is that seedlings coordinate the metabolic depletion of NAEs during seedling establishment through a complex interaction of hydrolysis (by fatty acid amide hydrolase, FAAH) and oxidation (by lipoxygenases, LOX) and that oxylipin metabolites of polyunsaturated NAEs help to coordinate seedling development and acquisition of photoautotrophy in response to appropriate environmental cues. Evidence suggests that ethanolamide oxylipins derived from NAEs can reversibly accumulate in seedlings and adjust/arrest seedling establishment and chloroplast development in conjunction with ABA signaling and light-signaling pathways. Three specific aims are proposed to elucidate the molecular details of the NAE regulatory pathway and further test our hypothesis: 1) Uncover mechanisms by which NAEs control seedling establishment by mutant analysis and chemical genetics, 2) Identify molecular targets of ethanolamide oxylipins specifically derived from NAE18:3 and NAE18:2, 3) Evaluate spatial factors (tissue/ cellular) important in the regulation of seedling establishment by ethanolamide oxylipins. We anticipate that results from our proposed studies will provide important new information linking the production

FY 2014 HIGHLIGHTS

Analytical methodology was developed to allow for the identification and quantification of two important and unknown metabolite pools—the N-acylphosphatidylethanolamines (precursors of NAEs) and the oxylipin metabolites of polyunsaturated NAEs. These technological advances facilitated the discovery and description of NAE metabolism during seedling establishment with unprecedented detail. Further, they have provided a new appreciation for the bioactivity of lipoxygenase-derived NAE metabolites, and have supported a bifurcating, complex action of NAEs with some species affecting only chloroplast assembly and others regulating root elongation. Transcriptional profiling suggests the involvement of both ABA and light signaling pathways in the action of NAE oxylipins. These results were published in part in Keereetaweep *et al.*, (2013; *Plant Cell*, 25:3824-40), and featured in an “In-Brief” summary article by Nancy Hoffmann (Ethanolamide Oxylipins: New Players in Seedling Development,

Plant Cell, 2013, 25: 3637). Recent attention to acylethanolamides as important regulatory molecules in plants is evidenced by a recent review published in a special issue on small molecule signaling in the Plant Journal (Blancaflor *et al.*, 2014, 79:568-83) and featured as part of the cover art on the Aug 2014 issue.

Regulation of Carbon Allocation to Phenylpropanoid Metabolism

Institution: Purdue University
Point of Contact: Clint Chapple
Email: chapple@purdue.edu
Principal Investigator: Clint Chapple
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The goal of this project is to understand the mechanisms that plants use to determine how much photosynthate is funneled into the phenylpropanoid metabolic pathway, the most abundant product of which is the phenolic cell wall polymer lignin. Consistent with the enormous commitment of energy and carbon it requires, the synthesis of lignin is under tight regulatory control. The picture emerging from recent work is that this control is effected by a complex, hierarchically organized network of transcription factors, many of them MYB and NAC domain-containing proteins, in which proteins near the top of the regulatory cascade act to regulate the expression of other transcription factors, while those located at the most downstream points in the network regulate the transcription of the phenylpropanoid biosynthetic enzymes directly. We have determined that the transcriptional co-regulatory complex Mediator plays an important role in integrating the input from these transcription factors into a coordinated transcriptional response. In particular the Med5 subunit of the complex is required for normal phenylpropanoid homeostasis. We have identified two previously uncharacterized components of the Mediator complex, REF4 and RFR1 that negatively influences the accumulation of phenylpropanoid metabolites. To gain more insight into the biological roles of REF4 and RFR1 and the influence of phenylpropanoid metabolism on plant growth and morphology, we will (1) determine the components found in REF4- and RFR1-containing Mediator complexes, (2) identify the specific regions in the genome to which REF4- and RFR1-containing Mediator complexes are targeted, and (3) determine whether there are functional differences between REF4 and RFR1. By completing this set of experiments, we will learn how REF4 and RFR1 function to coordinate transcription of genes required for lignin deposition and gain insights into how this pathway can be manipulated for human energy needs.

FY 2014 HIGHLIGHTS

We have found that the phenotype of the lignin-deficient *Arabidopsis ref8* mutant is dependent on an intact Mediator complex. Disruption of the genes encoding the Med5 subunits in a mutant blocked early in the pathway rescues not only its growth, but also its ability to synthesize wild-type levels of lignin. Cell walls of the rescued plant contain almost exclusively p-hydroxyphenyl lignin subunits and exhibit substantially facilitated polysaccharide extraction. These results implicate Mediator in an active process that causes dwarfing and inhibition of lignin biosynthesis. RNAseq experiments using Med5 mutants and Med5-deficient *ref8* plants indicated a fairly specific role for Med5 in the regulation of phenylpropanoid metabolism and a dramatic reprogramming of transcription in *ref8* when Med5 function was eliminated,

with over 90% of the genes mis-regulated in *ref8* no longer misregulated in *med5 ref8*. We have identified mutations in other Mediator tail subunits that appear to be important for REF4 function. We have completed soluble metabolite and lignin analysis on these lines and have found that some accumulate wild-type levels of sinapoylmalate, while others accumulate less than wild-type plants. We also found that disrupting one of these Mediator genes significantly rescues the growth of the lignin-deficient *ref8* mutant described above, although not to the same degree as did disrupting Med5. These results indicate that multiple Mediator tail subunits may be involved in repression of the phenylpropanoid pathway. We have also had significant recent success in generating molecular reagents that will be required to address many of our original research goals. We have generated a high avidity anti-Med2 antibody for use in chromatin immunoprecipitation experiments and have succeeded in expressing Med2, Med3, and Med5 in the baculovirus expression system. These additional proteins will be used for antibody production and will also be put into crystallization trials.

Asparagine Synthetase Gene Regulatory Network and Plant Nitrogen Metabolism

Institution: New York University
Point of Contact: Gloria Coruzzi
Email: gloria.coruzzi@nyu.edu
Principal Investigator: Gloria Coruzzi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This project concerns the regulatory mechanisms by which plants coordinate C, N, and energy use efficiency. We focus on mechanisms that regulate the most energy-intensive biochemical pathway in plants - assimilation of inorganic nitrogen onto C-skeletons. Specifically, inorganic N initially assimilated into reactive Gln (C₅:N₂) is converted into inert Asn (C₄:N₂), a more C-efficient amino acid used for CN-storage/transport under low energy states. Using a genetic screen, we discovered a master gene encoding a histone methyltransferase (SDG8) that mediates genome-wide responses to low energy/C sensing by coordinating expression of genes involved in photosynthesis, energy generation and C/N-metabolism. We studied how changes in chromatin, transcription, and metabolite signaling mediate genome-wide responses to changes in C and energy availability.

In Aim 1, we determined how histone methylation by SDG8 affected expression of genome-wide targets using three measures: i) SDG8-target binding, ii) H3K36 trimethylation and iii) Gene expression. Remarkably, >50% of the 728 high-confidence SDG8 targets are light-regulated genes that span energy generation and energy utilization. We also uncovered conserved cis-motifs in these SDG8 targets whose associated proteins are implicated in light-regulation.

In Aim 2, we explored how epigenetic targets of SDG8 lead to changes in expression of a network of downstream genes. We showed that GLK1, a target of SDG8, is a master regulator of genes involved in energy generation and use.

In Aim 3, we validated that signaling by N metabolites is affected via histone methylation of H₃K4 residues in target genes of SDG8. Our results support a model where SDG8 specifically targets the methylation of histones associated with genes involved in energy capture, conversion and use. This is the first implication of the histone code as a mechanism that enables plants to coordinate genome-wide responses to fluctuations in energy and metabolic state.

FY 2014 HIGHLIGHTS

Aim 1: Using Gene-chip mapping and complementation, we showed that the *sdg8-5* mutant defective in C and L regulation of *ASN1* carries a complete deletion of *SDG8*, a gene encoding a H3K36 methyltransferase. We determined the genome-wide targets of *SDG8* and how this histone methylation by *SDG8* affected expression of its targets by probing the targets of *SDG8* using 3 methods: i) *SDG8*-binding, ii) H3K36 trimethylation, iii) Gene expression. Remarkably, >50% of the 728 high-confidence direct targets of *SDG8* are light-regulated genes that span energy generation and utilization. We showed that the H3K36me3 marks on histones associated with *SDG8* target genes correlate with elevated levels of mRNA expression that is disrupted in the *sdg8-5* mutant. Finally, we uncovered conserved cis-motifs in the promoters of the *SDG8* targets: G-box and FORCA motif, a light- and defense- integrator motif whose associated proteins are implicated in light-regulation.

Aim 2: We validated that *ASN1* is a target of *GLK1* using an over-expresser and a *glk1/glk2* double mutant. We also identified global targets of *GLK1* using the TARGET system. Among the 196 identified *GLK1* direct target genes, GO-terms like photosynthesis, chlorophyll binding, and light-harvesting complex are significantly over-represented, confirming and extending the reported roles for *GLK1*. A significant overlap was observed between the 196 *GLK1* targets and the 728 *SDG8* targets, indicating that the H3K36me3 histone modification of ~13% of *GLK1* targets are dependent on *SDG8*. These studies show that *GLK1* is a master regulator of genes involved in energy generation and use.

Aim 3: To study how H3K36 methylation by *SDG8* affects plant responses to N- signals we assayed the global H3K36me3 profiles by CHIP-seq of plants treated with a 5 hr inorganic N-treatment, comparing the *sdg8-5* mutant to wt. Our preliminary results indicate that the *sdg8-5* mutant shows an impaired epigenetic response to the supply of N-nutrient signals.

Molecular Mechanisms of Plant Cell Wall Loosening

Institution: Pennsylvania State University
Point of Contact: Daniel Cosgrove
Email: dcosgrove@psu.edu
Principal Investigator: Daniel Cosgrove
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$475,000 (2014-2016)

PROGRAM SCOPE

We are studying the biophysical and molecular bases of plant cell wall loosening, which is essential for plant cell growth and is connected to many plant developmental processes, to plant defense, and to new technologies for engineering plant growth and for bioconversion of cell walls into useful materials and sustainable biofuels as a substitute for fossil fuels. Our current focus is on the molecular interactions of expansin proteins with plant cell wall polymers, with the aim of understanding how expansins modify wall polymer interactions and structures in the growing cell wall, resulting in physical effects such as wall stress relaxation, polymer creep, and increase in surface area of the cell wall. This is significant for an understanding of the molecular basis of plant cell growth and for a molecular understanding of important physical properties of plant cell walls such as strength, rheology, extensibility, anisotropy, enzyme accessibility and recalcitrance to physical treatments and biochemical conversion to simpler molecules. In this project we have discovered three groups of expansins: plants have α - and β -expansins (EXPA and EXPB), and some bacteria have expansins (EXLX) as well. Expansins do not have wall lytic activity, yet they induce wall relaxation and cell wall creep. Their mechanism is enigmatic in part

because our understanding of cell wall structure is woefully incomplete. We have made use of bacterial expansins for structure/function analyses by X-ray crystallography and site-directed mutagenesis combined with binding assays, wall creep assays and dynamic mechanical analyses of cell walls. We are also pioneering the use of sensitivity-enhanced solid-state NMR to identify the target of bacterial and plant expansins (a collaboration with Dr. Mei Hong, MIT).

FY 2014 HIGHLIGHTS

1. Elucidated the mechanism of glycan binding by the expansin (BsEXLX1) from *Bacillus subtilis*. This involved solving the structure of multiple protein:ligand complexes as well as use of site-directed mutagenesis and a variety of activity assays. In the crystal the protein:ligand packs in an exceptional configuration in which two proteins bind to a single ligand, with the proteins in opposite orientation and staggered register on the opposite sides of the ligand. This work also established expansin domain 2 (the C-terminal domain) as the founding member of Carbohydrate Binding Module family 63 (CBM63 in the CaZy database). Moreover we found that BsEXLX1 binding to whole cell walls was complex: the majority of binding was relatively nonspecific binding to pectins, driven by electrostatic interactions, and was nonproductive (meaning it reduced wall loosening activity of the protein); whereas the productive binding was between a β 1,4-glucan chain and a set of three aromatic residues set in line on the surface of domain 2.
2. We characterized the molecular target of the expansin BsEXLX1 by use of sensitivity-enhanced solid-state NMR in combination with a variety of site-directed mutants and C_{13}/N_{15} labeling. This was a collaboration with Dr. Mei Hong (currently at MIT). The result shows that expansin binds to cellulose with a conformation somewhat different (less organized) than that of bulk cellulose and that xyloglucan is in close proximity.
3. Discovered that maize EXPB1 dissolves the middle lamella of growing maize coleoptiles and facilitates separation of the cuticle from the epidermal cell walls. Biochemical mechanism is uncertain.

Center for Plant and Microbial Complex Carbohydrates

Institution: Georgia, University of
Point of Contact: Alan Darvill
Email: adarvill@ccrc.uga.edu
Principal Investigator: Alan Darvill
Sr. Investigator(s): Parastoo Azadi; Georgia, University of
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$850,000 (2014)

PROGRAM SCOPE

The Complex Carbohydrate Research Center (CCRC) of the University of Georgia is a national resource for the study of complex carbohydrates. The DOE Center enables the CCRC to provide services and training to academic, government, and industrial researchers who study the complex carbohydrates of plants and microbes by providing support of experts who operate, maintain, and assist in interpreting the data obtained from a variety of scientific instrumentation. The expanding need for expertise in studies of the structure/function of complex carbohydrates is rapidly growing as the importance of carbohydrate research in areas such as biomass conversion to biofuels and biomaterials is being recognized. The DOE Center enables several types of service to be offered to researchers. Scientists who request analytical service(s) receive a written report containing a description of the analytical

procedures used, publishable quality results (data), and an authoritative interpretation of the results. Personnel also provide collaborative service by becoming involved in “in depth” research projects with individuals from other laboratories. One hallmark of the service offered is the continued addition of new technologies originally developed within the CCRC. The DOE Center also provides researchers with often hard to obtain chemical and biological samples, including monoclonal antibodies specific for plant cell wall epitopes and nucleotide sugars for biosynthetic studies. Training students and scientists in various fields of carbohydrate science is a very important part of the Center’s mission. Training occurs when undergraduates, graduate students, postdoctoral fellows, and visiting scientists undertake research projects with or take formal courses from faculty and staff. In addition, several annual one-week training courses and one- and/or two-day specialized courses are offered for individuals from academic, industrial and government institutions.

FY 2014 HIGHLIGHTS

The DOE Center of the University of Georgia is a national resource for the study of complex carbohydrates. The DOE Center provides services and training to academic, government, and industrial researchers by supporting experts who operate, maintain, and assist in interpreting the data from a variety of scientific instrumentation. The expanding need for expertise in studies of the structure/function of complex carbohydrates is rapidly growing as the importance of carbohydrate research in areas such as biomass conversion to biofuels and biomaterials is being recognized. The DOE Center provides several 'high demand' analytical services to the scientific community, including (1) purification and analysis of plant and microbial polysaccharides; (2) isolation and characterization of plant and microbial glycoproteins; (3) molecular weight determination by SEC, MALDI-MS, or ESI-MS; (4) glycosyl composition analysis; (5) glycosyl linkage analysis; (6) determination of absolute configuration; (7) structural elucidation by ESI-MS and ESI-MS/MS, MALDI-MS and LC-ESI-MS/MS; (8) 1-D and 2-D NMR; (9) lignin and tannin analysis using Py-MBMS and Py-GC-MS; (10) CarboSource Services: production of rare nucleotide-sugars, acceptors for glycoconjugate biosynthesis, and of monoclonal antibodies reactive against plant cell wall epitopes; and (11) glycome profiling. In 2014, 1174 total analyses were performed on 600 samples. Training students and scientists in glycoscience is an important part of the DOE Center’s mission. Training occurs when undergraduate and graduate students, postdoctoral fellows, and visiting scientists undertake research projects or take formal courses from faculty and staff. In addition, several annual hands-on one week or two or three day specialized courses are offered to individuals from academia, government laboratories, and private industry. In 2014, 48 individuals from academic institutions and industry participated in these specialized courses.

Mechanistic Studies of Catalysis in Quinone Electron Transfer Using High-Resolution EPR

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Sergei Dikanov
Email: dikanov@illinois.edu
Principal Investigator: Sergei Dikanov
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our goal is on use of pulsed EPR spectroscopy to explore the catalytic domains trapped in states with semiquinone (SQ) as an intermediate. The catalytic sites we propose to study– the Q_A and Q_B sites of the

reaction center, the Q_i site of the bc₁ complex, and the Q_H site of the bo₃ quinol oxidase – all operate using ubiquinone, but have different electron transfer partners and different operating potentials. EPR probes interactions between the electron spin of SQ and local magnetic nuclei, which provide direct information about spatial and electronic structure of the SQ and the immediate protein and solvent environment. The main question to be addressed is that of how the protein environment modifies the spatial and electronic structure of the SQ in different sites to fit the physiological function.

FY 2014 HIGHLIGHTS

The 2-methoxy group generates a redox potential difference between SQ_A and SQ_B. Only quinones with a 2-methoxy group can act simultaneously as the Q_A and Q_B ubiquinone (UQ) electron acceptors in photosynthetic reaction centers from *Rb. sphaeroides*. ¹³C pulsed EPR measurements of 2-methoxy in the SQ_A and SQ_B states were compared with the ¹³C hyperfine (hfi) couplings calculated as a function of dihedral angle. X-ray structures support dihedral angle assignments corresponding to a redox potential gap between Q_A and Q_B of >160 mV. This is consistent with the failure of a UQ analog lacking the 2-methoxy to function as Q_B in wild type ($\Delta E_m \approx 60-75$ mV) and mutant ($\Delta E_m \approx 160-195$ mV) reaction centers. Auxotrophic strains for specific labeling in *Rb. sphaeroides*. A methionine (Met) auxotroph of *Rb. sphaeroides* has been generated by replacing the *metA* gene in the chromosome with a *cat* gene that provides chloramphenicol resistance. ¹³C isotopic labeling of the -CH₃ and CH₃O- substituents of UQ₁₀, was achieved using this Met auxotroph in *Rb. sphaeroides* strain BC17, supplemented with [methyl ¹³C] L-methionine, with the bc₁ complex expressed from a plasmid-borne *fbc* operon. 2D ESEEM was applied to study the ¹³C CH₃ and CH₃O hfi couplings in the SQ_i generated *in situ* in the bc₁ complex. A similar protocol will be extended to generation of auxotrophic strains for other amino acids or metabolites essential in biosynthesis of prosthetic groups ¹³C tensors of the ring carbons. The anion radicals of UQ₁₀ ¹³C chemically labeled at the CH₃O-C ring positions in alcohol have been studied by 2D ESEEM to define the hfi tensors with the ¹³C nuclei. The 2D spectra allowed us to conclude that the tensors are characterized by an anisotropic component T ~ 6 MHz and an isotropic coupling a ~ -3 MHz with support from DFT calculations. The results of this work form a basis for further studies of the SQs in the protein quinone sites using ¹³C-labeling of the ring carbons.

Tuning Directionality for CO₂ Reduction in the Oxo-Acid:Ferredoxin Superfamily

Institution:	Boston University
Point of Contact:	Sean Elliott
Email:	elliott@bu.edu
Principal Investigator:	Sean Elliott
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$360,000 (2014-2015)

PROGRAM SCOPE

Developing catalytic chemistry for bioenergy production requires a detailed understanding of the molecular mechanisms of multi-electron redox processes, particularly those that transform/capture CO₂, producing molecules useful as fuel sources or chemical feedstocks. Understanding the molecular details of how multi-electron catalysis can be achieved is a major challenge in modern energy science, particularly in the context of CO₂ transformations. While synthetic chemistry addresses the design and implementation of multi-electron transformations through the generation of homogenous or heterogenous catalysts, biological systems, such as plants and microorganisms, use diverse redox-active

enzymes to achieve CO₂ capture. Such enzymes can be highly powerful catalysts; however, very little is known about their mechanisms of action, let alone how a potential reversible catalyst can be tuned to favor CO₂ reduction chemistry. Through the completion of the project, this knowledge gap will be addressed in the context of the enzymatic chemistry of the oxo-acid:ferredoxin oxidoreductase (OFOR) superfamily, which is capable of CO₂ reduction. In this project, a series of electrochemical, structural and catalytic studies will be performed in order to ascertain the molecular details (e.g., FeS cluster redox potential) that guides the bias for reactivity in the OFOR superfamily.

FY 2014 HIGHLIGHTS

In FY2014, the project was initiated in September. Dr. Philip Steindel, a recent graduate of Brandeis University, with a background in enzymology and structural biology, was hired. Preliminary bioinformatics studies of the OFOR family has revealed further diversity in the enzymes that were previously under study, and we have expanded our efforts to the enzyme from the green sulfur microorganism *Chlorobium tepidum* and the magnetotactic bacterium *Magnetococcus sp.* MM1. Major research accomplishments thus far are that we have investigated the impact of the redox mediator upon the electrocatalytic signatures of the PFOR enzyme from *D. vulgaris*, and compared that activity to the enzyme KorAB (from *Hydrogenobacter*) which is known to be reactive in the direction of CO₂ reduction. Remarkably, we have found that while PFOR does have a latent bias toward oxidative activity, and KorAB does have a preference for CO₂ reduction (in comparison), a key feature to the development of their electrocatalytic properties is the nature of the Ferredoxin intermediary. We have found that the *Hydrogenobacter* makes use of very low potential ferredoxins ($E_m < -500$ mV) to achieve CO₂ reduction chemistry, and that the same low-potential ferredoxin can enhance the CO₂ reduction activity of a PFOR enzyme that has a preference for oxidation. The complementing case has also been demonstrated now: *D. vulgaris* possesses ferredoxins that are higher in potential ($E_m \sim -400$ mV), and these redox mediators stimulate the oxidative activity of both the native *D. vulgaris* PFOR, but also KorAB itself. The implication of this finding is that it is the nature of the redox relay system, and not the active site, that will ultimately guide the bias toward CO₂ reduction.

Extracellular Charge Transport in Microbial Redox Chains: Linking the Living and Non-Living Worlds

Institution: Southern California, University of
Point of Contact: Moh El-Naggar
Email: mnaggar@usc.edu
Principal Investigator: Moh El-Naggar
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project focuses on understanding the *in vivo* assembly, biophysical charge transport mechanism, and energetic consequences of extracellular redox chains that are proposed to mediate long-range (many cell-lengths) electron transport between microbial biofilms and inorganic surfaces ranging from natural environmental minerals to engineered electrodes. To gain a physics-based understanding, the research plan is designed to achieve three specific objectives:

- 1) Test whether electron transport measurements in bacterial nanowires and individual multiheme cytochromes agree with the theoretical predictions of a multistep redox hopping mechanism.

- 2) Quantify interfacial microbe-surface electron transfer at the level of single *Shewanella oneidensis* MR-1 cells, and discover how this fundamental single-cell respiration rate is impacted by the surface redox potential and selected mutations for membrane cytochromes and bacterial nanowires.
- 3) Monitor, *in situ*, the assembly of bacterial nanowires from individual cells, thereby identifying their composition, formation mechanism, and directly measure the impact of these structures on the extracellular respiration activity of live cells.

FY 2014 HIGHLIGHTS

Significant achievements (2013-2014):

- Using *in vivo* fluorescence measurements, immunolabeling, and quantitative gene expression analysis, we found that *S. oneidensis* MR-1 nanowires are extensions of the outer membrane and periplasm that include the multiheme cytochromes responsible for electron transport, rather than pilin-based structures as previously thought. These bacterial nanowires are associated with outer membrane vesicles and vesicle chains, structures ubiquitous in gram-negative bacteria. The localization of multiheme cytochromes MtrC and OmcA to these membrane extensions directly supports one of the two intensely debated models of electron transport through the nanowires (multistep hopping). We also found, for the first time, that the production of bacterial nanowires is correlated with an increase in cellular reductase activity. Paper published in the Proceedings of the National Academy of Sciences (PNAS).
- We performed scanning tunneling microscopy, single-molecule tunneling spectroscopy, and Kinetic Monte Carlo (KMC) simulations of multistep electron hopping in the multiheme cytochrome (MtrF) from the dissimilatory metal-reducer *S. oneidensis* MR-1. These are the first KMC simulations and single molecule measurements in MtrF. Paper published in ChemElectroChem.

New Perspectives on Acetate and One-Carbon Metabolism in the Methanoarchaea: Carbonic Anhydrase

Institution: Pennsylvania State University
 Point of Contact: James Ferry
 Email: jgf3@psu.edu
 Principal Investigator: James Ferry
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
 Funding: \$70,000 (2014)

PROGRAM SCOPE

Carbonic anhydrases catalyze the reversible hydration of carbon dioxide to bicarbonate. Although widespread in prokaryotes of the domains Bacteria and Archaea, few have been investigated and the physiological functions are largely unknown. Carbonic anhydrases are of biotechnological interest for carbon dioxide capture and sequestration at point sources. Prokaryotes encode three independently evolved classes (α , β , and γ). The α -class is restricted to a few pathogens and the other two are uniformly distributed in phylogenetically and physiologically diverse species. Although wide-spread in prokaryotes, only three γ -class enzymes have been biochemically characterized and the physiological functions have not been investigated. The γ -class is prominent in anaerobic acetate-utilizing methane-producing species of the genus *Methanosarcina* that encode three subclasses. Enzymes from two of the subclasses, Cam and CamH from *Methanosarcina thermophila*, have been characterized and found to

utilize iron in the active site which is the first example of an iron-containing carbonic anhydrase. No representative of the third subclass has been isolated, although this subclass constitutes the great majority of the γ -class. This grant application proposes to characterize γ -class carbonic anhydrases from diverse anaerobic prokaryotes from the domains Bacteria and Archaea to broaden the understanding of this enzyme. In particular, the three subclasses present the genetically tractable acetate-utilizing methanogen *Methanosarcina acetivorans* will be investigated to extend studies of acetate and one-carbon metabolism in this species. A genetic approach will be taken to ascertain the physiological functions. It is also proposed to delve deeper into the mechanism of Cam from *M. thermophila*, the archetype of the γ -class, via a high resolution neutron structure and kinetic analysis of site-specific amino acid replacement variants.

FY 2014 HIGHLIGHTS

The carbonic anhydrase (Cpb) from *Clostridium perfringens* strain 13, the only carbonic anhydrase encoded in the genome, was characterized both biochemically and physiologically. Heterologously-produced and purified Cpb was shown to belong to the Type I subclass of the β class, the first β class enzyme investigated from a strictly anaerobic species of the domain Bacteria. Kinetic analyses revealed a two-step, ping-pong, zinc-hydroxide mechanism of catalysis with K_m and k_{cat}/K_m values of 3.1 mM CO₂ and $4.8 \times 10^6 \text{ s}^{-1} \text{ M}^{-1}$. Analyses of a *cpb* deletion mutant of *C. perfringens* strain HN₁₃ showed that Cpb is strictly required for growth when cultured in semi-defined medium and an atmosphere without CO₂. Growth of the mutant was the same as the parent wild-type strain when cultured in nutrient-rich media with or without CO₂ in the atmosphere, although elimination of glucose resulted in decreased production of acetate, propionate and butyrate. The results suggest a role for Cpb in anaerobic CO₂ fixation reactions by supplying bicarbonate to carboxylases.

Integration of Sugar Transport, Metabolism and Sensing in *Arabidopsis*: Optimizing Energy Efficiency in Plants - Evaluating and Targeting Leaks

Institution: Carnegie Institution of Washington
Point of Contact: Wolf Frommer
Email: wfrommer@carnegiescience.edu
Principal Investigator: Wolf Frommer
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Optimizing energy efficiency of plants: Quantitative analysis of carbon flux Crop yield and yield potential are critical for both food and feedstocks. They play key roles for feeding the planet and for the potential of biofuels to compete for oil and coal. Due to the potential for competition between each other, the yield of crops and feedstocks has to be improved in parallel. Carbon allocation is key for yield. Regulatory networks that control carbon partitioning and allocation must therefore be prime targets for optimization. Transporters control the cellular entry and release of carbohydrates in source and sink and are therefore situated in strategic positions. For efficient engineering, we need to know key players, path and bottlenecks. For this, we need quantitative spatial models using quantitative information of the sugar fluxes at the cellular and subcellular levels. To decrypt the biological circuits novel diagnostic tools are needed that, analogous to oscilloscopes in electrical engineering of circuit boards, allow quantification of fluxes, here by monitoring sugar dynamics. Such probes can provide crucial information

on systems properties. To implement impedance measurements *in vivo*, the PI's lab constructed Förster Resonance Energy Transfer sensors. Probes will be used to monitor sugar dynamics in real time. This project deploys three convergent approaches: (i) systematic analysis of SWEET function and regulation, (ii) use quantitative FRET sensor technology for identifying the cellular sugar path map, find bottlenecks, identify regulatory systems, and (iii) develop fluorescent 'transporter activity sensors' that report the activity of specific sugar transporters. These data will contribute to the development of a tissue level map and mathematical model of sugar fluxes and lay the basis for the synthetic biology to create plants with optimized carbon allocation and improved productivity.

FY 2014 HIGHLIGHTS

A bio-based economy depends critically on sufficient feedstock supplies from photosynthetic organisms. Carbon allocation in plants is therefore key to the success of such an economy, especially in the context of the competition of feedstock for food. In addition, carbon sequestration from plants can be exploited for binding atmospheric carbon dioxide. For rational engineering we need to have the knowledge of how carbon is allocated within plants and sequestered in soil. Progress in addressing the mechanistic questions of carbon allocation and sequestration can be made if suitable tools were available to monitor carbon fluxes at the subcellular level. The goal of the previous funding period was to identify novel sugar transporters and to implement fluorescent sugar sensor technology for dynamic measurements of carbon dynamics in plants. We made significant progress in both areas – we used the FRET sensors for glucose and sucrose to identify a new class of sugar transporters, the SWEETs. Key discoveries in 2014 include: (i) identification and characterization of SWEETs as hexose and sucrose transporters in model species and crops; (ii) identification of SWEETs as key players in phloem loading, seed filling, nectar secretion and pathogen susceptibility; (iii) identification of a subset of SWEETs involved in vacuolar transport of hexoses; (iv) identification of bacterial and human SWEET homologs; (v) atomic structure of two bacterial SWEET homologs; and (vi) identification of oligomeric states of SWEETs as potential means of regulating activity. This series of discoveries lays the basis for more rational approaches towards rational engineering of carbon allocation in plants and beyond.

Mechanism and Function of the Chaperonin from *Methanococcus maripaludis*: Implications for Archaeal Protein Homeostasis and Energy Production

Institution: Stanford University
Point of Contact: Judith Frydman
Email: jfrydman@stanford.edu
Principal Investigator: Judith Frydman
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Archaea offer a potentially cost effective and renewable source of energy. This proposal is focused on understanding the cellular substrates and mechanism of action of the group II chaperonin complex Mm-Cpn, the central chaperone of the methanogen *M. maripaludis*, which obtains energy by sequestering H₂ and reducing CO₂ to methane by the methanogenic pathway. More recently, it has also been suggested that the methanogenesis pathway could be run in reverse, to produce H₂ growing the organism in formate. We envision these efforts as a first step in obtaining a multi-level understanding of archaeal protein homeostasis, which will be instrumental for improving the functionality and design of the

enzyme pathways and complexes involved in energy production and storage. One additional importance consequence of a better understanding of archaeal protein homeostasis will be to increase their stress resistance, since their utilization for the efficient large-scale production of methane (and eventually also of H₂) requires that the organisms are resistance to a range of growth conditions.

FY 2014 HIGHLIGHTS

1) Establish pipeline for proteomic analyses of chaperone interactions in *M. maripaludis*. The homo-oligomeric ring shaped Mm-Cpn is the central chaperone in *M. maripaludis*. Because several enzymes in the methanogenesis pathway were substrates of the chaperonin, we decided to examine the substrate flux through the chaperonin. To this end, we established a system to grow *M. maripaludis* in the lab under conditions where we can carry out stable isotope labeling by amino acids in cell culture (SILAC) using ¹⁴N or ¹⁵N containing media that provided either H₂ or formate as electron donors for methanogenesis. Because the commercially available mass spectra deconvolution programs lack information for this organism, we are collaborating with the lab of Al Burlingame (UCSF) who has developed an in-house algorithm for the deconvolution of SILAC data.

2) Develop a new approach for identifying covariation. Statistical coupling analysis (SCA) can identify clusters of co-evolving residues within a protein family which form spatially contiguous functional networks. Coupling analyses have heretofore largely been restricted to small domains and monomeric proteins and could not be applied to large proteins with conserved domain for which few (less than one thousand) sequences are available. We have devised and implemented a novel statistical coupling metric, named Mutual Information for Statistical Coevolution (MISC), which renders analysis of very conserved, sparsely sequenced protein families. MISC constitutes an agnostic information theoretical measure which quantifies the degree of coupling between two columns in a multiple sequence alignment. Formally, it consists of the well-known variation of information which has been normalized by the joint entropy. Importantly, MISC depends very little on conservation, which is a considerable failing of many other available coupling metrics.

Structure Biology of Membrane Bound Enzymes

Institution: Johns Hopkins University
Point of Contact: Dax Fu
Email: dfu3@jhmi.edu
Principal Investigator: Dax Fu
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014-2015)

PROGRAM SCOPE

The overall goal of the proposed research is to understand the membrane-associated active processes catalyzed by an alkane ω -hydroxylase (AlkB) from eubacterium *Pseudomonas oleovorans*. AlkB performs oxygenation of unactivated hydrocarbons found in crude oils. The enzymatic reaction involves energy-demanding steps in the membrane with the uses of structurally unknown metal active sites featuring a diiron [FeFe] center. At present, a critical barrier to understanding the membrane-associated reaction mechanism is the lack of structural information. The structural biology efforts have been challenged by technical difficulties commonly encountered in crystallization and structural determination of membrane proteins. The specific aims of the current budget cycle are to crystallize AlkB and initiate X-ray analysis to set the stage for structural determination. The long-term goals of our

structural biology efforts are to provide an atomic description of AlkB structure, and to uncover the mechanisms of selective modification of hydrocarbons. The structural information will help elucidating how the unactivated C-H bonds of saturated hydrocarbons are oxidized to initiate biodegradation and biotransformation processes. The knowledge gained will be fundamental to biotechnological applications to biofuel transformation of non-edible oil feedstock. Renewable biodiesel is a promising energy carry that can be used to reduce fossil fuel dependency. The proposed research capitalizes on prior BES-supported efforts on over-expression and purification of AlkB to explore the inner workings of a bioenergy-relevant membrane-bound enzyme.

FY 2014 HIGHLIGHTS

In the first three months of BES support, we have initiated large-scale production of AlkB by heterologous expression in *E. coli* and defined conditions for AlkB solubilization, purification and stabilization.

Functional Genomics Analysis of Plant Resistance to Pathogens: Impact of the Cell Wall

Institution: Minnesota, University of
Point of Contact: Jane Glazebrook
Email: jglazebr@umn.edu
Principal Investigator: Jane Glazebrook
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Relatively little is known about the types of cell wall alterations that affect disease resistance. In this research, we will investigate the effects of cell wall changes on disease resistance using the reference plant *Arabidopsis thaliana*. Aim 1. Create multiply-mutant plant genotypes with more severe cell wall structure and disease phenotypes. By testing *Arabidopsis* mutants with altered cell walls for changes in disease susceptibility, we have already identified several changes that impact disease resistance, including changes in the amount and methylation state of pectins. Due to genetic redundancy, most mutations have modest effects on the cell wall and on disease resistance. We will combine mutations with modest effects to create genotypes with larger changes in cell wall structure and disease resistance. These multiply-mutant genotypes will provide greater power for determination of the mechanisms underlying the effects of cell wall changes on disease resistance. Aim 2. Determine the nature of perturbations in the plant defense system responsible for altered disease phenotypes in cell wall mutants. Some changes in cell wall composition affect disease resistance through alterations in the levels of plant hormones involved in regulation of defense responses. We will examine mutants with altered cell walls to determine whether canonical defense signaling responses are affected. As our earlier work implicates a role for changes in pectin methylesterification in plant defense, we will also monitor activity of pectin methylesterases during responses to pathogen attack.

FY 2014 HIGHLIGHTS

We have published a paper describing our studies showing that the activity of pectin methylesterases increases in response to pathogen attack, with concomitant decreases in pectin methylesterification in the cell wall. These changes are under control of the jasmonic acid sector of the plant immune signaling

system. Plants with mutations in multiple pectin methylesterase genes are more susceptible to pathogen attack. Gerit Bethke, G., Grundman, R.E., Sreekanta, S., Truman, W., Katagiri, F., and Glazebrook, J. *Arabidopsis* PECTIN METHYLESTERASES Contribute to Immunity Against *Pseudomonas syringae*. *Plant Physiology* 164:1093-1107. DOI: doi:10.1104/pp.113.227637 (2014). We have nearly completed a second study showing that *gae1 gae6* double mutant plants have dramatically reduced levels of pectin in the cell walls, resulting in a brittle leaf phenotype. These plants are also more susceptible to the pathogens *Botrytis cinerea* and *Pseudomonas syringae*. This susceptibility may be due to differences in generation of oligogalacturonides, signaling molecules produced from pectin, as the mutant plants respond differently to treatment with macerozyme, an enzyme that releases oligogalacturonides from pectin. The mutants are also hyper-responsive to activation of jasmonate signaling. It is likely that the reduction in pectin causes perturbation of multiple processes affecting plant immune responses. A manuscript describing this work will be submitted for publication in early 2015.

Using the Corngrass1 Gene to Enhance the Biofuel Properties of Crop Plants

Institution: U.S. Department of Agriculture
Point of Contact: Sarah Hake
Email: hake@berkeley.edu
Principal Investigator: Sarah Hake
Sr. Investigator(s): George Chuck; California-Berkeley, University of
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The development of novel plant germplasm is vital to addressing our increasing bioenergy demands. The major hurdle to digesting plant biomass is the complex structure of the cell walls, the substrate of fermentation. Plant cell walls are inaccessible matrices of macromolecules that are polymerized with lignin, making fermentation difficult. Overcoming this hurdle is a major goal toward developing usable bioenergy crop plants. Our project seeks to enhance the biofuel properties of perennial grass species using the Corngrass1 (Cg1) gene and its targets. Dominant maize Cg1 mutants produce increased biomass by continuously initiating extra axillary meristems and leaves. We cloned Cg1 and showed that its phenotype is caused by over expression of a unique miR156 microRNA gene that negatively regulates SPL transcription factors. We transferred the Cg1 phenotype to other plants by expressing the gene behind constitutive promoters in four different species, including the monocots, Brachypodium and switchgrass, and dicots, *Arabidopsis* and poplar. All transformants displayed a similar range of phenotypes, including increased biomass from extended leaf production, and increased vegetative branching. Field grown switchgrass transformants showed that overall lignin content was reduced, the ratio of glucans to xylans was increased, and surprisingly, that starch levels were greatly increased. The goals of this project are to control the tissue and temporal expression of Cg1 by using different promoters to drive its expression, elucidate the function of the SPL targets of Cg1 by generating gain and loss of function alleles, and isolate downstream targets of select SPL genes using deep sequencing and chromatin immunoprecipitation. We believe it is possible to control biomass accumulation, cell wall properties, and sugar levels through manipulation of either the Cg1 gene and/or its SPL targets.

FY 2014 HIGHLIGHTS

The separation of male and female flowers in maize provides the potential for independent regulation of traits that affect crop productivity. For example, tassel branch number controls pollen abundance and

length of shedding time, while ear row number directly affects kernel yield. Mutations in duplicate SBP-box transcription factor genes, unbranched2 (*ub2*) and unbranched3 (*ub3*), affect both of these yield traits. Double mutants display a decrease in tassel branch number and an increase in ear row number, both of which are enhanced by loss of a related gene called tasselsheath4 (*tsh4*). Furthermore, triple mutants have more tillers and leaves, phenotypes seen in Corngrass1 mutants that result from widespread repression of SBP-box genes. Immunolocalization of UB2 and UB3 proteins revealed accumulation throughout the meristem, but absence from the central domain of the meristem where cells regenerate. Thus, *ub2*, *ub3* and *tsh4* function as redundant factors that limit the rate of cell differentiation to the lateral domains of meristems. When these genes are mutated, cells are allocated to lateral primordia at a higher rate, causing a net loss of cells from the central domain and premature termination of the inflorescence. The *ub3* locus is tightly linked to QTL for ear row number and tassel branch number in both the NAM and IBM populations of maize recombinant inbreds, indicating that this gene may be agronomically important. Analysis of ear and tassel QTL across biparental families suggests that multiple mutations in *ub3* independently regulate male and female inflorescence development.

Bioenergy Production by a Photosynthetic Bacterium

Institution: Washington, University of
Point of Contact: Caroline Harwood

Principal Investigator: Caroline Harwood
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Photosynthetic organisms are ideal models for understanding the biological basis of solar energy capture and as platforms for biofuel production. The purple nonsulfur photosynthetic bacterium *Rhodospseudomonas palustris* generates ATP from light by cyclic photophosphorylation, and thus its energy-generating machinery is separate from the rest of its metabolism. It has the ability to take up energy-poor compounds from its environment, remove electrons from them and then energize the electrons with energy from light for use in catalyzing reduction reactions that are not ordinarily thermodynamically favorable. It can do this at low light intensities. These capabilities provide *R. palustris* the opportunity to produce reduced carbon compounds that may be useful as biofuels or as substitutes for common petroleum-derived chemicals. The objective of this proposal is to understand at the molecular level how *R. palustris* adjusts to low light intensities to maximize photophosphorylation by dense layers of cells. *R. palustris* encodes a complex signal transduction system that allows it to respond to low light to increase its photosynthetic efficiency. The molecular details of how this low light signal transduction system operates will be investigated.

FY 2014 HIGHLIGHTS

An analysis of 16 closely related strains of *R. palustris* revealed that most strains have five sets of light harvesting genes. These are designed LH2a, LH2b, LH2e, LH3 and LH4. Two of these gene sets, LH2a and LH4 are expressed at much higher levels under low light conditions. Under extremely low light conditions ($< 1\mu\text{E}/\text{m}^2/\text{s}$; equivalent to the amount of light coming in through the crack at the bottom of a closed closet door), the LH4 genes are required for optimal growth. However, expression of other LH complexes compensates to a certain extent for the lack of LH4. We carried out experiments that lead to

a model for regulation of LH4 gene (*pucBA*) expression via a series of signaling proteins that respond to light and redox signals. We studied in detail two bacteriophytochromes (Bph2/Bph3) that are an essential component of the LH4 signal transduction cascade. These proteins sense light quality to fine-tune LH4 expression and are part of a phosphorelay leading to LH4 gene expression. We identified a protein (Rp3018) is responsible for sensing light intensity and we have evidence that it does so by sensing light intensity as a redox signal. We determined that it has two redox sensitive cysteines.

Structure, Function and Reactivity of CO Dehydrogenase from *Oligotropha carboxidovorans*

Institution: California-Riverside, University of
Point of Contact: Charles Hille
Email: russ.hille@ucr.edu
Principal Investigator: Charles Hille
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$168,320 (2014)

PROGRAM SCOPE

All biological metabolic pathways involve the storage and utilization of energy in the form of chemical bonds, and the biological interconversion of energy-relevant one-carbon compounds such as CO and CO₂ is directly relevant to the mission of the Department of Energy. The project focuses on the reaction mechanism of the enzyme CO dehydrogenase from *Oligotropha carboxidovorans*, which catalyzes the oxidation of CO to CO₂ and whose active site consists of a unique binuclear center comprised of μ -sulfido-bridged Mo(VI) and Cu(I) ions. This enzyme catalyzes the key step in the organism's growth on CO as sole source of carbon and energy. The reaction is a critical one in the interconversion of one-carbon compounds, and the unique binuclear active site constitutes an extremely promising new avenue to pursue in the development of a new generation of inorganic catalysts.

FY 2014 HIGHLIGHTS

In the past funding cycle we have completed and published two studies, focusing on the initial CO adduct formed in the course of the reaction of enzyme with H₂. In the first, we have used ENDOR spectroscopy to establish that CO binds to the Cu(I) of the binuclear center prior to being oxidized by the Mo(VI), allowing us to develop a comprehensive reaction mechanism that will be tested in future studies. In the second, we have fully characterized the oxidation of H₂ by the enzyme and developed a reaction mechanism modeled on that for reaction with CO. We have also identified a new EPR signal arising from the Mo(V)•Cu(I) binuclear center in complex with carbonate and are exploring the catalytic relevance of this putative enzyme•product complex.

G Protein Regulation of Energy Perception, Conversion, and Storage

Institution: North Carolina, University of
Point of Contact: Alan Jones
Email: alan_jones@unc.edu
Principal Investigator: Alan Jones
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$379,949 (2014-2015)

PROGRAM SCOPE

It is well established that sugars modulate photosynthesis both directly and through transcriptional control. This proposal deals with energy (glucose) perception, conversion (photosynthesis efficiency), and storage (carbohydrate sink). A body of new evidence, much of it from the last funding cycle, indicates that photosynthesis is regulated, in part, via a signaling pathway coupled by the single heterotrimeric G protein complex in *Arabidopsis*. Within this G protein complex resides a 7-transmembrane protein, AtRGS1, which likely serves as a cell surface co-receptor for D-glucose. Biochemical and structural properties of this complex make it stand out as unusual. First, AtRGS1 contains at its cytoplasmic C terminus a Regulator of G Signaling (RGS) box which accelerates the intrinsic GTPase activity of the *Arabidopsis* α subunit (AtGPA1). Second, unlike all known α subunits, the guanine nucleotide (GTP/GDP) exchange rate for AtGPA1 is spontaneous. In the previous grant cycle, we solved the structural requisites for this unique property and created novel α subunits with controllable activation states. We showed that the rate-limiting step in cycling between the active AtGPA1 (GTP bound) and inactive AtGPA1 (GDP bound) resides at the GTP hydrolysis step, not the nucleotide exchange step and that this is controlled by D-glucose, AtRGS1, AGB1, and WNK1 and WNK8 (kinases). We hypothesize that AtGPA1 is in equilibrium between two complexes and that glucose shifts the equilibrium to permit free AGB1 to recruit WNK kinases that phosphorylate AtRGS1 leading to physical uncoupling of AtRGS1 from self-activating AtGPA1 in a dose/duration-dependent manner. We will reconstitute these molecules *in vitro* and test association partners, rate constants, and affinities over a range of glucose. We will determine the structural requisites for association and the glucose effect using NMR and 2-D x-ray crystallography.

FY 2014 HIGHLIGHTS

Critical to success is the *in vitro* production of full-length AtRGS1 protein. Purification of seven-transmembrane proteins is difficult. We tried every expression system including, *E. coli*, plant cells, yeast, insect cells and human cells without significant enrichment of AtRGS1. Therefore, we turned to a cutting-edge technique of *in vitro* translation of membrane proteins. While *in vitro* translation is not new, this technique until the last few years could not be applied to membrane proteins. With *in vitro* translation, we are now able to express full-length AtRGS1 protein to the levels we need for biochemical analyses. We are presently optimizing expression and purification. Nanodisc technology is a method to stabilize membrane proteins in lipid disks that are scaffolded by belt proteins. We are currently examining the quality of these nanodisc particles using 2-D crystallography.

EARLY CAREER: Utilization of Protein Film Electrochemistry to Characterize the Mechanisms Imparting Aerotolerance and Bidirectionality in Soluble, Multimeric [NiFe]-Hydrogenases

Institution: Arizona State University
Point of Contact: Anne Katherine Jones
Email: anne.katherine.jones@asu.edu
Principal Investigator: Anne Katherine Jones
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Enzymes catalyze a number of energetically relevant multielectron redox transformations at metallocenter active sites that feature only earth abundant, first row transition metals. Importantly, this catalysis is often fast and reversible. Hydrogenases are the biological catalysts for the two electron reduction of protons to hydrogen, and, as such, they have received widespread interest for energy-related applications and as models for multielectron biological redox catalysis. However, it is still unclear how the catalytic properties of these enzymes are controlled at the atomic level, and, in particular, how ensembles of redox active cofactors work together to control movement of multiple electrons simultaneously. The objective of this project is to characterize the mechanisms controlling (1) the direction of catalytic bias towards either hydrogen oxidation or proton reduction, (2) the rates of catalysis, and (3) the susceptibility towards oxidative inactivation of the class of hydrogenases known as soluble, group 3 [NiFe]-hydrogenases and to compare these properties to those of other hydrogenases. These goals are being achieved via electrochemical characterization of hydrogenases from diverse biological sources including especially the hyperthermophilic archaean *Pyrococcus furiosus*.

FY 2014 HIGHLIGHTS

In Fiscal Year 2014, the electrocatalytic activity of the soluble hydrogenase I from *Pyrococcus furiosus*, (PfSHI) has been characterized under a number of conditions in collaboration with Prof. Michael Adams (UGA). This showed:

- 1) The proton reduction activity is highly dependent on temperature such that the bias of the enzyme shifts to strongly favor proton reduction under physiological conditions. This shift arises primarily from an increase in proton reduction activity since H₂ oxidation activity is unchanged;
- 2) PfSHI retains nearly 100% of its proton reduction activity in the presence of 1% oxygen over the entire temperature range investigated;
- 3) aerobic, oxidative inactivation results in the formation of two states with distinct redox properties;
- 4) PfSHI retains some hydrogen oxidation activity in the presence of brief bursts of oxygen. This oxygen-tolerance is more pronounced at higher temperatures;
- 5) Hydrogen oxidation activity is also maintained during long (15 minute) exposures to oxygen, but the inactive state requires longer reduction to reactivate.

The *Rhizobial* Nitrogen Stress Response and Effective Symbiotic Nitrogen Fixation

Institution: Washington State University
Point of Contact: Michael Kahn
Email: kahn@wsu.edu
Principal Investigator: Michael Kahn
Sr. Investigator(s): Svetlana Yurgel; Dalhousie University
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$360,000 (2014-2015)

PROGRAM SCOPE

We are investigating unusual mutants of *Sinorhizobium meliloti*, a symbiotic partner of forage crops like alfalfa and sweet clover. These mutants fix dinitrogen at a normal rate (e.g. they are Fix+) but they are not effective in supporting improved plant growth on nitrogen-free media (e.g. they are Eff⁻). Others

have reported a few Fix⁺Eff⁻ mutants, but our mutants appear to have the tightest and most reproducible phenotype. Our strains have a mutation in the N-terminus of *glnD*, the major NSR sensor in the bacteria that inactivates a domain responsible for uridylylating the PII proteins in response to nitrogen stress. Unlike the situation in *E. coli*, GlnD in *S. meliloti* appears to be able to regulate aspects of cellular physiology independently of the PII proteins. The Fix⁺Eff⁻ phenotype contains a puzzle—how is it possible for the bacteroids to fix nitrogen at a normal rate without benefiting the plants? The problem is not in general nitrogen assimilation; we have shown that the fixed nitrogen leaves the nodules and that the nodulated plants can assimilate other nitrogen sources, like urea. We proposed that the bacteria were synthesizing some nitrogen-containing compound that the plant could not catabolize and export of this compound from the nodules would not relieve the plant's nitrogen stress. We have identified a candidate compound, pyruvate canaline oxime (PCO), which is abundant only in mutant nodules and are focusing on its metabolism. In addition to representing a totally unexpected metabolism in the nodules, understanding the behavior could have very useful implications. One hypothesis is that, if we can divert a limited amount of nitrogen to a compound like PCO in a way that alfalfa was not overcommitting to this synthesis, it would compensate for the sink by fixing more nitrogen to restore normal nitrogen levels, increasing the total nitrogen fixation by the plants.

FY 2014 HIGHLIGHTS

In late 2013, we purified a compound that was substantially enriched in the mutant nodules. A preliminary structure was assigned on the basis of ¹³C-¹H NMR spectroscopy of the plant compound. This was confirmed in 2014 by synthesizing PCO in two steps: first by treating commercially available canavanine, a non-protein amino acid analog of arginine common in alfalfa, with an arginase we cloned from *S. meliloti*. This generates canaline, an ornithine analog that has an aminoxy group at the end of the R moiety of the amino acid; and then by reacting canaline with pyruvate. This compound has a ¹³C-¹H NMR spectrum identical to the GlnD nodule metabolite, confirming our identification. In collaboration with an analytical laboratory at UC Davis, we have developed HPLC procedures for quantifying PCO and related metabolites, including canavanine, canaline, homoserine and other oximes and are using this information in trying to figure out what is occurring in the mutant nodules. We have also made a ¹³C version of PCO to aid in quantitation using mass spectrometry.

Ferredoxin-Dependent Plant Metabolic Pathways

Institution: Texas Tech University
Point of Contact: David Knaff
Email: david.knaff@ttu.edu
Principal Investigator: David Knaff
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$300,000 (2014-2015)

PROGRAM SCOPE

The iron-sulfur protein ferredoxin serves as the physiological donor for many enzymes that play key roles in carbon, nitrogen and sulfur metabolism in oxygen-evolving photosynthetic organisms. Ferredoxin, which is reduced by Photosystem I in a light-dependent process, also serves as the electron donor for the thioredoxin-dependent regulation of enzymes involved in many metabolic pathways and as the electron donor in a key step in the synthesis of phycobilins – pigments involved in both light-harvesting and in signaling cascades. The proposed research is designed to elucidate the mechanisms of

five enzymes that use ferredoxin as the electron donor and to discover the details of the interactions of ferredoxin with these different enzymes, all of which form protein/protein complexes with ferredoxin.

FY 2014 HIGHLIGHTS

A flash-photolysis study has provided the first data on the kinetics of electron transfer from photo-reduced ferredoxin to a cyanobacterial nitrate reductase. The data demonstrate that the first electron transferred to the enzyme resides on its Mo center and that transfer of a second electron to the enzyme's Fe-S cluster is required to complete the catalytic cycle. Site-directed mutagenesis and computer modeling have produced a model for the 1:1 complex between a cyanobacterial ferredoxin and glutamate synthase. Conclusive evidence was obtained showing that a conserved 27-amino acid loop unique to this family of enzymes is not part of the ferredoxin-binding domain. The enzyme APS reductase provides the substrate for ferredoxin-dependent sulfite reductase. We have demonstrated, using deletion and over-expression *Arabidopsis* lines that one of the chloroplast isoforms of this enzyme also plays a key role in glucose signaling and flowering timing.

Transmethylation Reaction during Methylophilic Methanogenesis in Methanogenic Archaea

Institution: Ohio State University
Point of Contact: Joseph Krzycki
Email: Krzycki.1@osu.edu
Principal Investigator: Joseph Krzycki
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

Most methane produced from biological sources comes from methanogenic Archaea. Of these organisms, *Methanosarcina spp.* and their relatives have the most diversified substrate range. Our overall goal is to understand the enzymes and molecular biology underlying these methanogenic pathways. We have primarily focused on methanogenesis from monomethylamine (MMA), dimethylamine, and trimethylamine (TMA). Methanogenesis from these substrates is begun by three methyltransferases (respectively, MtmB, MtbB, and MttB) that methylate cognate corrinoid proteins (respectively, MtmC, MtbC, and MttC), which are then used to methylate coenzyme M, forming the direct precursor of methane. The methylamine methyltransferases are non-homologous, yet each of their encoding genes contains an in-frame UAG codon. Metabolism of methylamines obligately depends on translation of an amber codon as the 22nd amino acid, pyrrolysine (Pyl). In previous periods, we have made inroads into understanding how pyrrolysine is biosynthesized, and how it is genetically encoded. Our current focus is to examine the function of pyrrolysine in the methylamine methyltransferases. Our operating hypothesis has been that this amino acid acts to bind and orient methylamines for methyl transfer to the Co(I)-corrinoid protein. Our approaches include site directed mutagenesis of Pyl-containing methyltransferases, study of naturally occurring homologs lacking Pyl, and physical methods to detect pyrrolysine interaction with methylamines.

FY 2014 HIGHLIGHTS

We published a paper in PNAS in collaboration with D. Ferguson on DSY3156, a non-Pyl MttB homolog from *Desulfitobacterium hafniense*. We showed the enzyme is a glycine:corrinoid methyltransferase

operating at unit stoichiometry. DSY3157, an adjacently encoded protein to DSY3156, is a methylcobalamin:tetrahydrofolate methyltransferase, adding further support to our hypothesis DSY3156/3157 act to methylate THF for subsequent oxidation to catabolically reduce an external electron acceptor. DSY3156 cannot use TMA, unlike methanogen Pyl MttB enzymes. In still unpublished work, we predicted residues of the glycine betaine methyltransferase that would bind glycine betaine, and replacement of these residues was found to drastically reduce catalysis. Furthermore, we collaborated with Dr. Bing Hao who crystallized the protein in complex with glycine betaine. The preliminary structure confirmed our predicted binding site. An overlay of the structures of the pyl-MttB (in collaboration with Michael Chan) and the non-Pyl glycine betaine methyltransferase reveals that pyrrolysine occupies a position overlapping the glycine betaine binding residues of DSY3156. We have now obtained purified recombinant MttC and Pyl-containing MttB by expression of the *Methanosarcina barkeri* genes in *Methanosarcina acetivorans*. Additionally, we now have stable recombinant RamA, which activates the corrinoid protein. We have assayed MttB by direct MttC methylation and found an apparent turnover rate of 200 min⁻¹. We measured the preparations of two variant MttB lacking pyrrolysine, and found they possess an approximately 1000-fold lower activity relative to wild type MttB, consistent for a catalytic role for pyrrolysine. The residual rate in the mutants lacking pyrrolysine may be due to the presence of trace amounts of wild type MttB enzyme from the *M. acetivorans* host, but if we find it is due to the mutant enzyme, this may dictate re-evaluation of the current model for pyrrolysine function.

Unraveling the Regulation of Terpenoid Oil and Resin Biosynthesis for the Development of Biocrude Feedstocks

Institution: Washington State University
Point of Contact: Bernd Lange
Email: lange-m@wsu.edu
Principal Investigator: Bernd Lange
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

This project is aimed at developing single cell approaches to investigate plant cell types that are specialized for oil and resin biosynthesis. We are currently using three experimental model systems that accumulate valuable terpenoid feedstock chemicals: (1) peppermint glandular trichomes (l-menthol), (2) Citrus secretory cavities (d-limonene), and (3) loblolly pine resin ducts (α/β -pinene and abietic acid).

Peppermint: We have been very successful in modulating the endogenous essential oil pathway of peppermint to accumulate different intermediates, in particular l-limonene, (+)-pulegone and (+)-menthofuran.

Citrus: We have completed a comprehensive study of the ultrastructural changes associated with the development of secretory cavities in Citrus peel. We have been particularly interested in understanding the role of membrane contact sites between endoplasmic reticulum and leucoplasts, as these might be characteristic of epithelial cell types with high terpenoid secretory activity. We have also localized (+)-limonene synthase, the enzyme responsible for >90% of carbon flux into terpenoids in epithelial cells of secretory cavities, to specific areas of leucoplasts.

Pine: we have acquired cell type-specific transcriptome data for epithelial cells that surround resin ducts in loblolly pine needles. These data sets provide a first glimpse of the developmental and biosynthetic factors that play important roles in the initiation and filling of resin ducts.

Enzyme structure-function: We have acquired the first comprehensive data set to map the active site of a model monoterpene synthase ((-)-limonene synthase) and evaluated residues with a potential functions to stabilize carbocation reaction intermediates and to serve as catalytic base in the hallmark deprotonation reaction of this class of enzymes.

FY 2014 HIGHLIGHTS

Terpene synthases catalyze chain length-specific, electrophilic cyclization reactions that constitute the first committed step in the biosynthesis of structurally diverse terpenoids. During the current funding period, we used crystal structural data for (4S)-LS of spearmint (*Mentha spicata* L.) to infer which amino acid residues are positioned in close proximity to the substrate and carbocation intermediates of the enzymatic reaction. Mutation of residues W324 and H579 caused a significant drop in enzyme activity and formation of products (myrcene, linalool and terpineol) characteristic of a premature termination of the reaction. A double mutant (W324A/H579A) had no detectable enzyme activity, indicating that either binding of the substrate or the terminal deprotonation reaction was impaired. Exchanges to other aromatic residues resulted in enzyme catalysts with significantly reduced activity. These results are consistent with a critical role of W324 and H579 in the stabilization of carbocation intermediates. The ultimate step of the (4S)-LS reaction cascade is the deprotonation from a carbocation and release of the olefin final product. H579 has the properties of a catalytic base and, in one energy-minimized docking orientation of the α -terpinyl cation, is positioned close to the proton to be removed. W324 is situated close to the leaving proton in an alternative docking orientation of the α -terpinyl cation. The significant reduction of specific enzyme activity in all W324 mutants could be interpreted as evidence that the termination reaction (rather than the initial isomerization) has become rate-limiting. The fact that the W324/H579 double mutant had no measurable enzyme activity is consistent with a function of these residues as catalytic bases. A manuscript reporting these findings is currently in press at PNAS.

Electron Flow and Energy Conservation in a Hydrogenotrophic Methanogen

Institution: Washington, University of
Point of Contact: John Leigh
Email: leighj@u.washington.edu
Principal Investigator: John Leigh
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our goal is to understand electron flow and energy conservation in hydrogenotrophic methanogens. Until recently it was not understood how methanogenesis from hydrogen and carbon dioxide led to the conservation of net energy sufficient for ATP production. The suggestion that electron bifurcation took place at the heterodisulfide reductase step appeared to solve the problem. Part of our effort is to show that electron bifurcation indeed takes place in hydrogenotrophic methanogens, and to learn about the electron flow pathways through the electron bifurcating protein complex. We also tested a corollary to the electron bifurcation hypothesis, that an energy-converting hydrogenase called Eha plays an anaplerotic role. We are determining the nature of the requirement for Eha and identifying the genes that are essential for its function. We are also working to determine the basis for apparent differences in efficiencies of energy conservation that occur under hydrogen-excess and hydrogen-limited conditions, manifested in changes in growth yields. Another aim is to learn more about the role of formate as an

alternative electron donor to hydrogen. Finally, we are studying the maturation of the iron hydrogenase Hmd by determining the phenotypes of mutants containing deletions of genes hypothesized to participate in Hmd cofactor synthesis.

FY 2014 HIGHLIGHTS

Recent work has focused on the proteins that deliver electrons to the electron bifurcating complex of hydrogenotrophic methanogens, represented by *Methanococcus maripaludis*. Flavin-based electron bifurcation has recently been characterized as an essential energy conservation mechanism that is utilized by hydrogenotrophic methanogenic Archaea to generate low-potential electrons in an ATP-independent manner. Electron bifurcation likely takes place at the flavin associated with the alpha subunit of heterodisulfide reductase (HdrA). In *Methanococcus maripaludis* the electrons for this reaction come from either formate or hydrogen via formate dehydrogenase (Fdh) or Hdr-associated hydrogenase (Vhu). However, how these enzymes bind to HdrA to deliver electrons was unknown. We found that the delta subunit of hydrogenase (VhuD) is central to the interaction of both enzymes with HdrA. When *M. maripaludis* was grown under conditions where both Fdh and Vhu were expressed, these enzymes competed for binding to VhuD, which in turn bound to HdrA. Under these conditions, both enzymes were fully functional and were bound to VhuD in substoichiometric quantities. We also showed that Fdh copurifies specifically with VhuD in the absence of other hydrogenase subunits. Surprisingly, in the absence of Vhu, growth on hydrogen still occurred; we showed that this involves another hydrogenase, F420-reducing hydrogenase. The data presented represent an initial characterization of specific protein interactions centered on Hdr in a hydrogenotrophic methanogen that utilizes multiple electron donors for growth.

Lignin Biopolymer Assembly and Primary Structure: A (Bio)Chemical Characterization

Institution: Washington State University
Point of Contact: Norman Lewis
Email: lewisn@wsu.edu
Principal Investigator: Norman Lewis
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

Nature's most abundant terrestrial carbon forms (plant biomass) are studied globally to maximize potential for renewable energy, optimal photosynthetic capture, and as sustainable sources of intermediate/fine chemicals and bioproducts/biofuels. This renewable carbon is largely lignified plant cell walls, and associated metabolites. A major bottleneck is in understanding cell wall polymeric lignins, Nature's second most abundant biopolymers next to cellulose. We thus still have very much to learn about plant cell wall formation and how their biomechanical properties are influenced by various lignins in different cell types/subcellular wall layers, as well as physiological roles of other biochemically related metabolites in these tissues. Our 3 interlocking objectives are to further: (i) develop cell specific metabolomic, proteomic, and transcriptomic approaches for holistic determination of distinct cell wall forming processes involved in lignin biosynthesis and related metabolism in wild type (WT) and mutant/genetically modified plant lines. We have developed methodology for much enhanced *in planta* metabolomics imaging, as well as targeted and untargeted metabolomics analyses of WT/transgenic *Arabidopsis* and poplar lines. In addition, transcriptome and proteomic analyses of these WT and

differentially lignin reduced lines have given new insights into metabolic cross-talk not previously contemplated; (ii) determine lignin primary structures/assembly mechanisms via comparison of cell-wall specific, WT and genetically modified lignins. Here, we have developed mass spectrometric fragmentation processes allowing determination of, as a model system, polystyrene primary structure and its fragmentation, with this approach now being applied to lignin primary structure and (iii) correlating lignin primary structures with biomechanical properties in distinct vascular plant cell wall types. The latter is being done with non-destructive biophysical testing methods.

FY 2014 HIGHLIGHTS

1. First 3D structure of a dirigent protein at 1.95 Å resolution and proposed implications for lignification (Kim *et al.*, J. Biol. Chem., in press).
2. MALDI imaging mass spectrometry *in situ* to enable detection, identification, localization and quantification of various metabolic classes (Marques *et al.*, Molecular BioSystems, 2014, 10:2838).
3. Putative proton relay mechanism assessment in *Arabidopsis* cinnamyl alcohol dehydrogenase catalysis AtCAD5 (Lee *et al.*, 2013, Organic Biomolecular Chemistry, 11:1127).

Chemo/Mechanical Energy Conversion via Supramolecular Self-Assembly

Institution: Emory University
Point of Contact: David Lynn

Principal Investigator: David Lynn
Sr. Investigator(s): Vince Conticello; Emory University
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$380,000 (2014-2015)

PROGRAM SCOPE

The overall goal of this fruitful collaboration between Emory University and the Argonne/Oak Ridge/Brookhaven National Laboratories has been to development methods for directing the assembly of synthetic oligopeptide structures into nano-scale objects with a degree of order approaching that observed in biological systems. We have now designed and engineered a synthetic chemical gradient along the contour length of a series of peptide-based supramolecular assemblies. Two distinct, complementary self-assembling peptide nanostructures based on cross- β -based and α -helix-based nanotubes have made those accomplishments possible. We have already demonstrated organizing antenna complexes on a peptide bilayer surface for light harvesting and energy transfer, and are now positioned to engineer and define nanoscale actuators that mirror the complex biochemical cycle of physical and chemical energy inter-conversion via a completely new supramolecular form. These achievements are fundamental to creating a simple bio-inspired self-healing supramolecular assembly capable of emulating critical components of natural chemo/mechanical energy inter-conversion.

Multifunctional Ubiquitin-fold Proteins of Archaea

Institution: Florida, University of
Point of Contact: Julie Maupin-Furlow
Email: jmaupin@ufl.edu
Principal Investigator: Julie Maupin-Furlow
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014-2015)

PROGRAM SCOPE

The overall goals of this research project are to expand the scientific knowledge of archaeal cell physiology (with emphasis on an archaeal ubiquitin-like proteasome system) and use this insight to develop next-generation biocatalysts for the production of renewable fuels and chemicals. Ubiquitin is a small protein that is universal to eukaryotic cells and is isopeptide-linked to target proteins by an E1-E2-E3-mechanism named ubiquitylation. Ubiquitylation alters the stability and cellular localization of proteins and controls important processes of interest in metabolic engineering including cell division and metabolism. Recently, we found small archaeal modifier proteins (SAMPs) to be related to ubiquitin in 3-D structure, activated by an E1-like mechanism, and isopeptide linked to protein targets. SAMPs are also used for sulfur mobilization to form molybdopterin and 2-thiolated tRNA needed for anaerobic growth and translation fidelity at high temperature. The specific aims of this project are: 1) to determine the molecular factors that regulate the switch between sulfur mobilization and protein modification for the dual function SAMPs and 2) to ascertain whether SAMPs target proteins for degradation by proteasomes and can be used to alter protein stability. Our project supports DOE missions in alternative energy, global carbon cycling, and biogeochemistry and provides fundamental insights regarding the mechanisms non-medical microbes use to transduce and/or store energy. In particular, we expand the scientific knowledge of post-translational mechanisms that are linked to energy-dependent proteolysis by proteasomes which are essential in two domains of life (Eukarya and Archaea). In addition, we advance understanding of how ubiquitin-like proteins mediate sulfur relay (particularly during growth in conditions of anoxia and high temperature) and provide insight for their use in metabolic engineering.

FY 2014 HIGHLIGHTS

We hypothesize that non-covalent protein partners are important determinants in regulating the switch between sulfur mobilization and protein modification for the archaeal ubiquitin-proteasome system (UPS). Thus, initial investigations relied upon pull-down experiments to identify protein partners using SAMP1 as bait. SAMP1 was purified from recombinant *Escherichia coli*, immobilized on beads by amide linkage, and incubated in the presence of ATP with cleared cell lysate of *Haloferax volcanii* (the model archaeon of this study). Analysis of the proteins retained by the SAMP1-decorated beads revealed a prominent protein band of 250 kDa that was detected by SYPRO Ruby staining of non-reducing SDS-PAGE gels. Subsequent analysis by LC-MS/MS of tryptic peptides derived from this band identified proteins that were unique to the samples including Cdc48-type AAA ATPase, RNase J1 and RecJ-domain protein homologs. These findings were experimentally reproducible. Similar methods identified protein factors that associated with the E1-like UbaA including SAMP1-3 and rhodanese domain (RHD) proteins. To further understand these findings, genes encoding the RHD proteins were deleted, and the mutant strains were found deficient in sulfur relay but not ubiquitin-like protein modification. Our work also provides evidence for an ancient pathway of protein degradation in Archaea that is related to the N-end rule of eukaryotes. N-degrons were found to stimulate ubiquitin-like modification and subsequent degradation of certain proteins by proteasomes. Mutant strains deficient in various components of the archaeal UPS were found to stabilize specific N-degrons. In particular, phosphorylation of N-terminal penultimate serine residues, methionine aminopeptidase cleavage, protein acetylation, and fusion to N-StreptII tags were all found to alter protein stability by mechanisms that require archaeal UPS function.

Energetics and Kinetics of Syntrophic Aromatic Degradation

Institution: Oklahoma, University of
Point of Contact: Michael McInerney
Email: mcinerney@ou.edu
Principal Investigator: Michael McInerney
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 2 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Syntrophic metabolism plays an essential role in the recycling of organic matter to methane and carbon dioxide in many environments. Syntrophy is a thermodynamically necessary interaction between a hydrogen- and formate-producing microbe and its hydrogen- and formate-using partner. A distinctive feature of syntrophic metabolism is the need for reverse electron transfer. The production of hydrogen or formate from electrons generated in the oxidation of acyl-CoA intermediates to their respective enoyl-CoA intermediates represents a considerable energy barrier. The membrane components involved in the generation and use of ion gradients are, thus, critical components of syntrophic metabolism. The objectives of this proposal are to: (1) detect the membrane complexes involved in reverse electron transfer, (2) conduct gene expression and operon analyses to determine if key gene systems are induced under growth conditions that require reverse electron transfer, thus, implicating these genes in this important biological function, (3), determine the function of a butyrate-induced, membrane complex in *Syntrophomonas wolfei* and (4) determine if *S. wolfei* and *S. aciditrophicus* have electron-bifurcating hydrogenases and formate dehydrogenases that could be used for reverse electron transfer of electrons from NADH to hydrogen or formate. We will use a combination of proteomic, gene expression, and biochemical approaches to test the role of the above systems and to detect novel complexes involved in

reverse electron transfer in syntrophic fatty and alicyclic acid metabolism. This bioenergetic study of syntrophy integrates genomic, functional genomic, and biochemical approaches to understand an essential and poorly characterized process critical for carbon cycling on the planet and will demonstrate how bacteria operate at free energy changes close to equilibrium.

FY 2014 HIGHLIGHTS

We found that *Syntrophus aciditrophicus* uses a novel mechanism for ATP from acetyl-CoA. This specialized bacterium uses pyrophosphate, an important prebiotic energy source, and the AMP-forming, acetyl-CoA synthetase (Acs1) to produce ATP. *S. aciditrophicus* uses AMP-forming, acyl-CoA synthetases to activate benzoate, cyclohexane-1-carboxylate, and crotonate to their respective coenzyme A (CoA) derivatives. The pyrophosphate formed during substrate activation can then be used by Acs1 to produce ATP, indicating the importance of pyrophosphate cycling in *S. aciditrophicus*. We used a combination of genomic, transcriptional and enzymatic analyses to determine the mechanism of interspecies electron transfer by two model syntrophic microorganisms, *Syntrophomonas wolfei* and *S. aciditrophicus*. Butyrate metabolism and methane production by washed cell suspensions of *S. wolfei* and *Methanospirillum hungatei* were inhibited by hydrogenase inhibitors (cyanide and carbon monoxide), but not by a formate dehydrogenase inhibitor (hypophosphite). Syntrophic benzoate oxidation and methane production by washed cell suspensions of *S. aciditrophicus* and *M. hungatei* were inhibited by hypophosphite, but not cyanide and carbon monoxide. All three inhibitors halted syntrophic cyclohexane-1-carboxylate metabolism. Thus, these syntrophic microorganisms have flexible metabolisms that allow them to use either hydrogen or formate transfer depending on the substrate involved. We delineated the major conduit for electron flow from butyryl-coenzyme A to hydrogen and formate in *S. wolfei*, which involves a membrane-bound, iron-sulfur oxidoreductase and a hydrogenase (Hyd2). In *S. aciditrophicus*, we showed that Rnf catalyzes the energetically unfavorable reduction of ferredoxin with NADH. Quantitative real time-polymerase chain reaction and proteomic studies provided strong evidence for the involvement of these enzyme systems in syntrophic metabolism.

Energy Conservation During Methanogenesis in *Methanosarcina* Species

Institution: Illinois-Urbana Champaign, University of
Point of Contact: William Metcalf
Email: b-metcalf@life.uiuc.edu
Principal Investigator: William Metcalf
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The long-term goal of the proposed research is to expand our knowledge regarding energy-conservation during methanogenesis in *Methanosarcina* species. A central aspect of this study entails examination of the genotypic and phenotypic differences between *Methanosarcina barkeri*, an organism that grows well on H₂/CO₂, and *Methanosarcina acetivorans*, a closely related organism that is incapable of growth on H₂/CO₂. Our recent data show that hydrogen is a central intermediate in methanogenesis from all known substrates in *M. barkeri*, whereas *M. acetivorans* has evolved to specifically exclude hydrogen as an intermediate. The differences in hydrogen metabolism lie at the center of the energy-conserving electron transport chains of the two organisms. By examining the molecular, genetic, biochemical and physiological traits that underpin these differences we expect to deepen our overall understanding of

methanogenesis, hydrogen production/consumption and energy conservation during anaerobic metabolism; all of which are central themes in the BES Physical Biosciences research program. Three specific issues regarding the mechanisms of energy conservation in *Methanosarcina* are addressed in the proposed experiments. First, we will characterize the molecular mechanism of energy conservation via hydrogen-cycling in *M. barkeri*. Second, we will characterize the hydrogen-independent, energy-conserving electron transport chain in *M. barkeri*. Third, we will characterize the hydrogen-independent, energy-conserving electron transport chain in *M. acetivorans*. The proposed experiments will utilize recently developed methods for genetic analysis of *Methanosarcina*; however, physiological, biochemical and molecular approaches will complement the genetic approach. This strategy is expected to generate data that are both novel and complementary to the results of preceding studies.

FY 2014 HIGHLIGHTS

In the past year, our work has focused on characterizing mechanism by which hydrogen is efficiently recaptured during hydrogen-cycling electron transport. Two possible mechanisms were tested. In the first, the activity of the periplasmic hydrogenase would be much higher than that of the cytoplasmic hydrogenase. To examine this idea, we conducted a thorough analysis of hydrogenase activity in a panel of mutants that lack the periplasmic Ech and Vht hydrogenases, as well as the cytoplasmic Frh hydrogenase, in all possible combinations. These data show that the H₂ production/consumption of Vht and Frh are roughly balanced, with somewhat higher levels of Vht activity. Thus, while it remains a possibility, it is not obvious whether the excess uptake of H₂ by Vht suffices to explain the phenotype. In the second mechanism, H₂ produced by cytoplasmic Frh would be channeled to the periplasmic Vht in a way that would prevent diffusive loss. We hypothesized that such channeling would require close association of the cytoplasmic and periplasmic hydrogenases, perhaps involving a membrane protein channel to facilitate efficient hydrogen transfer. To examine this, we employed high-resolution fluorescence microscopy to visualize the localization of Frh. We showed that the SNAP system worked in *M. barkeri* and that Frh appears to be localized to the inner face of the cytoplasmic membrane in support of a channeling mechanism. Global transcriptional profiling (RNA-seq analysis) of the hydrogenase mutants showed that transcription of the hydrogenase genes was not significantly altered, but the *fpo* operon was strongly induced whenever *frh* was deleted. Thus, because the branched electron transport chain diverges at Frh/Fpo, it appears that electron flux between the H₂-cycling and H₂-independent electron transport chain is at least partially controlled at the transcriptional level in a manner that requires Frh.

Regulation of Plant Cells, Cell Walls, and Development by Mechanical Signals

Institution: California Institute of Technology
Point of Contact: Elliot Meyerowitz
Email: meyerow@caltech.edu
Principal Investigator: Elliot Meyerowitz
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$230,000 (2014)

PROGRAM SCOPE

The goal of the project is to test and extend a new view of plant development, in which mechanical signals between cells in growing tissues play a role as critical as that of chemical signals. Earlier work has shown that the microtubule cytoskeleton of the epidermal cells of the meristem aligns parallel to the

principal direction of maximal stress when stress is anisotropic, and that the PIN1 auxin transporter, responsible for auxin movement between shoot meristem cells in the inflorescence stage is mechanically controlled, such that it accumulates preferentially in the most stressed side wall of each epidermal cell. As auxin makes cells expand, and this expansion creates stress on neighboring cells, there is a general tendency for auxin to move from cells with lower auxin to those with higher. This has been shown by computational models to generate known phyllotactic patterns. Computational models of growing meristems that include these mechanical feedbacks show behavior very much like that of the meristems themselves. There are nonetheless many unanswered questions. The specific research goals of the current period of funding have been to answer several of these: first, can we show that the predicted mechanical effects are due to physical forces and not other forms of cell-cell communication? Second, can we extend the model to new aspects of meristem growth, such as cell wall biosynthesis and cell division? Third, does mechanical signaling control growth in parts of the plant other than the meristem? And fourth, can we use the predicted feedbacks and computational models to further probe the mechanics and behavior of plant cells and plant cell walls? Answers to these questions will provide a more detailed understanding of the structure and dynamics of complex biological nanomaterials such as plant cell walls and cytoskeletal elements involved in energy capture, transduction, and storage.

FY 2014 HIGHLIGHTS

We have created a set of reversible treatments that change the stress patterns in a shoot apex, such as changing turgor with mannitol solutions, flattening with a coverslip, and local treatment with cell wall loosening enzymes (for example cellulases), and they all cause the predicted changes in PIN1 localization. Thus, the effects seen earlier were due to mechanics, and not wounding. We performed extensive sets of experiments with pavement cells of developing cotyledons, and found that the stress pattern in these cells with complex shapes (as predicted by finite element method models of the cells and of the tissue) correspond with their microtubule arrays, and with cell wall reinforcements detected by atomic force microscopy that are consistent with the expected properties of cellulose fibrils. As stresses in these cells are determined largely by cell shape, and vary in different cellular regions, we can add a third source of stress (tissue shape, local tissue expansion, and now cell shape) that feeds back to plant cells, and can infer that the mechanism by which the microtubules align to anisotropic stress are subcellular. Further experiments showed that stress changes induce microtubule severing, and that microtubule realignment to stress in the pavement cells requires the severing enzyme katanin. One additional prediction of the stress model is that auxin flow patterns in the meristem will depend on the properties of the cell wall, as its viscoelasticity is regulated by stress (via microtubules and cellulose synthesis). Any mutation that changes the viscoelasticity or ability to grow of the cell wall could therefore change phyllotactic pattern, as could mutations that affect PIN1 localization. We thus have a new way of probing for cell wall mutants.

Conformational and Chemical Dynamics of Single Proteins in Solution by Suppression of Brownian Motion

Institution:	Stanford University
Point of Contact:	W.E. Moerner
Email:	moerner@stanford.edu
Principal Investigator:	W.E. Moerner
Sr. Investigator(s):	
Students:	2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$658,334 (2014-2016)

PROGRAM SCOPE

The primary objective of this project is to study and understand the behavior of individual photosynthetic proteins in a physiologically relevant solution environment. Single-molecule measurements have been firmly established as a cutting-edge technique for elucidating mechanistic details of numerous biological processes. These measurements are most powerful when they are applied over a long enough time to watch a process undergo multiple, statistically meaningful state transitions. Unfortunately, the immobilization of single biomolecules on surfaces that usually enables this long time window is often undesirably perturbative. To address this issue, we have constructed a microfluidic device, the Anti-Brownian ELectrokinetic (ABEL) trap, which uses microscopy and real-time feedback forces to cancel Brownian motion and trap a molecule in solution. Previously, we enhanced the performance of the trap to simultaneously measure fluorescence intensity, lifetime and spectrum for single fluorescent dyes. Because of these capabilities, the ABEL trap is particularly powerful in the study of the photodynamics of single photosynthetic pigment-protein complexes. For example, we discovered state-to-state transitions in the bacterial light-harvesting complex 2 (LH2) from purple bacteria which show that LH2 undergoes a photoactivated, reversible switch to a quenched conformation, providing a previously unknown photoprotective functionality. We are now addressing the critically important light-harvesting complex II (LHCII), the primary antenna from green plants, and other pigment-protein complexes. We are also developing and utilizing a dramatic new capability of the ABEL trap: the direct measurement of the transport properties of the trapped biomolecule in real-time, thus giving us access to the molecular size and charge. This capability is being used to sense protein-protein interactions, aggregation, and oligomerization.

FY 2014 HIGHLIGHTS

This project has yielded two significant accomplishments in the current fiscal year. In the first area, the ability of the ABEL trap to sense size and charge has been used to perform several unprecedented measurements of (a) the time-dependent hybridization and melting of an individual DNA molecule under equilibrium conditions, and (b) the dissociation and oligomerization state of single allophycocyanin (APC) pigment-protein complexes. The work paves the way toward multiple future studies of multi-component protein assemblies where it will be possible to directly measure the distribution and size of oligomers of biomolecules in a complex mixture. In the course of these explorations, the photoinduced pigment decay process in monomeric APC was fully determined. The second area addresses the known fact that higher plants and algae quench excess energy under high light, but the photophysical mechanisms behind this process are controversial. ABEL trap measurements of single LHCII complexes found an unusual array of transitions between states of different emission brightness and excited state lifetimes, which differ in several respects from more conventional measurements on surface-attached molecules. Extensive data acquisition and analysis led to the identification of three functional states, where one is an unquenched state and two are quenched states. The characterization of these newly-discovered states and measurements of the dynamics between them were performed. Simulation of conditions that mimic high light were achieved with pH changes and mutations of the pigment compositions. These experiments showed that, under the simulated high light conditions, the relative population of one of the quenched conformations increases, pointing to a possible molecular basis for quenching. To stimulate understanding, a theoretical model was developed to describe the microscopic mechanism behind the quenched states.

The Structure of Pectins

Institution: Oklahoma State University
Point of Contact: Andrew Mort
Email: andrew.mort@okstate.edu
Principal Investigator: Andrew Mort
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Pectin is the most abundant polysaccharide in primary plant cell walls of dicots and has a very complex structure. The function of pectin in cell walls is not well understood, but modifications of the structure occur naturally during plant development and some mutations leading to modifications in structure have severe phenotypes. Pectin is composed of four structurally distinct regions each of which has its own complexity and may or may not be linked to each other. About half of the xyloglucan in cell walls is covalently linked to pectin and there is fairly strong evidence that the cell wall protein extensin is also covalently linked to pectin. It is our expectation that the primary plant cell wall is a covalently crosslinked network of polysaccharides (and sometimes protein) analogous to the bacterial peptidoglycan network and the glucan-mannoprotein-chitin network in yeast. One goal of the project is to characterize the linkages between the various regions of pectin and between pectin and the other polymers. To find the crosslinkages we will use cloned (monospecific) enzymes to degrade the polymers and separate out fragments which retain characteristics of two different polymers. These will then be characterized by NMR and mass spectroscopy. We have isolated and characterized oligosaccharides representing the crosslinkages between homogalacturonan and rhamnogalacturonan (RG) and between galactans and arabinans and RG during the previous grant period. It remains to be determined how xylogalacturonan and rhamnogalacturonan are linked together. We have also found that xyloglucan and RG are crosslinked via a highly branched 1-5 linked arabinan. We plan to characterize the connections between the arabinan and the xyloglucan and between the arabinan and the RG using the same fragmentation, separation, and characterization approach mentioned above.

FY 2014 HIGHLIGHTS

Xiaoyu Qiao, the graduate student, repeated our experiments on showing the linkage between xyloglucan and pectin in *Arabidopsis* suspension culture cell walls. This will allow us to finalize a manuscript describing the linkage. Xiangmei Wu, the post doc, characterized fragments of pectin produced by a combination of HF solvolysis and pectate lyase digestion. Some of the pieces make the argument that homogalacturonan is linked linearly to rhamnogalacturonan water tight. She also helped me characterize the less abundant fragments of Karaya gum that I made by HF solvolysis. (We had characterized the major fragments the previous year). We now have fragments representing the whole backbone of the polymer. Only the placement of the neutral sugar sidechains remains to be determined. We will use the fragments of Karaya gum as standards so that we can recognize them in normal pectins. Karaya gum is a plant exudate, used in the food industry, which resembles rhamnogalacturonan, but has some interesting features such as frequent GlcA substituents on the GalA and sometimes two GalA residues between Rha residues.

Functional Analysis and Genetic Manipulation of Plant ABCB Organic Ion Transporters

Institution: Maryland, University of
Point of Contact: Angus Murphy
Email: asmurphy@umd.edu
Principal Investigator: Angus Murphy
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

In yeasts and plants, a large and diverse family of ATP-binding cassette (ABC) transporters mediates the movement of metabolites, cell wall monomers, secondary compounds involved in plant protection and signaling, lipids, xenobiotics, waxes, and metals. Implication of ABC transporters in monolignol and lipid export and secondary compound import make this class of transporters a primary target for efforts to enhance the quality of biomass destined for production of “drop in” biofuels and manufacturing precursors. At a mechanistic level, work from our lab has associated exclusion of hydrophobic compounds from the outer leaflet of cellular membranes with discrete sites in the B-subclass of ABC transporters and has associated substrate-specific binding and transport with protein sites associated with the inner leaflet of membranes. Reversible transport mediated by another group of ABCB transporters has been associated with unique regulatory sites in this subgroup of transporters. The goal of this project is to elucidate the structural basis of these interactions, to demonstrate that manipulation of these sites can be used to direct activity and specificity of the transporters and to ultimately custom design transporters that can move important energy-related precursors to improve accumulation and recoverability in plants, yeasts, and bacteria.

FY 2014 HIGHLIGHTS

Rapid turnover of plasma membrane ABC transporters is a limiting factor in efforts to express engineered, substrate-specific transporters. The ABCB4 substrate-activated transporter becomes unstable under multiple stress conditions and was used as a model to understand innate and transcriptional regulation of ABC transporter stability. The transcript level of ABCB4 was found to be negatively regulated by treatments with abscisic acid (ABA) or cytokinin (CK). Moreover, loss of function of an ABA and cytokinin regulated transcription factor, ABI4, resulted in significant increased levels of ABCB4 transcript level. However, this regulation at the transcription level does not fully explain the rapid turnover of ABCB4 rapid turnover following treatment with ABA, CK or auxin. The reduced stability of ABCB4 at the plasma membrane was reported to be regulated by sphingolipids interactions as ABCB4 was found to be accumulated in intracellular compartments following treatment with the sphingolipid biosynthesis inhibitor, FB1, or in the background of sphingolipid biosynthesis deficient mutant, *tsc10a*. A saposin-like Aspartyl Protase class A2 (APA2;At1g62290) was found to be positively regulated by ABA or CK via ABI4 and suggested to function in sphingolipids enriched membrane rafts. This information has now been used to engineer transformants wherein ABCB4 is transcriptionally and post translationally stable under stress conditions.

The Role of CslD Proteins During Polarized Cell Wall Deposition in *Arabidopsis* Root Hair Cell

Institution: Michigan, University of
Point of Contact: Erik Nielsen
Email: nielsene@umich.edu
Principal Investigator: Erik Nielsen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

The overall goal of this research proposal is to characterize the molecular machinery responsible for polarized secretion of cell wall components in *Arabidopsis thaliana*. We have used the polarized expansion that occurs during root hair cell growth to identify membrane trafficking pathways involved in polarized secretion of cell wall components to the expanding tips of these cells, and we have recently shown that CSLD3 is preferentially targeted to the apical plasma membranes in root hair cells, where it plays essential roles during cell wall deposition in these cells. The specific aims of the project are designed to answer the following objectives: (1) Examine how CSLD3 function is integrated with regard to other members of the CSLD family and other cell wall synthetic enzymes during cell wall synthesis in *A. thaliana*. (2) Determine if CSLD proteins assemble into multi-subunit complexes. (3) Characterize CSLD synthetic activity and examine the nature of the polysaccharides synthesized by these enzymes.

FY 2014 HIGHLIGHTS

1. Cyclin B turnover precedes CSLD5 accumulation during cell division. CSLD5 selectively accumulated in dividing cells. Using time-lapse microscopy we showed CSLD5 accumulation only occurred in late mitosis, and only after loss of cyclin B1. We also showed that CSLD5 was rapidly lost in the newly-formed daughter cells.
2. CSLD5 is rapidly degraded upon completion of cytokinesis. Loss of CSLD5 from cells after mitosis suggested it might be actively degraded. Using cyclohexamide to block protein synthesis, we showed CSLD5, but not other CSLD or CESA cell wall synthases, displayed rapid turnover. Degradation of CSLD5 was ubiquitin-dependent, as treatment with the 26S proteasome inhibitor, MG132, stabilized this protein.
3. Heterologous expression and detergent-solubilization of CSLD3 in yeast. To determine the enzymatic activity of CSLD proteins, we wanted to express CSLD, CESA, and CSLA proteins in heterologous systems. We have successfully expressed and detergent-solubilized CSLD3, CESA6 (glucan synthase), and CSLA9 (mannan synthase) in *S. cerevisiae*. This is a significant advancement, and will provide the foundation for testing the biochemical activities of CSLD3 and other cell wall synthases with purified components.

Two Dimensional Electronic Spectroscopies for Probing Coherence and Charge Separation in Photosystem II

Institution: Michigan, University of
Point of Contact: Jennifer Ogilvie
Email: jogilvie@umich.edu
Principal Investigator: Jennifer Ogilvie
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$475,000 (2014-2015)

PROGRAM SCOPE

The basic photosynthetic architecture consists of antenna complexes to harvest solar energy and reaction centers to convert the energy into a stable charge separated state. In oxygenic photosynthesis, the initial charge separation event occurs with near unit quantum efficiency in the photosystem II reaction center (PSII RC). PSII is the only known natural enzyme that uses solar energy to split water, making the elucidation of its design principles critical for our fundamental understanding of photosynthesis and for our ability to mimic PSII's remarkable properties. This proposal focuses on key deficits in our current understanding of the PSII RC and aims to address the following open questions: 1) What is the electronic structure of the PSII RC? 2) What are the charge separation pathways in the PSII RC? 3) Does coherence facilitate charge separation in the PSII RC? To address these open questions we will apply broadband 2DES in isolated PSII RCs and in larger PSII complexes containing light-harvesting antennae, and continue development of new 2D spectroscopy methods to probe charge separation. 2DE-Stark spectroscopy will utilize an applied electric field to aid in separating excitonic and charge transfer states and enable identification of charge separation processes. These studies will enable us to further test and refine electronic structure models of the PSII RC and our description of the charge separation process. Our extensive studies of the PSII RC address the fundamental structure-function relationship in this important system to meet the grand challenge of elucidating the design principles used by nature to converting sunlight into chemical energy. The proposed studies will push the development of new methods for spectroscopic simulation and refinement of electronic structure. The newly developed experimental tools will be widely applicable to artificial light-harvesting systems, giving important experimental feedback for improving their design.

FY 2014 HIGHLIGHTS

The primary events of photosynthesis involve the absorption of light and the conversion of that absorbed energy into charge separation. This process is extremely rapid and in oxygenic photosynthesis it takes place in the photosystem II reaction center (PSII RC). Using two-dimensional electronic spectroscopy (2DES) we were able to track the energy transfer and charge separation events with exquisite time resolution. This high time resolution enabled us to see modulations in the optical signals at very specific frequencies that we identified as arising from coupled motions of the electrons and nuclei of the PSII RC. We carefully characterized these frequencies and correlated our observation of the coherent dynamics with specific electronic and mixed electronic-vibrational states of the system. We were able to reproduce the key features in our experimental data using a model that couples the key

vibrational modes identified by our experiments with specific electronic states. The simulations showed that vibrations possessing energies that match the energy gaps between the electronic states in the system strongly enhance the speed of charge separation. These observations indicate that electronic-vibrational resonances may be a key design principle of natural photosynthetic systems to promote efficient charge separation. In other progress, we have developed a new experimental implementation of 2DES that enhances the signal-to-noise-ratio. We have developed a new method to enable rapid and high signal-to-noise characterization of coherent dynamics. We have performed polarization-dependent 2DES on isolated PSII RC and PSII core complexes that contain additional CP43 and CP47 antennae. We have developed a novel dynamic Stark spectroscopy to specifically observe kinetic processes of charge separation and have collected data on the PSII RC. We are using the new array of spectroscopic data on the PSII RC to refine our model of its electronic structure.

Identification and Characterization of Glycosyltransferases Involved in the Synthesis of the Side Chains of the Cell Wall Pectic Polysaccharide Rhamnogalacturonan II

Institution: Georgia, University of
Point of Contact: Malcolm O'Neill
Email: mao@ccrc.uga.edu
Principal Investigator: Malcolm O'Neill
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Terrestrial plants are estimated to annually assimilate at least 100 billion metric tons of CO₂ through the process of photosynthesis. Much of the resulting photosynthate is used to produce the polysaccharide-rich walls that surround plant cells. We are studying the biosynthesis and structure of rhamnogalacturonan II (RG-II), a structurally conserved pectic polysaccharide that exists as a borate ester cross-linked dimer in the primary cell walls of all vascular plants. Incomplete borate cross-linking of RG-II and mutations that lead to altered RG-II structure or cross-linking adversely impact wall assembly and function and severely impair plant growth. However, the relationship between RG-II structure, cell wall organization, and plant growth is poorly understood. Few of the genes and proteins involved in RG-II synthesis have been identified and functionally characterized. Apiose is a key component of RG-II as it links two of the four oligosaccharide side chains to the homogalacturonan backbone and is involved in borate cross-linking of two RG-II molecules. We hypothesized that UDP-apiose (UDP-Api), the activated form of apiose used in RG-II synthesis, is a key factor in controlling RG-II formation. We also hypothesized that the appearance of functional UDP-Api synthase was a critical event in vascular plant evolution. RG-II is present in the cell walls of all vascular plants, but appears to be absent in avascular plant (bryophytes) cell walls. We are using a combination of molecular, biochemical and chemical techniques to investigate UDP-Api formation in land plants and to identify glycosyltransferase involved in RG-II synthesis. We are also using NMR spectroscopy together with mass spectrometry to characterize RG-II structure and cross-linking in diverse plants. Our long-term goal is to describe features of RG-II that are important for its self-assembly into a borate cross-linked dimer and how this dimer contributes to the functions and properties of the wall.

FY 2014 HIGHLIGHTS

A UDP-Api synthase (UAS) from the duckweed which has apiose-rich cell walls, was expressed as a recombinant protein and characterized. Duckweed UAS is being used to form UDP-Api for apiosyltransferase assays. We identified two protein sequences from a seagrass with high amino acid sequence homology with duckweed UAS. A recombinant version of one of the seagrass proteins was shown to have UDP-Api synthase activity. The moss *Physcomitrella patens* contains a homolog of UAS, but a recombinant version of the protein had no UAS activity. Domain swapping studies indicate that changes in the amino acid sequence between aa 1-215 prevent the moss “UAS-like” protein from being a functional UDP-apiose synthase. In collaboration with Russell Carlson (U. Georgia) and Gary Stacey (U of Missouri), we have shown that 95% of the RG-II exists as the borate ester cross-linked dimer in the cell walls of soybean (*Glycine max*) roots and root hairs. In collaboration with Paula McSteen (U. Missouri), we have shown that borate cross-linking of RG-II is reduced by 42% in the immature tassels of the maize tassel-less1 (*tls1*) mutant. This mutant has defects in inflorescence development, and in severe cases vegetative development, similar to the effects of boron deficiency. The reduction of RG-II dimers in the *tls1* mutant tassels suggests that the defects observed in mutant plants are, at least in part, due to defects in the cell wall.

Novel Microbial Based Enzymatic CO₂ Fixation/Carboxylation Mechanisms

Institution: Montana State University
Point of Contact: John Peters
Email: john.peters@chemistry.montana.edu
Principal Investigator: John Peters
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

This project's goal is to provide mechanistic insights into novel carboxylation reactions that occur in the microbial metabolism of alkenes and ketones. In *Xanthobacter autotrophicus* Py2 (Xa), two convergent pathways have been characterized for the metabolism of these compounds. These pathways culminate in carboxylation reactions catalyzed by either acetone carboxylase (AC) or 2-ketopropyl CoM carboxylase (2-KPCC). These enzymes are mechanistically distinct and have unique cofactor requirements. Our experimental approach combines biochemical characterization and X-ray structure determination of these enzymes in the presence of their substrates, products, and inhibitors to elucidate the carboxylation mechanisms. An outgrowth of these studies is our investigation of the Xa CoM biosynthetic pathway. The requirement for CoM in this metabolic pathway was unexpected, as it was previously thought that CoM was used only by methanogens. The AC carboxylation reaction does not utilize biotin and is ATP dependent. AC is unusual among carboxylases as its mechanism results in hydrolysis of ATP to 1 mol AMP and 2 mol of Pi. Previous studies suggest that ATP hydrolysis is coupled to both the activation of acetone to form a phosphoenolacetone intermediate and the activation of bicarbonate to carboxyphosphate. These studies suggest that acetone carboxylase is a fundamentally new class of carboxylase. Our crystal structure of 2-KPCC shows CO₂ in the active site, ideally positioned for electrophilic attack on the hypothetical enolacetone intermediate to yield acetoacetate. Kinetic studies show a side reaction occurs in the absence of CO₂ in which protons substitute as the attacking electrophiles yielding acetone instead of acetoacetate. We are using kinetics, mutagenesis and x-ray

crystallography to determine how 2-KPCC discriminates between CO₂ and protons as substrate electrophiles.

FY 2014 HIGHLIGHTS

We have purified recombinant AC from Xa, *Aromatoleum aromaticum* (Aa), and *Azotobacter vinelandii* (Av). Our data shows AC occurs in two variants which differ in ATP stoichiometry. For Xa, one ATP is consumed per acetone; for Aa and Av, two ATP are consumed. Phylogenetic analysis supports this distinction: we have shown that AC from Xa lies on a different clade than AC from Aa and Av. Our kinetic studies have identified that the reaction proceeds through a phosphorylated isopropene intermediate. Structural characterization of AC is ongoing; we have Xa crystals that diffract to ~3Å and crystallization conditions are being optimized for Xa, Aa, and Av. We hypothesize that several features surrounding the 2-KPCC active site may affect substrate discrimination: the N- and C-termini, a cis-proline flanked loop and a hydrophobic pocket encapsulating the CO₂ substrate. We are assessing the impact of CO₂ concentrations on carboxylation in wild-type 2-KPCC. Analysis of 2-KPCC variants is underway. We have purified a 2-KPCC variant with the cis-proline loop deleted. Other variants to be constructed include deletion of both termini, and mutation of CO₂ binding site residues. A gene cluster near the epoxide carboxylase pathway is implicated as the putative CoM biosynthetic operon in Xa. To define the biosynthetic intermediates, we have cloned the putative operon and individual ORFs for expression in *E. coli*. One of these ORFs, *xcbE1*, is homologous to D-cysteine desulfhydrases, a group of PLP-dependent enzymes that extract sulfur from D-cysteine and produce pyruvate, H₂S and ammonium. Kinetic studies are underway using purified recombinant XcbE1. Supplying XcbE1 with cysteine yields H₂S and pyruvate. Our kinetic data show that XcbE1 does not have a strict preference for L- or D-cysteine, unlike its homologs that do not catalyze a reaction in the presence of L-cysteine.

Enzymology of Methanogenesis: Mechanism of Methyl-Coenzyme M Reductase

Institution: Michigan, University of
Point of Contact: Stephen Ragsdale
Email: sragdsal@umich.edu
Principal Investigator: Stephen Ragsdale
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The goal of this project is to determine the enzymatic mechanism of methyl-CoM reductase (MCR), the key enzyme in the synthesis of methane, which is the primary constituent of natural gas and accounts for 22 percent of the energy consumption of the U.S. This enzyme is responsible for more than 90% of the earth's atmospheric methane. MCR catalyzes the formation of methane and a heterodisulfide (CoB-S-S-CoM) from methyl-Coenzyme M (methyl-CoM) and Coenzyme B (HSCoB). There is controversy about whether methane is formed via methyl-Ni(III) or methyl radical intermediates. By using substrate analogs and MCR variants, we have trapped reaction intermediates in the catalytic cycle to resolve this controversy. We also are attempting to determine the crystal structure of the Ni(I) state of MCR and the structures of catalytic intermediates in the catalytic cycle. We also are determining how MCR is activated *in vivo*. Protocols have been developed to activate MCR for performing mechanistic studies; however, we do not yet know how MCR undergoes activation in the cell. We have recently discovered

that CO and CODH can replace H₂ and hydrogenase in the cellular activation system. Thus, we are in an excellent position to determine the common cellular pathway for activation of MCR by H₂ and CO.

FY 2014 HIGHLIGHTS

Transient kinetic studies of the MCR-catalyzed reaction of methyl-SCoM with CoB6SH, a CoBSH analog lacking one methylene group in the heptanoyl group, suggest a new MCR mechanism involving conversion of Ni(I) to a Ni(III) intermediate (MCRox1) in a reaction tightly coupled to methane formation. Transient and steady-state kinetic studies of the MCR reaction with native substrates allowed definition of each of the individual steps in the MCR reaction along with their rate constants. This will represent the first published transient kinetic study of active MCR with its native substrates. These studies suggest a novel mechanism by which MCR, which uses an ordered BiBi ternary complex mechanism, dictates a strict order of substrate binding (methyl-SCoM first, CoBSH second), required for the chemical reaction. While some enzymes prevent binding of the “incorrect/second” substrate to the free enzyme and recognize only the “correct/first” substrate, MCR can form a binary complex with either substrate. It appears to couple binding of methyl-SCoM to expulsion of any pre-bound CoB7SH from its nonproductive binding mode. It also uses conformational energy to promote CoB7SH binding to the productive binary complex and to effect the synergetic movement of substrates in position for the chemical reaction. Activation energies for each step in the MCR reaction have been determined by presteady-state and steady-state kinetics. These are serving as input parameters for computational studies of the MCR mechanism.

Understanding the Role of the Exocyst in Regulating the Dynamics of Vacuole Trafficking and Secretion

Institution: California-Riverside, University of
Point of Contact: Natasha Raikhel
Email: natasha.raikhel@ucr.edu
Principal Investigator: Natasha Raikhel
Sr. Investigator(s): Glenn Hicks; California - Riverside, University of
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$555,000 (2014-2016)

PROGRAM SCOPE

Enhanced mobilization of vacuolar cargoes by: 1) Defining cellular mechanism(s) involved in uptake/compartimentalization/mobilization of energy-relevant nutrients and soluble/membrane proteins. 2) Defining genes for mobilization of reserves in vacuoles of vegetative/seed tissues. 3) Understand how reserves/proteins/metabolites are partitioned dynamically between vacuoles and sites of intra/extracellular use. 4) Improving biomass/yield/fitness by efficient storage and utilization of energy-rich stores. We will use plasma membrane (PM) proteins such as the auxin transporter PIN₂ which controls vacuolar trafficking via auxin and will serve as vesicle markers to the vacuole and PM to study trafficking dynamics. Goals will contribute to biomass as renewal energy via knowledge/tools to manipulate vacuolar trafficking. Due to reduced funding, we focused on bioactive chemical ES2 and its target, the exocyst.

Objective 1. Understand the exocyst in regulating vacuole trafficking. We hypothesize the exocyst is part of a mechanism controlling dynamics of vacuole trafficking and exocytosis. As a separate chemical biology approach with non-DOE seed money, we screened for chemicals perturbing endomembrane trafficking, including aberrant targeting to the vacuole. Our early data indicates the cognate target of the chemical ES2 as the exocyst protein EXO70A1 which may regulate vacuole targeting and exocytosis. This

is an opportunity to understand regulation of vacuole trafficking by dissecting the role of EXO70s/exocyst.

Objective 2. Determine the structure of EXO70A1 and map ES2 binding domains. We hypothesize that the ES2 binding site will reveal regions regulating vacuole trafficking and exocytosis. Our results will provide insights into mechanisms enabling biotechnology to enhance efficiency of protein/carbohydrate storage in vacuoles.

FY 2014 HIGHLIGHTS

During this review period we have achieved the following towards our program goals:

1. An EXO70 protein with a C-terminal truncation resulted dominant ES2 resistance, uncovering possible distinct regulatory roles for the N-terminus and C-terminus of the protein. We have been using this mutant as a starting point to uncover novel features of the exocyst and its role in regulating the dynamics between targeting of key metabolites to the vacuole vs. plasma membrane (PM).
2. Utilizing the bioactive compound ES2 we identified its cognate target as the EXO70A1 subunit of the exocyst complex which is necessary for exocytosis and is highly conserved. This was done using a combination of genetics and chemical proteomics. We have recently demonstrated by NMR that ES2 physically interacts with EXO70 from *Arabidopsis* and mouse indicating that conserved nature of the binding site. Mutations in the plant EXO70 subunit reduce binding interaction.
3. We have shown that the compound affects the polar targeting of EXO70 and FRAP shows that the compound inhibits the plasma membrane association of the EXO70 subunit of the exocyst.
4. We have been working towards the crystal structure of *Arabidopsis* EXO70A1 and have been able to obtain high quality crystals that can be used to determine structure in the presence or absence of ES2. This will be the first plant EXO70 structure to be reported.
5. To the extent of our knowledge, there are no other compounds known to target the exocyst. Beyond our studies to understand the regulation of vacuole vs. PM targeting of vacuole and other cargoes from the viewpoint of improved energy reserves for plant biotechnology, exocyst function have been linked to diabetes and even some cancer. So the target site may be novel and could provide a drug lead for increased human health.

EARLY CAREER: Engineering Self-Assembled Bioreactors from Protein Microcompartments

Institution: California-Berkeley, University of
Point of Contact: David Savage
Email: dsavage@berkeley.edu
Principal Investigator: David Savage
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$159,224 (2014)

PROGRAM SCOPE

Biological systems use organization to segregate incompatible processes. Many metabolic pathways are confined to specific organelles to insure pathway fidelity, catalyzing reactions out of chemical equilibrium within the cell, and limiting pathway toxicity. However, the ability to spatially organize important processes *in vivo* remains a major challenge to the field of biological engineering. A reliable method for constructing spatial organization in the form of a synthetic organelle would be useful in metabolic engineering, where it could be used to improve the rate and yield of biochemical reactions.

One biological assembly that could form the basis of a synthetic organelle is the bacterial microcompartment (BMC). BMCs are enzyme-containing complexes that catalyze reactions unfavorable to the host. They have a modular structure and consist of self-assembling shell proteins and packaged, targeted enzymes. Many of the genes required for BMC assembly have been identified, and recent genetic manipulations suggest that BMC are suitable for engineering. We propose experiments to define the assembly process of BMCs, identify the BMC components sufficient for function, and to develop synthetic organelles capable of catalyzing a model pathway. Our goals are:

Aim 1: To define BMC assembly and function within cyanobacteria. How BMCs function *in vivo* is poorly defined. Here, we will use a model BMC to define the nature and mechanism of particle formation and degradation. We will also probe the interplay between BMC function and cellular growth and metabolism *in vivo*.

Aim 2: To develop a model BMC for synthetic biological applications. We will apply our understanding of BMC assembly and function to the long-term goal of creating synthetic organelles. We will develop a minimal and modular BMC chassis for further protein engineering. We will then define how proteins are targeted to BMCs and use this as a means of creating a novel BMC capable of catalyzing ethanol fermentation.

FY 2014 HIGHLIGHTS

The goal of our work is to develop an understanding of how proteinaceous bacterial microcompartments (BMCs) assemble and function in their *in vivo* context and to use this knowledge for the rational engineering of compartments with novel catalytic properties. This proposed work is broken down into two major aims: i). To probe assembly and function of using the cyanobacterial model BMC system (i.e. the carboxysome) from *Synechococcus elongatus* PCC7942 developed in my postdoctoral work and ii). Develop and engineer a heterologous carboxysome (CB) expression system based upon the CB regulon from *Halothiobacillus neapolitanus* (HnCB). Briefly, the major advances during the 2013-2014 funding period are the following:

1. Developed optimal instrumentation for live-cell cyanobacterial imaging.
2. Begun to tease apart the mechanism of carboxysome assembly, the initial results of which were published (Chen *et al.* PloS One 2013).
3. Discovered the stringent response my control polyphosphate and, ultimately, photosynthetic carbon fixation in cyanobacteria.
4. Deciphering the mechanism of CB assembly in the model *Halothiobacillus*.
5. Exploring thermophilic 'nanocompartment' encapsulins in *E. coli* as an alternative to microcompartments.

Molecular and Genetic Basis of Sodium/Potassium Transport and Distribution in Plants

Institution: California-San Diego, University of
Point of Contact: Julian Schroeder
Email: jischroeder@ucsd.edu
Principal Investigator: Julian Schroeder
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$179,565 (2014)

PROGRAM SCOPE

Salinity stress is progressively detrimental to renewable bioenergy capture and storage in plants and interferes with photosynthetic activity and metabolism. Sodium (Na^+) is toxic to most plants at high concentrations. Elucidation of the fundamental basic molecular and biophysical mechanisms underlying Na^+ uptake and distribution throughout plant tissues and cellular organelles can lead to new approaches for enhanced energy capture and storage in plants. Our DOE supported research has identified the AtHKT1;1 transporter and revealed that it constitutes a key mechanism for protection of plants from salinity stress by excluding toxic alkali-metal sodium (Na^+) ions from leaves. Recent mapping of salinity resistance quantitative trait loci (QTL) in grasses, and analyzing candidate HKT genes in rough mapping domains suggest that analogous HKT transporter-mediated salinity tolerance mechanisms that the P.I.'s lab has identified in *Arabidopsis* are key salinity resistance mechanisms in grasses. Our DOE research focuses on the basic biophysical, physiological, and regulatory mechanisms through which HKT sodium cation transporters and Potassium (K^+) transporters play central roles in mediating salt tolerance in plants. Chloroplast transporters are predicted to be of key importance for efficient photosynthesis. However, the genes encoding many chloroplast transporters, including the molecular K^+ transport mechanisms across chloroplast membranes, remain unknown. Our research is identifying and characterizing chloroplast-targeted K^+ transporters and determining their roles in plant growth, chloroplast function, and salinity responses.

FY 2014 HIGHLIGHTS

The molecular identity and the fundamental functions of transport proteins facilitating K^+ transport across the chloroplast envelope membranes remained unknown. Our analyses of prokaryotic organisms indicated members of the KEA family as candidates. To address overlapping gene functions, we designed and developed artificial microRNAs (amiRNAs) on a genome-wide scale in *Arabidopsis*. Since no loss-of-function mutants had been identified in K^+ transporters that affect chloroplast function and photosynthesis, we used amiRNAs and found that co-knock-down of KEA1 & KEA2 gives rise to plants with a decreased maximum efficiency of photosystem II (Fv/Fm) determined by pulse amplitude modulated (PAM) measurements of whole rosettes in the P.I.'s lab (Kunz *et al.*, 2014 PNAS). We found that KEA1 and KEA2 proteins are targeted to the inner envelope membrane of chloroplasts, while KEA3 is targeted to the thylakoid membrane. *kea1kea2* double mutants, but not single mutants, showed impaired photosynthesis in young plants and pale green leaves. The pH component of the proton motive force across the thylakoid membrane was found to be significantly decreased in *kea1kea2* plants. Electron microscopy of leaf cells revealed swollen chloroplasts, dramatically reduced chloroplast starch levels, disrupted envelope membranes and reduced thylakoid membrane density (Kunz *et al.*, 2014). Unexpectedly, exogenous NaCl application reversed these phenotypes via a proposed osmotic stabilization. Furthermore, the *kea1kea2* background enabled genetic analyses of the functional significance of other chloroplast transporters using higher order mutants: *kea1kea2 Na⁺/H⁺ antiporter1 (nhd1)* and *kea1kea2kea3* triple mutants showed an enhanced impairment in photosynthesis (Kunz *et al.*, 2014). Taken together, our characterization of the plastidial inner envelope KEA1&2 transporters demonstrates their fundamental roles in chloroplast osmoregulation, integrity, and chloroplast pH regulation.

Reduction of CO₂ to Hydrocarbons Catalyzed by Nitrogenase Will Be Investigated

Institution: Utah State University
Point of Contact: Lance Seefeldt
Email: lance.seefeldt@usu.edu

Principal Investigator: Lance Seefeldt
Sr. Investigator(s): Dennis Dean; Virginia Polytechnic Inst. and State U.
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$190,000 (2014)

PROGRAM SCOPE

The research objectives of this project are to gain a molecular level understanding of the activation and reduction of CO₂ to hydrocarbons catalyzed by the bacterial enzyme nitrogenase. Nitrogenase normally catalyzes the multi-electron/proton reduction of dinitrogen (N₂) to two ammonia (NH₃). We have discovered that the protein surrounding the active site metal cluster, FeMo-cofactor, can be remodeled, allowing larger compounds to become substrates for nitrogenase. In one such remodeled nitrogenase, we were able to demonstrate that nitrogenase could reduce CO₂ by 8 electrons/protons all the way to methane (CH₄) in a catalytic reaction unprecedented in biology. Our goals are to understand these reactions and to improve the reactions through further remodeling of the active site of nitrogenase.

FY 2014 HIGHLIGHTS

We have made significant advances in our understanding of the metal hydrides at the active site that are certainly involved in CO₂ reduction to hydrocarbons in the remodeled nitrogenase. The state of our understanding was presented in a Chemistry Review paper that appeared in early 2014. We also have made good progress using isotopes to understand the rate limiting steps in the multi-step reduction of CO₂ to hydrocarbons.

Nanotube-Supported Phospholipid Bilayers

Institution: North Carolina State University
Point of Contact: Alex Smirnov
Email: Alex_Smirnov@ncsu.edu
Principal Investigator: Alex Smirnov
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The overall long term objective of this project is to develop a new class of nanoscale biotechnological objects - substrate-supported lipid nanotubes - and to utilize these nanoscale structural elements for building robust hybrid biological nanodevices that are based on functionally active membrane proteins. Specifically, we aim at: (1) developing efficient experimental protocols for loading and self-assembling bilayer membranes of various lipid compositions inside the nanochannels formed in anodic aluminum oxide (AAO) substrates; (2) improving technology for fabricating homogeneous AAO with desired pore dimensions and low light absorbance to enable biophysical studies of light-harvesting biomolecular systems; (3) investigating effects of surface chemistry on the lipid self-assembly and the properties of the lipid bilayers formed by surface modification of nanoporous substrates; (4) demonstrating initial feasibility of employing lipid nanotube technology for building hybrid nanostructures based on membrane proteins. The ultimate outcome of the program will be experimental methods and protocols for building robust functional hybrid nanostructures that could be used for biomimetic solar energy conversion and/or bioinspired energy transduction and separation technologies.

FY 2014 HIGHLIGHTS

- 1) Developed centrifugation-based method and accessories to increase loading of lipid bilayers into AAO nanochannels by at least twofold regardless the phospholipid composition.
- 2) Developed and optimized a number of high throughput procedures for fabricating high quality nanoporous substrates with pore diameters ranging from 25 to 90 nm and exceptionally narrow (4 to 5 nm) pore diameter distributions.
- 3) Developed nanoporous substrates that are transparent at wavelength above 260 nm for biophysical studies of light-harvesting biomolecular systems.
- 4) By using lipid nanotube technology showed that the Pf1 helix tilt angles in two lipid systems are not entirely governed by the membrane thickness but could be rationalized by hydrophobic interactions of lysines with lipids at the bilayer interface.
- 5) Carried out initial experiments on incorporating rhodopsins into lipid nanotubes formed inside macroscopically aligned ceramic nanoporous substrates for NMR and EPR structural studies as well as for biosensor applications.

Engineering Selenoproteins for Enhanced Hydrogen Production

Institution: Yale University
Point of Contact: Dieter Soll
Email: dieter.soll@yale.edu
Principal Investigator: Dieter Soll
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Hydrogenases are crucial enzymes in the production and utilization of hydrogen, a possible fuel of the future. A fundamental understanding of the function of these redox enzymes is required to make biogenic hydrogen production a viable fuel source. The element selenium is found in a subset of hydrogenases that have greater catalytic power than their sulfur-containing homologs. Selenium is found in proteins in the form of selenocysteine (Sec), an amino acid in which a selenol group replaces the thiol moiety of cysteine. It is thought that the unique catalytic potential of selenium is required for certain redox enzymes to function in their native environment (e.g., glutathione peroxidase in mammals or formate dehydrogenase in bacteria). Some organisms (e.g., methanogens) simultaneously contain homologous [NiFe] hydrogenases with either Sec or cysteine in their catalytic center. In [NiFeSe] hydrogenases, the selenium always coordinates the Ni atom in the metal cluster and three cysteines complete the coordination shell surrounding the NiFe center. The reason for this evolutionarily conserved structural arrangement and the answer as to how Sec enhances the catalytic potential of hydrogenases and other redox enzymes remains unknown. The versatile amino acid Sec is formed by the conversion of serine while attached to tRNA^{Sec} resulting in Sec-tRNA^{Sec}. Sec is co-translationally inserted into proteins directed by a UGA codon in the mRNA; a special tRNA^{Sec} and a particular mRNA structure-mediated recoding event are involved in this process. Given this precise recoding mechanism, mutagenesis methods to generate proteins where Sec is inserted at any desired position are currently unavailable. The aim of this proposal is (1) to develop a method that will make protein design and engineering with selenocysteine feasible, and (2) to use this method to enhance the activity of hydrogenases by conversion of critical active site cysteine residues to selenocysteine.

FY 2014 HIGHLIGHTS

Aim 1: By designing a synthetic tRNA^U (a tRNA^{Sec} that is recognized well by elongation factor Tu) and by evolving from wild-type EF-Tu the variant EF-Sel (with improved recognition properties of Sec-tRNA^U) we have generated a translation system that can generate any desired selenoprotein in *E. coli* with high specificity and yield.

Aim 2: We have chosen the *Methanocaldococcus jannaschii* [Fe]-hydrogenase Hmd as a model protein to convert its active site cysteine (position 176) to selenocysteine. Expression of an HmD gene containing UAG as codon 176 in *E. coli* with our UTu system (see Aim 1) yielded a Sec-containing Hmd protein in good yield (2-3.5 mg/L culture). Sec incorporation was confirmed by LC-MS/MS analysis. Biochemical characterization of this selenoenzyme will be carried out in the laboratory of Dr. Rudolf Thauer, Marburg, Germany.

Plant Response to LCO/CO Signals

Institution: Missouri, University of
Point of Contact: Gary Stacey
Email: staceyg@missouri.edu
Principal Investigator: Gary Stacey
Sr. Investigator(s):
Students: 5 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Plants are sessile organisms and, therefore, have evolved complex mechanism by which they sense and respond to their external environment. Chitooligosaccharides (CO), released from pathogen fungi, induce plant innate immunity while, in legume plants, lipo-chitooligosaccharides (LCO) induce the establishment of the nitrogen fixing symbiosis with rhizobia. Our project seeks to understand how very similar signals (CO and LCO), recognized by similar LysM receptor-like kinases, can elicit such different plant responses. For example, recently we elucidated the heterotetrameric structure of the CERK1-LYK5 CO receptor complex, which is very similar to the LCO receptor. It has been the dream for many years to leverage knowledge about the rhizobial-legume symbiosis to develop similar symbioses with non-leguminous plants (e.g., corn). Until recently, it was thought that non-legumes cannot form such a symbiosis due to an inability to recognize and react to the LCO signal. However, we recently showed that many non-legumes, perhaps all, do recognize the LCO but this result in a suppression of innate immunity and not symbiosis. Indeed, we hypothesized that this role of LCO may have predated its symbiotic function to promote infection by the bacterium. CO and LCO signals trigger the release of extracellular ATP by the plant, which may also act as a signal; a role that is well documented in animal systems. We recently identified the first plant receptor for eATP, DORN1 (doesn't recognize nucleotides). Mutants defective in *dorn1* do not react to ATP addition. There is a significant overlap between the genes induced by ATP and those induced by CO addition, as well as treatment with a variety of biotic and abiotic stressors. The data suggest that eATP is a previously overlooked, critical signal that explains a significant amount of the gene expression previously assigned strictly to the stress treatment.

FY 2014 HIGHLIGHTS

Adenosine 5'-triphosphate (ATP), the universal energy currency of all organisms, is released into the extracellular matrix and serves as a signal among cells, where it is referred to as an extracellular ATP (eATP). In mammals, eATP is perceived by plasma membrane P2-type purinoceptors. However, similar ATP receptors do not exist in plants, although extracellular ATP has been shown to play critical roles in plant growth, development, and stress responses. Recently, we identified the first plant receptor for extracellular ATP, DORN1, by isolation of an *Arabidopsis thaliana* mutant that failed to show an intracellular calcium response upon ATP addition (Choi *et al.*, 2014). DORN1 encodes a legume-type lectin receptor kinase (i.e., lectin receptor kinase I.9; At5g60300) that is structurally distinct from the mammalian extracellular ATP receptors. DORN1 binds ATP with high affinity (K_d : 45.7 ± 3.1 nM), as well as other nucleotides, and is required for ATP-induced calcium response, MAPK activation, and gene expression. Ectopic expression of DORN1 increased the plant response to physical wounding. We propose that DORN1 is essential for perception of extracellular ATP and likely plays a variety of roles in plant stress resistance.

Choi, Jeongmin, Tanaka, Kiwamu, Cao, Yangrong, Xi, Yue, Qiu, Jing, Liang, Yan, Sang Yeol Lee, Stacey, Gary (2014) Identification of a plant receptor for extracellular ATP. *Science* Vol. 343 no. 6168 pp. 290-294

Regulation of Actin Stochastic Dynamics: Single Actin Filaments as Tracks for Delivery of Materials to the Cell Wall

Institution: Purdue University
Point of Contact: Christopher Staiger
Email: staiger@purdue.edu
Principal Investigator: Christopher Staiger
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$350,000 (2014-2015)

PROGRAM SCOPE

Plant cell walls represent the largest renewable source of carbon for use in biofuel production. Maximizing extraction of wall-stored carbon for industrial purposes requires a detailed understanding of polysaccharide composition, biophysical properties, and assembly mechanisms. Understanding how, how much, and where noncellulosic polysaccharides are delivered and incorporated into walls is a major knowledge gap which currently impedes efficient use of biomass for biofuels. In plants, a cytoplasmic network of dynamic filamentous structures, the actin cytoskeleton, functions as tracks or highways for long-distance transport. Although it is widely believed that actin provides the transportation infrastructure to deliver matrix polysaccharides and biosynthetic enzymes to the PM and cell wall, there is little direct evidence to this effect. Using state-of-the-art fluorescence imaging methods, we have previously described the dynamic remodeling of actin filament arrays in living plant cells and quantified key properties of individual filament turnover. Moreover, we have established genetic control over actin filament dynamics by overexpressing and downregulating several actin-binding proteins. One such player, capping protein (CP), modulates the availability of filament ends and controls filament length and lifetime. We predict that the single filaments serve as highways for secretory vesicle traffic; thus, when these tracks are long and long-lived, cargo delivery is most efficient. Therefore, we will test the central hypothesis that single actin filament lengths and lifetimes regulate exocytosis, thereby controlling the rate of deposition of matrix polysaccharides and the delivery of cell wall biosynthetic

enzymes to the PM. Our objectives include: 1) establishing whether single actin filaments serve as tracks for trafficking of matrix polysaccharides and cell wall biosynthetic enzymes; and 2) testing whether filament length and lifetime alter exo- and endocytosis.

FY 2014 HIGHLIGHTS

- We demonstrated that overexpression of *Arabidopsis* capping protein (CP OX) has the opposite cell expansion and cytoskeletal phenotypes compared to cp knockdown lines. Specifically, CP OX lines have reduced axial cell expansion in etiolated hypocotyls as well as less dense cytoskeletal arrays. Changes to single filament turnover in CP OX lines results in actin filaments with reduced annealing frequency, shorter maximum length and decreased lifetime. This work was published in *Molecular Biology of the Cell*.
- We performed subcellular fractionation, sucrose-density gradient separations and immunocytochemistry to establish that CP is a membrane-associated protein and associates with endomembranes such as Golgi. This work was published in *Plant Physiology*.
- We established collaborations to determine cell wall composition in cp mutants and showed that crystalline cellulose content was significantly reduced compared to wild-type plants, in preliminary experiments. We also analyzed monosaccharide content in cp and found an increase in xylose and fucose, whereas total glucose was essentially unchanged compared to wild type. This is consistent with an increased xylan content in cpb-1 walls. In contrast, arabinose and galactose content decreased significantly, suggesting a reduction in pectin or arabinogalactan proteins.

Molecular Mechanism of Energy Transduction by Plant Membrane Proteins

Institution: Wisconsin-Madison, University of
Point of Contact: Michael Sussman
Email: msussman@wisc.edu
Principal Investigator: Michael Sussman
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$144,535 (2014)

PROGRAM SCOPE

The plasma membrane is the point of contact between a cell and its external environment and plays a critical role in the growth and development of all organisms. The proteins within this membrane that act as pumps, carriers, and channels together convert the chemical energy of ATP into gradients of organic and inorganic solutes that support life. In higher plants and fungi, foremost among these transport proteins is the proton pump (H^+ -ATPase) since it alone generates the proton motive force (composed of both a transmembrane electrical potential and a proton chemical gradient) that drives the transport of solutes essential for cell growth. A unique aspect of this enzyme is its ability to generate very large membrane potentials and a low extracellular pH whose magnitude is regulated by changes in light, hormones and other environmental perturbations such as drought and salt stress. The overall research goal of this project is to use genetic and chemical technologies for understanding the molecular structure and function of this protein, both in terms of what precise physiological and developmental roles it is playing in everyday plant life, as well as in learning how it converts chemical energy into electrical energy and how this process is tightly regulated. Our specific approach is to mutagenize the gene encoding this enzyme either in intact *Arabidopsis* plants or in yeast, and study the resultant phenotypes. A major recent focus has been on identifying posttranslational modifications and

interacting partners of the enzyme, and substantial progress has been made in developing and using the tools required for understanding the role of kinase-mediated phosphorylation.

FY 2014 HIGHLIGHTS

In *Arabidopsis* and all other plants, this protein is encoded by a family of 11 genes called AHA (*Arabidopsis* H⁺-ATPase)'s. AHA1 and AHA2 appear to be functionally redundant and together produce mRNA and protein corresponding to ca. 70% of the enzyme found in plant extracts. In previous years we performed a comprehensive study of the effects of genetically reduced plasma membrane proton pump activity for AHA1 and AHA2. We have recently used a system for obtaining a translationally fused 'tagged' pump that, importantly, rescues growth of the lethal double mutant and allows us to readily purify the enzyme from plants treated for short periods of time with various effectors. In addition to the well-known penultimate threonine at the carboxy terminus, we have recently identified other serine and threonine residues in the protein whose phosphorylation status regulates this enzyme in response to a peptide hormone known as RALF (Rapid Alkalinizing Factor). With the tagged enzyme and isotope-assisted methods for quantitation with tandem mass spectrometers, we are measuring posttranslational changes in the ATPase and elucidating how these affect the three dimensional structure and catalytic functions of this critical energy transducing protein.

Endomembrane Cation Transporters and Membrane Trafficking

Institution: Maryland, University of
Point of Contact: Heven Sze
Email: hsze@umd.edu
Principal Investigator: Heven Sze
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

A long-range goal is to understand how plants regulate cation and pH homeostasis of intracellular compartments which form the dynamic endomembrane system of all eukaryote cells. Emerging evidence indicates that distinct physico-chemical environment of endomembrane compartments is important for protein sorting, membrane trafficking, osmoregulation, signaling and possibly the synthesis and remodeling of plant cell walls. However, specific transporters involved in altering ion balance, pH or both of intracellular compartments in plant cells are poorly understood. We had uncovered a subfamily of predicted cation/H⁺ exchangers (CHX) that are prevalent in higher plants, but rare or absent in metazoans. Studies in yeast and plants indicate that CHXs members are distinct in function from the better-studied NHX1-related members some of which are also localized to endomembranes. *Arabidopsis* CHX20 in guard cell is important for stomatal opening, and two other CHXs affect the guidance of pollen tubes, whereas the functions of four AtCHXs in roots are not well-defined. Based on localization and mutant analyses, we hypothesize that CHXs modulate the ion balance, pH or both in micro-regions of endoplasmic reticulum, endosomes and prevacuolar compartment (PVC), and so affect signaling and membrane trafficking resulting in altered osmoregulation in guard cells and polar tip growth of pollen tubes.

FY 2014 HIGHLIGHTS

Two papers are being prepared for publication.

1. Role of CHX17-19 genes in reproduction and seed development. Analyses of triple mutants show that one of three homologous genes, CHX17, CHX18 or CHX19, is critical for male fertility. Although triple mutant pollen tubes grow a bit slower than Wt pollen, they target and enter ovules. Yet half of the targeted ovules per pod fail to develop into seeds and appear unfertilized. Moreover, a fraction of ovules within each pod are fertilized, though embryo development is delayed when mutant pistil is pollinated by mutant pollen. Results suggest that CHX17, 18 or 19 activity is critical for successful fertilization and the development of embryo and endosperm.
2. Modeling and mutagenesis reveal the active core in a plant cation/proton exchanger CHX17. By generating a 3D model of CHX17 using known crystal structures of bacterial Na/H antiporters, we identified potential residues involved in cation binding and transport. Results from mutagenesis experiments support a model of a cation/H⁺ exchanger with a four-helix bundle where the active core is located near the discontinuous alpha-helices of TM4 and TM11. Three dimension modeling also revealed a universal stress protein-like domain at the C tail. Taken together, our studies suggest that pH and stress conditions could regulate cation and pH homeostasis and so alter plant reproduction and seed development.

Photosynthetic Energy Capture, Conversion and Storage: From Fundamental Mechanisms to Modular Engineering

Institution: Michigan State University
Point of Contact: Michael Thomashow
Email: thomash6@msu.edu
Principal Investigator: Michael Thomashow
Sr. Investigator(s):
Students: 11 Postdoctoral Fellow(s), 10 Graduate(s), 11 Undergraduate(s)
Funding: \$2,500,000 (2014)

PROGRAM SCOPE

We are conducting a highly interactive, multidisciplinary research program that addresses fundamental questions concerning the capture, conversion and storage of solar energy by photosynthetic organisms. The issues tackled are complex in nature, ranging from addressing both long-standing and emerging questions in photobiology, to developing first principles enabling rational design of cellular and subcellular modules for enhanced carbon fixation and high-energy redox reactions. The research program focuses on three major themes—"Robust Photosynthesis in Dynamic Environments," "Integrating Energy Status, Growth, and Energy Deposition," and "Characterizing and Engineering Subcellular and Cellular Modules for Photosynthetic Productivity"—that comprise multiple interrelated lines of research. The core research group includes 14 faculty members who bring a broad spectrum of formal training, basic research interests, and experimental expertise to the program, and a team of talented postdoctoral research associates, graduate research assistants, and research technicians. The program includes the development and use of novel high-throughput, non-invasive phenotyping technologies—the Dynamic Environmental Phenotyping Imager (DEPI) and the Environmental Photobioreactor (ePBR)—that enable investigators to monitor an array of fundamental photosynthetic properties and growth in dynamic environments. In addition, the program includes a series of forward-looking lines of investigation to understand the structural and biochemical bases of energy-storing modules using rational, engineering-based approaches. We anticipate that the data and technologies

resulting from the proposed research will have substantial impact on photosynthesis and related energy research as they are disseminated to the larger scientific community.

FY 2014 HIGHLIGHTS

In the “Robust Photosynthesis” project, we developed a series of new enabling technologies for high throughput measurements of photosynthetic phenotypes under dynamic environmental conditions, including new instrumentation and software platforms, and used these resources to advance our understanding of: the mechanisms of photosynthetic responses to fluctuating environmental conditions (light, temperature, humidity); the roles for the chloroplast proton motive force in regulating the photosynthetic apparatus; the importance of Golgi, ER and peroxisomes in maintaining robust plant growth; the effects of antenna composition on fitness and productivity in cyanobacteria and algae; and the role of light-quality in regulating photosynthesis, physiology and morphology in plants and cyanobacteria.

In the “Integrating Energy and Growth” project, we developed a new model that describes how photosynthetic products are partitioned to various organs of the model plant *Arabidopsis*, and made the unanticipated finding that large increases in leaf area growth, and thus light capture capacity, can result from small reductions in carbon partitioning to leaf thickness. In addition, we identified regulatory proteins with key roles in controlling the partitioning of carbon between growth and defense in *Arabidopsis* and obtained further evidence that carbon sink strength regulates photosynthetic efficiency in cyanobacteria.

Finally, in the “Modules for Photosynthetic Productivity” project, we are breaking down the complexity of photosynthesis into multiprotein modules that carry out light-harvesting or form cellular “nanoreactors” that fix CO₂. By determining the detailed structures of specific proteins that make up these modules, we have identified novel features that underlie function and are informing our design of new types of modules to enhance photosynthetic productivity.

Molecular Dissection of the *Arabidopsis* Holo-26S Proteasome

Institution: Wisconsin-Madison, University of
Point of Contact: Richard Vierstra
Email: vierstra@wisc.edu
Principal Investigator: Richard Vierstra
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

The 26S proteasome is an ATP-dependent protease complex responsible for degrading many important cell regulators in plants, especially those targeted by ubiquitylation. Its 64 or more subunits generate two subparticles: a 20S core protease (CP) that houses the proteolytic active sites and a 19S regulatory particle (RP) that binds to both ends of the CP and recruits appropriate substrates for breakdown. It has become clear that the currently defined proteasome actually represents the nucleus of an even more elaborate and dynamic particle harboring multiple routes for substrate recognition and sophisticated mechanisms to control its assembly, function, and turnover. The goal of this project is to better define 26S proteasome function and diversity by a thorough description of the particle from *Arabidopsis* using reverse genetics combined with mass spectrometric (MS) analyses of affinity-purified proteasomes. Specific goals are to: (i) define the functions of many of its core subunits, (ii) identify various accessory

proteins that aid in assembly and regulate substrate specificity, (iii) study alternative proteasomes generated by the combinatorial assembly of individual paralogs for many subunits, (iv) define how proteasomes are regulated by post-translational modifications including ubiquitylation, (v) confirm our hypothesis that the 26S proteasome is recycled by autophagy, and (vi) define the proteasome-stress transcriptional regulon that coordinately adjusts synthesis to meet proteolytic demand. Taken together, this project should reveal how the population of 26S proteasomes in particular, and protein turnover in general, are used by plants to regulate their growth, development, and responses to environment. By exploiting this knowledge, we hope to develop strategies to manipulate proteasome levels and functions to benefit agricultural yield, the growth of crops under adverse environments, and the production of renewable biofuels.

FY 2014 HIGHLIGHTS

In 2014, we generated a battery of essential tools and completed a number of objectives. We developed transgenic *Arabidopsis* plants and affinity methods to separately isolate the CP and RP subparticles based on individual isoforms. MS analyses of these seedlings detected a number of interacting factors, including a set of assembly chaperones, including PBAC2, PBAC3 and UMP1 for the CP, and ECM29, NAS2, NAS6, and HSM3 for the RP. We also detected two new factors that likely represent here-to-fore unknown CP chaperones. By MS analysis of isoform-specific particles, we observed the random incorporation of isoforms into 26S proteasomes, indicating the likelihood that distinct proteasome subtypes are not deliberately assembled by plants. By transcriptome studies on *Arabidopsis* deficient in active proteasomes, we identified an extensive regulon impacted by proteasome stress, which includes core and accessory components of the 26S proteasome, assembly chaperones, heat shock proteins, oxidative-stress responsive factors, and a number of transcription factors. Through co-expression, protein interaction, and promoter element studies, we identified a common cis DNA element that binds the NAC-type transcription factors NAC53 and NAC78, that is, at least, partially responsible. Studies with nitrogen-starved and proteasome-inhibited plants revealed that proteasomes are also rapidly removed by autophagy. This inhibitor-induced proteophagy is concomitant with extensive ubiquitylation of the proteasome and involves the ubiquitin receptor RPN10 that also exists in a free form in addition to its integration into the RP subparticle. By simultaneously interacting with ubiquitylated proteasomes and lipidated ATG8 lining the enveloping autophagic membranes, RPN10 helps sequester and transport damaged proteasomes to the vacuole.

Proteomic Study of Brassinosteroid Responses in *Arabidopsis*

Institution: Carnegie Institution of Washington
Point of Contact: Zhiyong Wang
Email: zywang24@stanford.edu
Principal Investigator: Zhiyong Wang
Sr. Investigator(s): Alma Burlingame; California-San Francisco, University of
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

The goal of this research project is to understand the molecular and cellular mechanisms that control plant growth. Specifically, this project uses proteomic approaches to identify cellular proteins that respond to the growth-promoting hormone signal, brassinosteroid, and that contribute to cell growth processes such as cell wall synthesis, secretion of cell wall proteins, and organization of cytoskeleton.

The specific objectives are to (1) develop quantitative proteomic methods to identify brassinosteroid-regulated proteins, (2) identify microtubule-associated proteins that respond to brassinosteroid treatment; (3) study brassinosteroid regulation of cellulose synthases (CESAs); (4) study brassinosteroid regulation of vesicle trafficking. Brassinosteroid (BR) is a major growth-promoting hormone in plants and is considered a major target for increasing biomass productivity. Brassinosteroid controls many major cellular growth processes including chloroplast development, cell wall synthesis, cytoskeleton organization, and vesicle secretion, which are all critical for biomass accumulation. We have established methods of metabolic labeling of *Arabidopsis* for quantitative mass spectrometry analysis, and have identified a large number of BR-regulated proteins in separate cellular compartments. Our study is generating fundamental knowledge of the molecular mechanisms underlying cellular growth, which is important for improving biomass productivity.

FY 2014 HIGHLIGHTS

Microtubules, assembled from tubulins, are important for many cellular activities, including the movement of cells, cargo vesicles transport, cell morphogenesis, cell wall deposition. We performed proteomic analysis of tubulin/microtubule-associated proteins. To achieve high-confidence quantitation, we used the metabolic ¹⁵N-labelling method in our liquid chromatography tandem mass spectrometry (LC-MS/MS) analysis. After immunoprecipitation of tubulin6-GFP (TUB6-GFP) and GFP proteins from metabolic labeled plants, LC-MS/MS analyses identified over 500 proteins as candidates for tubulin-associated proteins. These include about one hundred proteins annotated with functions related to cytoskeleton. Additional proteins include MAP kinases, calcium dependent protein kinases; several phosphatase, the 14-3-3 proteins, actin, actin depolymerizing factors, lipid transfer proteins, and cellulose synthase family proteins. Some of these proteins potentially regulate microtubule functions. We have performed several BR treatment experiments followed by LC-MS/MS analysis, using ¹⁵N-labeling. We purified phosphopeptides from total protein samples of BR treated and untreated seedlings, and LC-MS/MS analysis identified and quantified 11,047 phosphopeptides on 3,135 proteins. We found phosphorylation decreases at 80 sites and increases at 25 sites on 91 proteins upon BR treatment. These include 7 known proteins of the BR pathway, and the rest unknown previously for a function in BR response. These new BR-responsive phosphoproteins represent new links from BR signaling to various cellular processes, including signaling by other receptor kinases, RNA splicing, translation, and crosstalk with other signaling pathways, as well as cellulose synthesis, cation exchangers, microtubule-associated proteins, and vacuolar protein sorting factor. In summary, our proteomic analyses have identified a large number of proteins with potential functions in steroid regulated cellular growth.

Functional Analysis of Plant Sucrose Transporters

Institution: Minnesota, University of
Point of Contact: John Ward
Email: jward@tc.umn.edu
Principal Investigator: John Ward
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

The goal of this project is to develop a fundamental understanding of the mechanism used by plants transport sucrose. The disaccharide sucrose is the predominant sugar transported in the phloem (vascular tissue) in most plants from photosynthetic leaves to tissues that depend on the import of fixed carbon. Sucrose transporters (SUTs) function in loading sucrose into the phloem in source leaves and in sucrose uptake into cells of sink tissue (such as seeds, roots and other non-photosynthetic tissues). Therefore SUTs function at critical points in the phloem transport pathway. Sucrose transporters are encoded by small gene families in plants and are found in three phylogenetic clades (types). This project has successfully analyzed the transport activity of representatives of each of the three types of sucrose transporters encoded by plants. We can now distinguish each Type by their sequence, activity and subcellular localization. The goal of the project is to study the biochemical transport activities (substrate affinity and specificity, regulation by pH and membrane potential) of SUTs and determine specific amino acid positions in SUTs that control differences in function. During the current DOE-funded project we developed a new assay based on uptake of esculin, a fluorescent substrate, by plant sucrose transporters expressed in yeast. We used a modified gene shuffling technique called Synthetic Template Shuffling (STS) to generate libraries of chimeric sucrose transporters. We expressed these libraries in yeast and selected single yeast cells by fluorescence activated cell sorting (FACS) that were able to transport esculin. In this way we were able to identify five amino acid positions that control the differences in substrate specificity between type I and type II SUTs. This is significant because type I SUTs load the phloem in eudicots while type II SUTs load the phloem in monocots. We used this information to switch the substrate specificity of sugarcane SUT1.

FY 2014 HIGHLIGHTS

We previously identified four amino acid positions that control the difference in substrate specificity between type I and II SUTs (Reinders *et al.*, 2012). We hypothesize that mutagenesis of these positions will produce changes in substrate specificity and/or affinity and will be informative about the function of SUTs. We took advantage of two new approaches we developed during the previous funding period: fluorescent substrate-based transport assay for sucrose transporters (Gora *et al.*, 2012) and selection for single yeast cells expressing active sucrose transporters using FACS (Reinders *et al.*, 2012). We used gene shuffling and mutagenic PCR to generate a library of OsSUT1 mutants that have random codons at the four positions. The library was used to transform yeast which were then treated with esculin and subjected to FACS to select mutant OsSUT1 clones that allow yeast to accumulate esculin. In four rounds of yeast transformations followed by FACS we were able to screen 53,000 library clones and select 16 clones that conferred esculin uptake. The results show that two sequences were isolated. This strategy was successful but was labor intensive. We are going to characterize the two novel clones that were isolated and we may return to this strategy. We are using an additional strategy to first look at each of the four positions with all 20 amino acids substituted. All A86 mutants were functional for sucrose uptake when expressed in yeast. The highest activity was achieved with A86K and lysine is the amino acid conserved at this position in type I SUTs. Solubilization tests were performed with StSUT1-6His and we found that after yeast are lysed, the protein could be efficiently solubilized using 1% Triton X100. The protein was then bound to a Talon NTA column and eluted using imidazole.

Secondary Wall Formation in Fiber Cells

Institution: Georgia, University of
Point of Contact: Zheng-Hua Ye
Email: yh@uga.edu

Principal Investigator: Zheng-Hua Ye
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$185,000 (2014)

PROGRAM SCOPE

The objective of this funded project is to carry out biochemical and genetic studies of genes involved in the biosynthesis of xylan, the second most abundant polysaccharide in secondary cell walls. Secondary walls in the form of wood and fibers are the most abundant biomass produced by plants. Understanding how secondary walls are synthesized not only is of importance in basic plant biology but also will potentially provide novel means to modify cell wall composition on the basis of our needs, such as engineering walls more suitable for biofuel production. The goal of this project is to identify and biochemically characterize all the genes involved in xylan biosynthesis. Xylan in dicots is composed of a linear backbone of beta-1,4-linked xylosyl residues, some of which are substituted with glucuronic acid or 4-O-methylglucuronic acid residues and may be acetylated at O-2 and/or O-3. The reducing end of xylan contains a unique tetrasaccharide sequence beta-D-Xylp-(1->3)-alpha-L-Rhap-(1->2)-alpha-D-GalpA-(1->4)-D-Xylp. Xylan from monocots has side chains of arabinosyl residues in addition to glucuronic acid, and the arabinosyl side chains may be cross-linked with each other or with lignin by ferulate. We proposed to genetically and biochemically study genes responsible for xylan substitution and modification. Our proposed work on the study of xylan biosynthesis will not only contribute to our understanding of cell wall biosynthesis in general but also have important economic and agronomic implications, such as providing tools for custom-designing cell wall composition tailored for biofuel production.

FY 2014 HIGHLIGHTS

Xylan, a major polysaccharide in plant lignocellulosic biomass, is acetylated at O-2 and/or O-3 and its acetylation impedes the use of biomass for biofuel production. In *Arabidopsis*, about 60% of xylosyl residues in xylan are acetylated and the biochemical mechanisms controlling xylan acetylation are largely unknown. We have found the essential role of a DUF231 domain-containing protein, ESKIMO1 (ESK1), in xylan acetylation in *Arabidopsis* as the *esk1* mutation caused specific reductions in the degree of xylan 2-O or 3-O-monoacetylation and in the activity of xylan acetyltransferase. Our finding indicates that ESK1 is a putative xylan acetyltransferase required for 2-O- and 3-O-monoacetylation of xylosyl residues in xylan. In *Arabidopsis*, about 10% of xylosyl residues in xylan are substituted with glucuronic acid, of which 60% are methylated at O-4. By contrast, all of the glucuronic acid substituents in *Populus* xylan are methylated at O-4. It is not known how the degree of glucuronic acid methylation in xylan is controlled. We found that simultaneous T-DNA knockout mutations of the three glucuronoxylan methyltransferase genes led to a complete loss of glucuronic acid methylation in xylan in *Arabidopsis* stems. Overexpression of the methyltransferases in wild-type *Arabidopsis* resulted in an up to 5-fold increase in glucuronoxylan methyltransferase activity and as a result, up to 90% of the glucuronic acid side chains in xylan were methylated as opposed to 60% seen in the wild type. Our findings suggest that the degree of glucuronic acid methylation in xylan is largely controlled by the level of methyltransferase activities. We have also performed biochemical characterization of four wood-associated glucuronoxylan methyltransferases in poplar and found that two of them exhibit much higher substrate affinities than *Arabidopsis* ones, which may account for the complete methylation of glucuronic acid residues in poplar xylan.

Cell-Type Specific Hemicellulose Structures in the Root Cell Walls of *Arabidopsis* and *Brachypodium*

Institution: Georgia, University of
Point of Contact: William York
Email: will@ccrc.uga.edu
Principal Investigator: William York
Sr. Investigator(s): Maria Pena; Georgia, University of
Malcolm O'Neill; Georgia, University of
Students: 2 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Hemicelluloses comprise a family of abundant polysaccharides in the cell walls of land plants. These include xyloglucan and xylan. The basic structures of these polysaccharides are highly conserved among all land plants, but the more complex structural features vary from plant to plant and from tissue to tissue. This research tests our hypothesis that the structural features of hemicellulosic polysaccharides are tailored to the biological functions of the cell walls into which they are deposited, distinguishing the walls of different cell types and/or cells at different developmental stages. To achieve this end, we use a combination of chemical, enzymatic, immunological and spectroscopic methods to examine the structures of hemicellulosic polysaccharides with high accuracy and sensitivity. For example, we use monoclonal antibodies to implement immunohistological studies that allow us to visualize specific structural variations in different cells. We also perform detailed structural characterization of hemicelluloses extracted from different plants and from mutant plants in which hemicellulose biosynthesis has been impaired. By comparing the immunohistological and chemical analyses for many different cell types, we are able to distinguish species-specific and cell-specific differences in hemicellulose structure. These analyses continue to support our overall hypothesis and provide the fundamental structural information that is required to understand how these polysaccharides function in different cell walls and how the plant modulates these functions by changing specific aspects of hemicellulose biosynthesis.

FY 2014 HIGHLIGHTS

During 2014, we have continued to investigate the biological functions of hemicelluloses by examining differences in root and root hair walls of monocots and dicots and have expanded our efforts to explore differences in the structures of the hemicelluloses in vegetative (flag leaf) and reproductive tissues (tassels) of maize and differences in the structures of the hemicelluloses in selected members of the Lemnaceae. These results have confirmed our previous results that the cell walls of root hairs, which grow by a different mechanism than most plant cells, contain xyloglucan with distinctive structures. We previously discovered that the xyloglucan in *Arabidopsis* root hairs contain an unusual acidic sidechain not found in other tissues of this plant. We have now cloned and expressed the gene encoding the galacturonosyl transferase responsible for attaching the acidic sugar to the sidechain and are in the process of thoroughly characterizing its biochemical and catalytic activity. We also showed that soybean root hairs contain this unusual acidic xyloglucan structure. In addition, we established that xyloglucan with fucose-containing sidechains and a high degree of branching is present in maize cell walls, but only in specific cell types. We obtained convincing new evidence that xyloglucan lacking certain structural features is dysfunctional and can actually harm the plant more than eliminating this polysaccharide altogether. We look forward to performing systematic structure/function analyses that reveal the molecular bases for our observations.

DOE National Laboratories

Metabolic Plasticity, Macromolecular Organization, and Post-translational Regulation of Lignin Biosynthesis

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: Chang-Jun (C-J) Liu
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$776,000 (2014)

PROGRAM SCOPE

Phenylpropanoid biosynthesis in plant engenders a myriad of phenolics each with specific biological functions. In particular, as one of the structural components of the cell wall, lignin imparts rigidity and strength to vascular tissues but, meanwhile, it lowers the cell wall's digestibility and negatively affects the conversion efficiency of cellulosic biomass to liquid fuels. The long-term goals of this project are to elucidate the molecular- and biochemical- mechanisms underlying the synthesis and deposition of lignin, and to dissect the concurrent regulatory mechanisms of phenylpropanoid-lignin biosynthesis. Ultimately, we anticipate designing and developing novel biotechnological strategies for improved manipulation of the quantity and structure of lignin in the cell wall. Currently, we have two research objectives: 1) To explore the post-translational regulations and the potential macromolecular organization in phenylpropanoid- lignin biosynthesis, and to define their biological significance; and 2) To evolve monolignol 4-O-methyltransferases to modify the conventional lignin precursors, or to produce novel monomeric precursors, and use these to explore the chemical- and biochemical- mechanisms of lignin polymerization and to modulate lignin content and structure. Previously, we demonstrated that chemically modifying the para-hydroxyl of monolignol via an engineered 4-O-methyltransferase substantially reduced lignin content in the cell wall. We are now developing methods to further tailor its substrate specificity to create a subset of functionally specialized enzymes that are able to discriminate particular monolignols, thereby, to disturb the incorporation of particular lignin precursors into lignin polymer.

FY 2014 HIGHLIGHTS

Phenylalanine ammonia-lyase (PAL) is the first enzyme in the pathway directing carbon flux into the phenylpropanoid branch. By Yeast-Two-Hybrid (Y2H) screening, we identified four *Arabidopsis* Kelch repeat-domain containing F-Box (KFB) proteins that physically interact with PAL isozymes, and mediate PALs' turnover via the ubiquitination-26S proteasome pathway. Manipulating KFB genes' expression reciprocally affects the stability of PAL enzymes and the production and accumulation of phenylpropanoids. Our data suggest that KFB-mediated ubiquitination and degradation of PALs act as a post-translational regulation mechanism, negatively controlling phenylpropanoid metabolism. Using Co-Immunoprecipitation coupled with liquid chromatography-mass spectrometry analysis, and the mating-based split ubiquitin Y2H system, we also explored the potential enzyme complexes associated with the membrane-bound P450 enzymes C₄H, C₃H and F₅H, the hydroxylases involved in lignin biosynthesis. We found that those membrane-bound enzymes strongly and specifically interact with a couple of common scaffold proteins, which result in a unique subcellular localization pattern. Previously, we evolved a set

of monoglignol 4-O-methyltransferases (M4OMTs). To further explore their effects on the energy crop's lignification, we expressed a M4OMT variant in poplar, which results in more than a 50% decrease in S-lignin subunit, along with a considerable increase in condensed cross-linkages, pointing to a substantial alteration in lignin composition and structure in the transgenic poplar. Nevertheless, the saccharification efficiency of wood biomass of the transgenic poplar was increased by up to 62%, compared to the control, suggesting that condensation of lignin is not necessarily correlated with the digestibility of wood biomass in poplar, and that M4OMT-mediated alteration of lignin composition might globally affect the cell wall's structure and the interactions between the cell wall's polymers.

Mass Spectrometric Imaging of Plant Metabolites

Institution: Ames Laboratory
Point of Contact: Cynthia Jenks
Email: cjenks@ameslab.gov
Principal Investigator: Basil Nikolau
Sr. Investigator(s): Robert Houk; Ames Laboratory
Young-Jin Lee; Ames Laboratory
Students: 0 Postdoctoral Fellow(s), 11 Graduate(s), 1 Undergraduate(s)
Funding: \$485,000 (2014)

PROGRAM SCOPE

This program is making advances to 1) enhance mass spectrometric imaging (MSI) techniques for determining the distribution of metabolites at very high spatial resolution within plant tissues and cells; and 2) applying these techniques to understand the organization of complex metabolic processes at the levels of single cells and subcellular compartments. Achievements in these interrelated objectives is enabling the unprecedented analysis of genetic stocks that dissect complex metabolic processes and thus bear on the better understanding of biological processes. The application to the plant sciences however, is highly significant to the mission of DOE for the purpose of advanced understanding and thus ultimately the development of technologies for sustainable energy, integrated with food and feed production. This program includes two analytical chemistry groups and a plant metabolic biology group. The team is enabling the integrated development of the imaging technology with its application to the plant sciences, and is thus making significant contributions to the wider plant biology community. This integrated multi-disciplinary team approach is ensuring the development of new technologies to “push” the understanding of complex metabolic processes by enabling the tracking of metabolic intermediates as they move through a distributed metabolic network, and simultaneously become chemically inter-converted. As biological insights are gained via these imaging technologies, are further developing new questions that will “pull” the technology development to enable data acquisition to address specific biological hypotheses. This integrated pull-push strategy that has been developed within this program via the close interactions among the unique team members is further advancing the dissection of plant metabolic biology at high-spatial resolution to levels that are currently unavailable.

FY 2014 HIGHLIGHTS

We made major technological advances that include: 1) ultra-high 5 micron spatial resolution mass spectrometric imaging (MSI) ; 2) enhanced multiplex MSI techniques that increase the speed of data acquisition; 3) development of new matrices for high sensitivity detection of a broader chemical range of plant metabolites; 4) improved sample preparation methods for MSI for analyzing intracellular metabolites; and 5) development of new laser ablation electrospray ionization (LAESI) based MSI using

ultraviolet lasers. These technological advances have been applied to address questions in biological cellular and subcellular imaging of complex metabolic processes, including: 1) C₄ cells of maize leaves; 2) plant-bacterial and plant-insect interactions; 3) specialized metabolism that integrates isoprenoid and polyketide biosynthesis in leaf translucent glands; and 4) cuticle lipid deposition on flower organs.

Quantitative Analysis of Central Metabolism in Seed Storage Synthesis

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: Jorge Schwender
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$679,000 (2014)
PROGRAM SCOPE

Plant biomass is of increasing importance as renewable resources for the production of fuels and of chemical feedstocks that replace petroleum-based materials. Our goal is to increase the basic understanding of the functioning of metabolic processes that define storage metabolism in plants, as a basis for rational engineering of plant storage organs like seeds. By computational modeling of metabolic networks, stable isotope metabolic flux analysis, and biochemical analysis, we study the metabolism of storage synthesis in oil storing seeds. In particular, we study plant species of the cabbage family (oilseed rape, *Brassica napus*, Field Pennycress, *Thlaspi arvense*) that store oil in seeds. Developing embryos are cultured under different light and nutritional conditions. Under each condition, this will provide a detailed view of the particular metabolic state. By comparing the different states, the plasticity of the central metabolism network is revealed. Together, this will increase understanding of the biochemical processes involved in partitioning carbon and nitrogen into seed storage compounds. These studies support the DOE mission to perform fundamental research to lay scientific foundations for new and improved energy technologies. In particular, the analysis and optimization of biochemical pathways relates to fundamental understanding of chemical transformations, photosynthetic energy conversion and energy flow in living systems. This research impacts numerous DOE interests, including improved biochemical pathways for biofuel production.

FY 2014 HIGHLIGHTS

We explored to which extent changes in metabolic flux in central plant metabolism can be inferred by changes in transcripts and metabolites. For this purpose two oilseed rape (*Brassica napus*) accessions which contrast for seed lipid accumulation were compared. On the basis of Metabolic Flux Analysis with *in vitro* culture of immature embryos, the flux distribution in the central metabolism network of both genotypes was determined. In parallel to the flux analysis, metabolite levels of 79 metabolic intermediates within the central metabolism were determined and transcriptome analysis was performed. We found that a large number of genes were differentially transcribed in the two genotypes, including some enzymes/proteins active in major metabolic pathways. However, with a few exceptions, differential activity in the major metabolic pathways was not reflected in contrasting abundances of the relevant transcripts. The conclusion was that transcript abundance on its own cannot be used to infer metabolic activity/fluxes in central plant metabolism. This limitation needs to be borne in mind in evaluating transcriptome data and designing metabolic engineering experiments.

Modification of Plant Lipids

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: John Shanklin
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,019,000 (2014)

PROGRAM SCOPE

This program is designed to provide fundamental understanding of chemical transformations and energy flow in systems relevant to DOE missions. Specifically to understand the molecular mechanisms involved in the capture of light energy and its conversion into chemical energy through biological pathways. Our overall goal is to create the knowledge needed to improve plant and microbial oils as alternative and improved energy and chemical feedstocks; which will contribute to United States energy and fossil feedstock independence. Lipids and oils are energy-dense compounds that occur in a wide variety of forms, including the storage lipids of higher plants. The molecular mechanisms involved in chiral lipid-modification reactions using fatty acid desaturation as a model are being studied. X-ray crystallography, spectroscopy, molecular genetics, and biochemistry are employed to probe structure-function relationships within these enzymes. Understanding the factors that control the selectivity and specificity of these processes is allowing us to redesign lipid-modification enzymes with improved function. The ultimate goal of this program is to provide the knowledge to enable the optimization of chemical transformations necessary for creating improved plant lipid accumulation in non-food crops.

FY 2014 HIGHLIGHTS

Studies on the oligomerization led to the finding that FAD2 and FAD3 desaturases form hetero-dimers that facilitate metabolic channeling *in vivo*. This finding has implications for the engineering of unusual fatty acid accumulation in crop plants and was published in the Journal of Biological Chemistry. In a follow up study to our work in *Arabidopsis* regarding the engineering of omega 7 fatty acids as renewable chemical feedstocks, we engineered the crop plant camelina to accumulate greater than 70% of omega 7 fatty acids in its seeds. This represents a new source for this feedstock that is an alternative to petrochemicals and was published in the Plant Biotechnology Journal. Collaborative work with BNL PI Changcheng Xu resulted in the elucidation of the triacylglycerol accumulation pathway in *Arabidopsis*. This work resulted in double mutants that accumulated approximately 7% oil in plant leaves. This work, published in The Plant Cell lays the foundation for engineering crop plants to accumulate oil in their leaves as well as in their seeds.

Intracellular Lipid Transfer in the Biosynthesis of Photosynthetic Membranes Lipids and Storage Triacylglycerol

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: Changcheng Xu
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$485,000 (2014)

PROGRAM SCOPE

Intracellular lipid transfer is essential for membrane proliferation, organelle biogenesis and accumulation of storage lipids, but the underlying molecular mechanisms of lipid transfer remain elusive. The overall goal of this project is to understand the molecular mechanisms involved in the biosynthesis and intracellular trafficking of lipids in plants. The specific objectives are to: (1) identify the genes affected in two lipid-trafficking mutants isolated in a forward genetic screen; (2) determine the functional role of the encoded proteins at the molecular, biochemical, and physiological levels; and (3) investigate oil biosynthesis and regulation in vegetative tissues of plants. The results from this study should create the knowledge base to enhance our ability to manipulate the processes that regulate photosynthetic membrane biogenesis and carbon storage in plants, and lay the intellectual foundation for future engineering endeavors aimed at the development of novel biomass crops for the production of nutrition-rich feed and renewable fuels.

FY 2014 HIGHLIGHTS

Two mutant loci were identified through a map-based cloning approach. One encodes a putative membrane protein of unknown function and was designated trigalactosyldiacylglycerol5-1 (*tgd5-1*) because the mutant accumulates trigalactosyldiacylglycerol in leaves similar to previously described four *tgd* mutants. Genetic analysis showed that TGD5 functions in the same lipid trafficking pathway as TGD4. Chloroplast import assays revealed that TGD5 is localized in envelope membranes of the chloroplast. The second mutant locus represents a new allele of *tgd2* mutants. Additional work focused on analyzing the pathway of triacylglycerol (TAG) biosynthesis and its physiological significance in vegetative tissues of plants. We found that phospholipid: diacylglycerol acyltransferase (PDAT) is critical in mediating oil biosynthesis in rapidly growing tissues. Disruption of PDAT1 in the *tgd1-1* mutant background causes serious growth retardation, gametophytic defects and premature cell death in developing leaves. Lipid analysis data indicated that knockout of PDAT1 results in increases in the levels of free fatty acids and diacylglycerol. *in vivo* radiotracer labeling experiments showed that, compared with wild-type, *tgd1-1* exhibits a 3.8-fold higher rate of fatty acid synthesis, which is unaffected by disruption or over-expression of PDAT1. Coexpression of PDAT1 with oleosin boosts leaf TAG content by up to 6.4% of the dry weight without affecting membrane lipid composition and plant growth. PDAT1 overexpression stimulates fatty acid synthesis and increases fatty acid flux toward the prokaryotic glycerolipid pathway. The combined overexpression of PDAT1 with oleosin in *tgd1-1* increases leaf TAG content to 8.6% of the dry weight and total leaf lipid by fourfold. Collectively, these results reveal a dual role for PDAT1 in enhancing fatty acid and TAG synthesis in leaves, thereby protecting against free fatty acid-induced cell death in fast-growing tissues of plants.

Separations and Analysis

Sr. Investigator(s): Paul Lahti; Massachusetts, University of
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$420,000 (2014-2017)

PROGRAM SCOPE

Our research is focused on development of new material platforms and analytical spectroscopy methodologies for probing inter- and intra-molecular electronic processes in conjugated nanomaterials. A detailed understanding of the connection between molecular architecture, supramolecular/polymer assembly, and optoelectronic function is critical to the improvement in polymer-based optoelectronics, yet many questions remain outstanding as to how to 'program' specific inter-molecular couplings via molecular structure in order to achieve desired device performance (photostability, charge-separation and charge-transport efficiency). We combine single-molecule spectroscopy tools and new synthetic methodologies to probe intra- and inter-molecular coupling in small-molecule, oligomeric complex structures and crystalline nanoscale supramolecular assemblies in order to understand in detail, the structure-excitonic property relations and elucidate molecular design rules (distances, angles, etc.) for improved performance in organic optoelectronics.

FY 2014 HIGHLIGHTS

The family of rylene dyes is attracting wide research interest as a material platform for small-molecule organic electronics. Recent synthetic work has realized a novel (n-type) small-molecule acceptor, 7,8,15,16-Tetra-aza-terrylene (TAT), single-crystals of which can be grown oriented along the c-axis crystallographic direction for use in organic photovoltaic devices. However, characterization of single TAT crystals reveals highly variable emission spectra and excited state dynamics – properties that strongly influence photovoltaic performance. With our chemical imaging techniques (combined wavelength and time-resolved photoluminescence and resonance Raman imaging) applied to isolated single-crystals, we were able to show that this variability derived from crystal packing defects. This work has recently been published as a cover feature in *PhysChem ChemPhys* (PCCP 16, 15825, 2014) and more recently featured in *Materials Today* (17, 464, 2014). The TAT system also presents an interesting platform for probing directional exciton coupling and charge-separation processes. In a recent collaborative paper published in the *Journal of Physical Chemistry C* ("H-J Aggregate Behavior of Crystalline Tetraazaterrylene: A New Design Paradigm for Organic Materials," 118, 28842, 2014) we showed that crystalline TAT exhibits two distinct coupling mechanisms: A Frenkel (point-dipole) excitonic coupling that is oriented primarily transverse to the crystal growth axis (i.e. along the pi-stacking direction), and a charge-transfer interaction that is oriented primarily parallel to the crystal growth axis. The former gives rise to spectroscopic signatures associated with H-aggregates, while the latter gives rise to J-aggregate behavior. This presents some very exciting opportunities to probe

orientational effects on isolated nanocrystals to, for example, selectively excite charge-transfer states with linearly polarized excitation.

Combinatorial and High Throughput Membrane Synthesis and Testing: Tailoring Membrane Surfaces to Applications

Institution: Rensselaer Polytechnic Inst.
Point of Contact: Georges Belfort
Email: belfog@rpi.edu
Principal Investigator: Georges Belfort
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$160,000 (2014-2016)

PROGRAM SCOPE

The goals of our 3-year research program are to expand, refine and optimize the discovery and separation characteristics of new surfaces using the 96-membrane well format with the high throughput-atmospheric pressure plasma (HTP-APP) method and to elucidate the behavior of protein-resistant chemistries. In short, we use combinatorial chemistry to prepare a vastly expanded library of vinyl monomers (AIM 1), graft these newly synthesized monomers, test their efficacy for improving filtration performance, and select winners (AIM 2); fine-tune the grafting and filtration conditions of selected winners (AIM 3), and investigate the underlying mechanistic reasons why the successful monomers are able to perform best (AIM 4). That is, we wish to use combinatorial chemistry to prepare an expanded library of vinyl monomers for APP-grafting of PES UF membranes. Then, use our high throughput 96 membrane-well format to graft, test, and screen for the best performing graft polymerized membranes from Aim 1 using single protein feed filtration. Based on the screening results, we optimize and fine-tune the grafting and filtration conditions of selected winners using our high throughput 96 membrane-well format. Finally, we investigate the underlying mechanistic reasons why the successful monomers are able to perform best. The mechanism can be probed using various different analytical techniques, such as 2D Nuclear Magnetic Resonance (2D NMR), Sum Frequency Generation (SFG), and Mass Spectrometry (MS). We believe that fundamental mechanistic understanding of protein interactions at surfaces and with water will give great insight into the fouling process.

FY 2014 HIGHLIGHTS

Using combinatorial chemistry, a set of diverse monomers were synthesized and tested using our unique high-throughput screening platform to reduce biological fouling on synthetic filtration membranes. To demonstrate its efficacy, the novel monomers were graft-polymerized onto light sensitive poly(ether sulfone) (PES) membranes via Atmosphere Pressure Plasma (APP) polymerization (AIMs 1 & 2). A diverse library was synthesized by reacting a common vinyl ester linker with a library of maleimides containing various different functional groups. This allowed us to produce a library of nine different surfaces and graft them all using the same linker chemistry. Some of the chemistries discovered here are novel R groups (tri-cyclic, ester, azo, and heterocyclic) while others (amide, carboxylic acid, zwitterionic, PEG, and hydroxyl) have been known for some time. This allowed for screening new and interesting monomers and comparing them directly with previously identified “winners”. The modified surfaces were then tested and screened for the best protein-resistant (non-fouling) properties (AIM 3). Membranes, functionalized with carboxylic acid, zwitterionic, and ester groups, had the lowest protein adhesion compared with an unmodified control PES membrane after a static fouling test. After dynamic

fouling, these same functionalities as well as a hydroxyl group exhibited the highest permeability. These monomers performed better than our best previously synthesized amide monomers as well as our best PEG monomers. Hansen solubility parameters qualitatively predicted which monomers performed best indicating favorable interactions with water molecules. Mechanism studies (AIM 4) with SFG and MS were initiated in collaboration with Prof. Poul Petersen, Cornell University, and Prof Daniele Fabris, University at Albany, respectively. Two provisional patents were applied for in 2014: One on chiral surfaces and the other on a new class of synthetic brush membranes.

Molecular Aspects of Transport in Thin Films of Controlled Architecture

Institution: Notre Dame, University of
Point of Contact: Paul Bohn
Email: pbohn@nd.edu
Principal Investigator: Paul Bohn
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$330,000 (2013-2014)

PROGRAM SCOPE

The project has two major objectives. (1) We seek to understand the complex factors that couple reactions to transport when confined in nanoscale architectures. We are developing both single molecule and ensemble measurements to determine the fundamental chemical and physical factors that determine how transport and reactivity are coupled under confinement and crowding in nanocavities, nanopores and nanochannels. We employ single molecule studies of bound redox enzymes and small molecule fluorophores in order to understand redox processes under confined conditions, studying both chemical redox processes catalyzed by oxidoreductase enzymes and electron transfer to small tethered electroactive molecules. In addition, we study electron transfer in nanoscale architectures under conditions designed to alter the fundamental kinetics, e.g. with an added electrocatalyst or in the presence of surface-bound or solution-phase viscosogens. (2) We study reactions in organized geometries that support vectorial transfer of reactants and products in sequential chemical transformations. Quasi-one-dimensional flow in nanopores and nanochannels - characterized by extreme anisotropy between radial and axial transport - presents opportunities to organize coupled reactions for high efficiency chemical transformations. We are studying reactions in special architectures, where chemical reactions are directed to occur at specific locations. This allows us to model and construct high efficiency nano-reactors using electrochemical and photochemical driving forces to generate small molecule reagents at high efficiency in confined geometries. In addition, we utilize both enzymes (oxidoreductases) and inorganic catalysts downstream to carry out high efficiency reactions with the reagents generated *in situ* at the upstream site, thereby leveraging the quasi-1D nature of the flow structure to sequence chemical transformations in space and time.

FY 2014 HIGHLIGHTS

We completed studies of nanopore-mediated redox cycling events and vectorial coupling of transport and electron transfer under both weak-coupling (microchannel) and strong-coupling (nanochannel) conditions. The nanopore-mediated electron transfer studies illustrated the unusual features of chemical reactions carried out in sub-fL volumes, showing, for example, a 100x increase in current at low concentrations when voltammetry is carried out without a background electrolyte, thus implicating electromigration as an effective means of mass transport at the nanoscale. Studies of electron transfer

coupled to electrokinetic flow in the weak coupling conditions that apply in microscale fluidic environments show a split of the applied potential between components that (a) drive fluid motion (iR drop) and (b) drive heterogeneous electron transfer. A model was developed that quantitatively explains the electrochemical behavior under weak coupling. Under the strong coupling conditions that apply in a nanofluidic environment, this is no longer possible, but the shifts in electrochemical waves can still be understood based on the coupling of electric fields generated by the external (field-inducing) electrode and the working electrode. These studies together illuminate the special character of electron transfer reactions carried out in nanometer-scale structures where the physical scaling lengths characteristic of electrified fluids, e.g. Debye length, are commensurate with the size of the structure.

Targeting DOE-Relevant Ions with Supramolecular Strategies

Institution: Kansas, University of
Point of Contact: Kristin Bowman-James
Email: kbjames@ku.edu
Principal Investigator: Kristin Bowman-James
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

The effectiveness of three popular strategies for supramolecular anion recognition is being evaluated and compared targeting ions important to the DOE mission, particularly tetrahedral ions such as sulfate and perrhenate. The goal of the first objective is to assess the influence of secondary, tertiary and quaternized amines as well as macrocyclic size on anion binding using mixed amine/amide macrocyclic hosts. Competitive binding studies are focusing on ions of differing charges: perrhenate (-1) as a surrogate for pertechnetate, sulfate (-2), and phosphate (-3). These ions are problematic in tank remediation (Low Activity Wastes, High Level Wastes, and in tank run-off). The goal of another objective is to synthesize connected molecular organic frameworks (MOFs) to leverage and expand the anion binding capabilities of the hosts. Ag(I) (noted for its linear coordination propensity) is being used for one-dimensional MOFs, and Pd(II) and Pt(II) for square arrays. A new “duplex” Pd(II) connector is also being explored for additional linear MOF linkages. Pyridine groups appended to the macrocycles are being used to link the hosts through metal ion coordination. The goal of a third objective is to explore tricyclic molecules with both anion and cation binding sites as ion pair hosts. The targeted cation in these studies is cesium ion, due to the relevance of cesium-137 in nuclear waste remediation.

FY 2014 HIGHLIGHTS

During the past year, we made considerable progress on refining synthetic strategies for hosts and on the development of novel extended molecular frameworks based on macrocyclic anion hosts. In the area of synthetic strategies, we are now able to isolate significant quantities of 3+3 and 4+4 condensates of diethylene triamine or dipropylene triamine with 2,6-disubstituted pyridines. These expanded macrocycles could potentially bind multiple anions/cations. We also found that mixed amide/amine macrocycles that possess at least one secondary amine readily react with carbon dioxide in the atmosphere, forming 1:1 (in the 2+2 macrocyclic condensate) and 1+2 (in the 4+4 macrocyclic condensate) macrocycle:carbon dioxide adducts. The resulting carbamates are stabilized by intramolecular hydrogen bonding, but carbon dioxide is released on heating. This chemistry is being explored further. Exciting progress has been made in the synthesis of extended macrocyclic molecular

frameworks. We have successfully attached pyridine side-chains to the 2+2 macrocycles, resulting in two arms for linking macrocycles through metal ion coordination. We have also isolated and crystallographically characterized a Ag(I)-connected extended framework in the 2+2 adduct and a single macrocyclic unit with Pd(II) pincer complexes attached to the two pendant pyridines. While binding studies indicate that the new complexes bind anions, we have no structural specifics as to mode of binding to date. To extend the dimensionality of the pincer-containing macrocycles, we synthesized and crystallographically characterized what we believe is the first example of a di-Pd(II) “duplex” pincer complex with a 2,3,5,6-tetraamido-substituted pyrazine. A porous gelatin-like salmon-colored product is obtained when the di-Pd(II) duplex is reacted with the pyridine-appended 2+2 macrocycle. The physical and chemical properties of this jello-like product are currently under investigation.

Electrically Driven Ion Separations in Permeable Membranes

Institution: Michigan State University
Point of Contact: Merlin Bruening
Email: bruening@chemistry.msu.edu
Principal Investigator: Merlin Bruening
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

This project explores whether applied electrical potentials can greatly enhance rejections and selectivities in energy-efficient, membrane-based ion separations. Thus, one facet of the research includes synthesis of dense membranes with conductive skins to enable application of electrical potential drops at the membrane surface. Positive membrane potentials with respect to the feed solution should lead to exclusion of cations and provide selectivity between cations with differing charge. At sufficiently high potentials, exclusion of cations may lead to complete salt rejection, which is potentially valuable for desalination. However, the effects of applied potential are greatest at low ionic strength. Thus, the combination of applied potentials and a membrane skin that dissolves only a low concentration of ions may prove especially powerful. A second area of the research applies potentials across porous membranes to investigate whether countercurrent electrophoresis can separate ions in membranes with high throughput. In these separations, convective flow forces ions through the membrane, whereas electromigration moves ions in the opposite direction. This leads to extensive rejection of ions with high electrophoretic mobilities and less rejection of ions with lower mobilities to give high selectivities. However, challenges in these separations include concentration polarization at the membrane-feed interface and inhomogeneous flow. Current research aims to overcome these challenges. The final area of this research examines electrodialysis through remarkably selective polyelectrolyte multilayer films on ion-exchange membranes. Electrically driven transport yields much higher selectivities than flow through membranes because significant flow occurs through membrane defects. Studies of selectivity as a function of ion concentration and current density are elucidating the effects of concentration polarization and ion adsorption on these separations.

FY 2014 HIGHLIGHTS

Electrodialysis membranes typically exhibit modest selectivities between monovalent and divalent ions. In contrast, this research shows dramatic enhancement of the monovalent/divalent cation selectivities of ion-exchange membranes through coating with multilayer polyelectrolyte films. Remarkably, even

with overlimiting currents, K^+/Mg^{2+} electro dialysis selectivities reach values >1000 , and similar monovalent/divalent cation selectivities occur with feed solutions containing K^+ and Ca^{2+} . For comparison, the corresponding K^+/Mg^{2+} selectivity of the uncoated membrane is only 1.7. When the source phase contains high salt concentrations (0.1 M KNO_3 and 0.1 M $Mg(NO_3)_2$), K^+ carries essentially all the current, and the K^+/Mg^{2+} selectivity is $>20,000$, presumably because the applied current drops below the diffusion-limited value for K^+ . The high selectivities of these membranes may enable electro dialysis applications such as purification of salts that contain divalent or trivalent ions. Studies of countercurrent electrophoresis show that applied potentials lead to selective rejection of K^+ compared to Li^+ . However, concentration polarization limits both rejection and selectivity in this system, so future work will examine new cross-flow geometries. Other research highlights include development of methods to coat membranes with a thin, conducting Au layer to apply electrical potentials at the membrane surface. The coating procedure includes formation of Au nanoparticles and subsequent electroless deposition.

Preparation of Chemically Functionalized Surfaces through Ion Soft Landing and Ion/surface Reactions under Vacuum and in the Ambient Environment

Institution: Purdue University
Point of Contact: Robert Cooks
Email: cooks@purdue.edu
Principal Investigator: Robert Cooks
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$330,000 (2013-2014)

PROGRAM SCOPE

This project seeks to explore the capabilities of gas-phase ions as reagents to modify surfaces. The method of interest is ion soft landing (SL), where low energy atomic and polyatomic ions are deposited onto surfaces. Traditionally, SL experiments are performed under vacuum where there is exact control of the chemical nature of the reagent, but limitation in the number of ions available for surface modification (low current). To circumvent this, our lab has demonstrated the ability to modify surfaces in the ambient environment, where higher currents are possible at the cost of complete control of the chemical nature of the reagent ions. With these abilities, we began to seek methods to produce surfaces of highly desirable chemical properties, including catalytic properties. New ionization methods are being developed which produce both atomically precise and larger nanoparticles. The properties of the nanomaterials are being investigated for uses in catalysis, surface enhanced Raman spectroscopy, and electrochemistry. Collaborations with PIs T. Pradeep (IITM, India) and Libor Kovarik (PNNL, WA) are carried out to expand the applicability of ion deposition modified surfaces.

FY 2014 HIGHLIGHTS

Ambient ionization and deposition of noble metals (Au, Ag, Cu, Pd) has been developed to synthesize nanomaterials for heterogeneous catalysis. Electrolytic spray ionizes bulk noble metals directly to atomic dispersion in the charged spray plume. Depositing this plume creates noble metal clusters and nanoparticles without capping agents, which is ideal for heterogeneous catalysis. A heterogeneous redox catalysis reaction was carried out in solution phase, the result of which indicated that the catalyst prepared in this way is extremely active and efficient. Adding ligands to the electrolytic spray solution, organometallic catalyst was synthesized and used for polymerization reactions. Besides individual

nanoparticles for heterogeneous catalysis, ambient noble metal ion beams have been used to modify surfaces to create functional materials. Depositing noble metal ion plumes onto various surfaces, composite nanostructures have been created *in situ*. Nanostructured surface patterns have been created by electrostatically manipulating the ion plume. The modified surfaces were functionalized using only nanograms of noble metal. Surface enhanced Raman spectroscopy (SERS) has been carried out to demonstrate the rapid surface modification for optical sensing applications. Another new ionization source for production of atomically precise metal clusters based on electrospray ionization was developed. Metal salts of interest are electrosprayed, passed through a heated loop, and undergo harsh collisions, allowing for the decomposition of the metal salt to produce atomically precise metal clusters. This ion source has been used to generate cluster cations and anions of silver, palladium, and bimetallic palladium-silver. These ions have been reacted in the open air with various reagents to study their initial reactivity, and study of their reactivity under vacuum is underway for industrially important reactions such as propylene epoxidation.

Fluoropolymers, Electrolytes, Composites and Electrodes

Institution: Clemson University
Point of Contact: Stephen Creager
Email: screage@clemson.edu
Principal Investigator: Stephen Creager
Sr. Investigator(s): Joseph Thrasher; Clemson University
Darryl DesMarteau; Clemson University
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

New fluoroionomer electrolytes and fluoroionomer / carbon nanocomposite electrodes suitable for use in fuel cells, batteries and other electrochemical devices (e.g. water desalination, electrodialysis, flow batteries) are being created and their properties examined. Work is pursued in three principal areas; (1) new fluorinated monomers and ionomers; (2) membrane separators made from new ionomers; and (3) catalytic electrodes made from fluorinated ionomers combined with nanoporous carbon electrocatalyst supports. The research exploits a unique capability at Clemson University for the safe handling of large amounts (kilogram quantities) of tetrafluoroethylene (TFE) gas, as is needed to make experimental quantities of new TFE-based fluoropolymer ionomers. New ionomers and ionomer / carbon nanocomposite electrodes are created with the aim of simultaneously increasing transport rates for electrons and ions, and fuels, oxidants and water, throughout the full three-dimensional structure in fuel-cell and battery electrodes and membrane separators. The combination of high-activity electrodes with high-conductivity fluoropolymer ionomers having very good chemical and thermal stability will provide a route to devices having high activity and long service life.

FY 2014 HIGHLIGHTS

Tetrafluoroethylene (TFE) is normally a highly explosive gas but we have found that when mixed with CO₂ it may be rendered completely safe. Fundamental studies on the relative reactivity of various trifluorovinylether (TFVE) monomers with TFE were pursued with the aim of understanding how to combine monomers to achieve specific ion-exchange capacities in ionomers. New TFVE monomers containing organocation groups as hydroxide salts were studied with the aim of preparing alkaline fluoropolymer ionomers suitable for use in alkaline exchange membrane (AEM) fuel cells. Alkaline fuel

cells offer the prospect of electrochemical energy conversion with a dramatically diminished need for platinum-group-metal catalysts, but they have not yet been widely developed due principally to limitations on the alkaline stability of ionomers. We hope to create new ionomers having high ionic conductivity with much improved alkaline stability. We also studied the properties of mixed ionic / electronic conductive (MIEC) electrodes. We reported a means for independently measuring electronic and ionic contributions to electrical conductivity and are using that method to study new electrodes made from mesoporous carbon supports in which fluoroionomer electrolytes are covalently bound to the interior of the support pores. These studies will reveal the degree to which ionomer electrolytes can facilitate ion transport inside the pores of mesoporous materials, as is needed to achieve high activity. We also reported on the oxygen reduction reaction (ORR) activity of platinum catalyst on supports that had been modified by covalent attachment of fluoropolymer electrolyte. Specific ORR activity was increased by approximately 20% for supports having bound electrolyte relative to those that did not.

Separations and Analysis using Bipolar Electrodes

Institution: Texas-Austin, University of
Point of Contact: Richard Crooks
Email: crooks@cm.utexas.edu
Principal Investigator: Richard Crooks
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our objective during the current project period was to further understand and expand bipolar electrodes (BPEs) employed for: (1) the efficient evaluation of large arrays of electrochemical catalysts and (2) to perform continuous ion separations. BPEs do not require a direct electrical connection because they can be powered by an externally applied potential bias. Therefore, BPEs lend themselves to the rapid parallel analysis of dense microscale arrays of electrochemical catalyst candidates where making direct electrical measurements is difficult and serial readout slows throughput. With regard to our separations work, we have combined our experiments with numerical simulations carried out by our collaborator, Prof. Ulrich Tallerek (Philipps-Universität Marburg, Germany). These simulations have supplemented our experiments to provide an increased understanding of the underlying physical phenomena driving BPE driven ion separations.

FY 2014 HIGHLIGHTS

Bipolar electrodes (BPEs) provide a powerful and convenient means for evaluating electrocatalyst candidate materials in parallel for electrochemical reactions related to energy applications. BPEs used for screening experiments rely on the fact that the two types of electrochemical reactions, oxidations and reductions, must occur at the same rate because of electroneutrality. This means that an oxidation reaction (for example) can report on the progress of an electrocatalytic reduction reaction. The main advantage of BPEs for screening is that large arrays of electrodes can be operated and monitored in parallel using simple instrumentation: a DC power supply and an optical microscope. Our approach for screening electrocatalysts using BPEs is simple: candidate catalyst materials are dispensed onto the cathodic poles of individual BPEs, the arrays are placed inside a bipolar electrochemical cell consisting of a confined fluidic space and a pair of driving electrodes, the fluidic space is filled with electrolyte solution, and then a voltage is applied between the two driving electrodes. This results in the reductive

screening reaction being driven at the same time and same rate as a reporting oxidation reaction, such as the electrodisolution of a thin metal film. During this project period we used BPEs to screen 11 distinct compositions of each of three bimetallic electrocatalysts and tested their effectiveness for the oxygen reduction reaction (ORR). The Pd-Co electrocatalysts proved to be more effective than the Pd-Au or Pd-W bimetallic analogs. However, we showed that interpretation of the results of studies such as this requires caution due to catalyst instability and differences in the morphologies of the catalysts that depend on the relative amounts of the two metals present.

Self-Assembled Ionophores: Continuing in New Directions

Institution: Maryland, University of
Point of Contact: Jeffrey Davis
Email: jdavis@umd.edu
Principal Investigator: Jeffrey Davis
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

Overall research goals: Our goal is to build “self-assembled” ionophores that selectively bind and transport ions. We have used non-covalent interactions to synthesize such receptors. For example, lipophilic guanosine nucleosides hydrogen bond to give G-quadruplexes that selectively bind and transport cations. We have also developed a series of anion transporters based on molecular self-assembly strategies. Our goals include: 1) learning how to control structure & dynamics of self-association and ion binding; 2) design self-assembled ionophores that selectively bind various ions and 3) construct supramolecular structures that function as synthetic ion channels.

FY 2014 HIGHLIGHTS

Supramolecular Assemblies that Form Robust and Functional Hydrogels. We recently published a communication in the Journal of the American Chemical Society (DOI: 10.1021/ja507506c) that described an extraordinarily stable and functional hydrogel made from guanosine and potassium borate. We took advantage of the self-assembly of guanosine to make supramolecular hydrogels for use in drug delivery, cell culture, and tissue engineering. The hydrogel remains intact for over a year in salt water. The hydrogel assembles into G·K⁺ quartets. Borate ions enhance its self-assembly by reacting with guanosine, we found by examining the hydrogel with cryogenic transmission electron microscopy, circular dichroism, and solid-state NMR spectroscopy. We introduced cationic dyes, as well as other nucleosides, into the gel. The gel's stability and adaptability to these additions suggest that it could be developed for a variety of clinical and research applications, including metal ion separations.

New Cl⁻ Anion Receptors/Membrane Transporters. We extended our use of self-assembly to prepare compounds that transport Cl⁻ and HCO₃⁻ anions across bilayer membranes. Using liposomes we compared the H⁺/Cl⁻ co-transport activity and the Cl⁻/HCO₃⁻ anion exchange properties of a series of synthetic molecules and natural products, the prodigiosins. These compounds' ability to transport Cl⁻ and HCO₃⁻ at micromolar concentrations, their low molecular weight and simple preparation make them lead platforms for building new approaches toward selective ion separations.

Optical Mass Spectrometer and Photoacoustics

Institution: Brown University
Point of Contact: Gerald Diebold
Email: Gerald_Diebold@brown.edu
Principal Investigator: Gerald Diebold
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

Experiments are being carried out to determine the characteristics and sensitivity of a photoacoustic pyrometer. The device is based on a photoacoustic cell equipped with two entrance windows to a single chamber, which, when irradiated by two different sources with different radiances, an acoustic signal is generated. When calibrated, the pyrometer has the capability to determine temperature differences. The salient characteristic of the pyrometer is that a null can be determined with high precision as a result of the remarkable sensitivity of the photoacoustic effect. To date, experiments have shown a sensitivity of tens of mK for the temperature difference between two black radiators. A theory for the motion of a sphere in an intensity modulated, focused light beam has been formulated. It has been shown that the motion of the levitated object obeys an inhomogeneous Mathieu equation. As such, there are regions of stable, oscillatory motion and other regions where the amplitude of motion is large. By varying the modulation frequency, it has been shown that the ratio of the optical force to the gravitational force can be determined. When an additional force from, for instance, gas flow is included, the mathematics show that it is possible to determine the mass of the particle. Experiments are proceeding to realize a device capable of measuring radiation forces and masses of levitated objects. In another project, the mathematics for a photoacoustic effect excited by continuous radiation have been developed to show that spontaneous oscillation of an absorbing gas in a resonator is possible. The principle of the effect is based on the fact that a photoacoustic increase in pressure at an antinode of a resonator is accompanied by an increase in absorption. Research is being carried out to determine if the effect can be generated with a carbon dioxide laser.

FY 2014 HIGHLIGHTS

Experiments have shown the feasibility of using a special photoacoustic cell that alternately views two surfaces through two optical chopping wheels as an infrared "optical" pyrometer. The device generates a signal proportional to the difference in the infrared radiation flux from the two bodies. An important feature of the pyrometer is that it is based on the photoacoustic effect, which is known to have high sensitivity to weak absorptions. As a consequence, the pyrometer becomes a highly sensitive null detector so that the radiance of one object can be compared with that of a standard. Experiments have shown that the device can detect temperature differences of 49 mK for two blackened surfaces. When a short pulse laser irradiates an optically absorbing surface in a transparent fluid, enormous thermal gradients are produced between the surface and the fluid. For instance, for a 1 J, 10 ns laser beam directed at an absorbing water layer having an absorption coefficient of 0.1 cm^{-1} , temperature gradients on the order of 105 K m^{-1} are generated. A theory showing the effects of large thermal gradients on photoacoustic waveforms has been completed based on a new wave equation derived from the coupled differential equations that describe the photoacoustic effect. The wave equation predicts high frequency pressure transients caused by rapid heat flow generated as a consequence of the laser-induced thermal

gradients. In experiments using a 10 ns, 532 nm beam from an Nd:YAG laser used to irradiate weakly absorbing bodies and thin films, the waveforms predicted by theory have been shown to exist.

Binding Anions Selectively with Modular Triazolophanes and Releasing Them with Light

Institution: Indiana University
Point of Contact: Amar Flood
Email: aflood@indiana.edu
Principal Investigator: Amar Flood
Sr. Investigator(s): Krishnan Raghavachari; Indiana University
Students: 0 Postdoctoral Fellow(s), 6 Graduate(s), 1 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

The goals of this project are to (Aim 1) investigate the fundamental properties of shape-persistent receptors for selectively recognizing polyatomic large anions, and, (Aim 2) to regulate anion concentrations using light-active receptors. This knowledge should provide practitioners with greater guidance during the design of receptors for specific goals: e.g., in the light-gated extraction of specific anionic salts of radionuclides for the management of waste in the nuclear fuel cycle.

FY 2014 HIGHLIGHTS

Towards Aim 1, we have been investigating how to design receptors for polyatomic anions with potential for use in the nuclear fuel cycle. To this end, we examined bifluoride recognition, a linear triatomic anion, F-H-F. Initial computations indicated bifluoride and chloride to have similar binding to the triazolophanes in gas phase. However, solution studies showed they were different. Computations suggested a tilting of the bifluoride could account for the difference. Structural variations to the triazolophane were screened using density functional theory yielding a design that eliminated tilting. Correspondingly, the bifluoride binding affinity was now found to match chloride. Our findings demonstrate the promising ability of computer-aided design to fine-tune the match between receptors and a desired anion. (J. Am. Chem. Soc. 2014, 136, 5078) We have encountered a challenge in describing polyatomic anions because their charges are situated on multiple sites thus creating issues with the design of receptors. We have started to address this challenge using cyanide as a model anion. We used three approaches to show the N end of cyanide forms slightly better hydrogen bonds even though it is not the site of protonation or covalent bond formation. (J. Phys. Chem. A 2014, 118, 7418)

Towards Aim 2, aryltriazole-based foldamers have been created to catch and release Cl anions upon light irradiation of end-appended azobenzenes. A hydrogen-bonding array interlocks the ends of the foldamer together with its helical core. This hydrogen-bonding array has a greater influence on stabilizing the helix than the π -stacked seam. Thus, we show how to enhance the difference between Cl binding and release using light-dependent control over the foldamer's helix stabilization. We achieved a 10-fold improvement over our first design. (J. Org. Chem. 2014, 79, 8383)

Fundamental Structure/Property Studies of Gas Separation Membrane Polymers

Institution: Texas-Austin, University of
Point of Contact: Benny Freeman
Email: freeman@che.utexas.edu
Principal Investigator: Benny Freeman
Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

The overarching goal of this fundamental, experimental research program is to systematically synthesize, characterize, and, ultimately, rationally tailor a novel class of polymeric membrane materials with the chemical and thermal stability as well as separation properties required for gas separation applications. This program has exploited and further developed our discovery (Science 318, 254 (2007)) that polymers prepared by thermal rearrangement of soluble aromatic polyimides containing ortho-positioned functional groups, such as OH, exhibit unusually high gas permeability and selectivity values. Furthermore, early studies of this class of materials suggest that they are very robust chemically (i.e., insoluble in all known solvents) and resistant to plasticization.

FY 2014 HIGHLIGHTS

There has been a worldwide debate in the literature regarding the exact chemical structure of thermally rearranged (TR) polymers, and we made what we believe is a definitive contribution to unambiguously answer this question, at least for one of the most promising TR polymers (Polymer 55, 6649 (2014)). We also published an extensive review article on polymeric gas separation membranes in August 2013 (Polymer 54, 4729 (2013)); it has been cited 54 times and was one of the most downloaded articles in Polymer for much of 2014. We have worked closely with a major industrial gas separation company to reduce TR polymers to commercial practice. These polymers are scheduled to begin to be used shortly in On-Board Inert Gas Generation Systems (OBIGGS) aboard commercial aircraft to blanket fuel tanks with nitrogen-rich gas to reduce fire hazards.

EARLY CAREER: Design Synthesis and Characterization of Triptycene-Containing Macromolecules with Hierarchically Controlled Architectures as Functional Membrane Mate

Institution: Notre Dame, University of
Point of Contact: Ruilan Guo
Email: rguo@nd.edu
Principal Investigator: Ruilan Guo
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$195,000 (2014)

PROGRAM SCOPE

The overarching goal of this project is to develop advanced triptycene-containing polymer membranes with hierarchically controlled architecture and morphology over multiple length scales for important energy intensive separations and clean energy production. The key thrusts of the work are: 1) macromolecular design, synthesis and characterization of a new series of triptycene-containing polymers with systematically varied structures, and 2) determination and analysis on membrane transport properties caused by the structure variations. A diverse but systematic set of triptycene-based diamine monomers will be synthesized for polyimides synthesis, which will allow us to explore effects of substituent groups, linkage geometry, chain rigidity, macromolecular packing on free volume architecture and consequent final membrane transport properties. We will evaluate fundamental transport parameters (diffusivity and solubility) to understand thermodynamic vs. kinetic factors

contributing to separation performance. A special focus will be upon the correlation between free volume architecture (size and size distribution) induced by triptycene-monomer structure variations and membrane properties. The knowledge obtained will aid in predictably creating highly controlled yet tunable macromolecular architectures and morphologies enabling highly efficient membrane separation technologies.

FY 2014 HIGHLIGHTS

A major development that has come out of the studies during this past contract period has been the discovery that free volume architecture (size and size distribution) in the triptycene-containing polyimides can be feasibly tuned via alteration of the substituent groups neighboring the triptycene moiety along the polymer backbone. This finding provides a new dimension in finely tuning the membrane transport properties via rational macromolecular design using triptycene, or more generally, triptycene unit. Specifically, we have successfully synthesized a first set of key monomers, i.e., triptycene-1,4-diamines, along with the corresponding new polyimides. The obtained robust membranes are both highly permeable and highly selective. We are in the process of sorption tests to evaluate respectively kinetic (diffusivity) and thermodynamic (solubility) contributions to separation. We continue to pursue a second set of specialty monomers, i.e. triptycene-2,6-diamines, which has proven much more difficult to synthesize. We have also started the synthesis of dually-selective membranes by incorporating CO₂-philic PEO segments into triptycene-based polyimides and are in the process of polymer synthesis and film casting and tests.

Analytical Spectroscopy Methods for Liquid/Solid Interfaces

Institution: Utah, University of
Point of Contact: Joel Harris
Email: harrisj@chem.utah.edu
Principal Investigator: Joel Harris
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Liquid/solid interfaces play a key role in numerous aspects of energy-related chemistry. Many steps in chemical analysis (separation, preconcentration, selective detection) involve adsorption or binding of target species to chemically-modified solid surfaces in contact with liquids. Applications of liquid/solid interface chemistry including catalysis, adsorption or selective binding of molecules or metal ions, chromatographic separations, and environmental remediation, generally employ porous support materials for immobilizing ligands or catalytic sites. The high specific surface area of porous particulate materials (porous oxides or polymers) provides large capacities for adsorption, binding, or catalysis. The challenge for spectroscopic investigation of porous materials is that nearly all of their surface area resides within the porous structure; thus relevant methods to investigate these materials must be capable of interrogating chemistry inside the porous structure. Porous solid surfaces often exhibit heterogeneity in structure and reactivity; thus spectroscopic imaging methods within the porous material are needed to characterize spatial distributions of chemical structure and interfacial interactions. To address these measurement challenges, the scope of this research program is to develop spectroscopic imaging methods for analysis of chemical processes within porous particles. Specifically, we employ confocal Raman microscopy to determine the chemical composition and

structure of interfacial species within individual porous particles. The kinetics of molecular transport within porous particles are being characterized by intraparticle single-molecule fluorescence imaging, to understand their impact on the efficiency of chemical separations and on the time response of separations and sensors.

FY 2014 HIGHLIGHTS

Extraction of PAH compounds into small (sub-pL) volumes was accomplished by using a single chromatographic particle as a collector and Raman microscopy for in-situ detection. By comparing Raman scattering intensity of the analyte to that of the C₁₈-chains in the particle, it is possible to quantify the extracted compound within the particle. The gain in concentration for pyrene was a large factor, 48,000, allowing this PAH compound to be detected from a 10-nM solution. The method requires only selective accumulation of molecules into a high surface-area porous particle, which provides Raman microscopy with nanomolar detection capabilities. Small polymeric particles are increasingly employed as adsorbent materials, as molecular carriers, and in preconcentration applications. The Harris group employed Raman microscopy to investigate the synthesis, structure, and application of individual porous polymeric surfactant particles produced by polymerization of sodium 11-acrylamido-undecanoate. These particles contain hydrophobic domains that can be used to accumulate molecules for adsorption applications, which was also evaluated by Raman microscopy. To investigate the dynamics of molecular transport within porous particles, imaging-fluorescence-correlation spectroscopy was adapted to measure diffusion of small numbers of fluorescent molecules within chromatographic silica particles, to compare with their diffusion at a planar surface. The results show that diffusion on a planar substrate is much faster than diffusion through the particle. By accounting for the greater surface area that a molecule must explore to diffuse macroscopic distances through a nanoporous particle, the molecular-scale diffusion rates on the two surfaces could be compared and were found to be equivalent. These results provide support for the relevance of surface-diffusion measurements on model planar surfaces to the dynamics of molecules on the internal surfaces of porous particles.

Elucidation and Reduction of Interference Effects in Inductively Coupled Plasma Spectrometry

Institution: Indiana University
Point of Contact: Gary Hieftje
Email: Hieftje@indiana.edu
Principal Investigator: Gary Hieftje
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$472,864 (2014-2017)

PROGRAM SCOPE

Rare-gas plasmas are among the most useful tools of analytical chemistry. They take several forms, from the ICP used for atomic emission and mass spectrometry to the DART (Direct Analysis in Real Time) employed in ADI-MS. Plasmas provide exceptional sensitivity, flexibility, and selectivity. Unfortunately, their performance for quantitative analysis often falls short of what is needed. Of necessity, plasma-based methods are relative; that is, they rely on standards to calibrate an instrument. As a result, any difference in response between those standards and the species to be determined (the "analytes"²) causes an error, and yields values that might be either higher or lower than the true value. Such errors can arise from many sources, but the root problem arises because the overall composition of a sample (the sample 'matrix') influences the analyte signal. We believe the most promising path for overcoming

matrix interferences is by a thorough fundamental understanding of what causes them. From this understanding, it might then be possible intelligently to select sample additives, to modify the atomic or ion source, or to alter operating conditions in a way that alleviates or eliminates the interferences. Alternatively, if enough is understood about the source, the emission or mass spectrometer, or the interferences themselves, it might be possible to devise monitoring and diagnostic strategies that can detect the presence of an interference and modify the instrument operation in a way that minimizes it. Failing this capability, such strategies should at least be able to flag a sample in which an interference is sensed. It is the goal of the proposed studies to provide such fundamental knowledge and to devise appropriate diagnostic approaches.

FY 2014 HIGHLIGHTS

Because our DOE-funded program has several facets, progress in each facet will be briefly highlighted here.

- Detecting and correcting matrix interferences in ICP emission spectrometry: We have devised a new strategy for detecting matrix interferences when an ICP is viewed in an end-on fashion and fed with a sample in an organic solvent. The method is based on the fact that the ratio of chosen spectral lines changes in the presence of an interference when the sample solution is diluted. The same gradient dilution apparatus can then be used to calibrate the instrument.
- Ambient desorption/ionization mass spectrometry with a flowing afterglow source (FAPA): We have characterized the interaction of the FAPA plume with a sample surface by means of schlieren imaging. The same method allows us to optimize fundamentally the sampling of the resulting material into a mass-spectrometer interface. In addition, we have determined the effect of ambient conditions (temperature, humidity) on the resulting mass spectra. A new FAPA design, based on a microwave discharge, has also been evaluated, and the FAPA used to detect counterfeit electronic components.
- Distance-of-flight mass spectrometry (DOFMS): We have coupled an inductively coupled plasma ion source to our DOFMS and used it with a laser-ablation system for sample introduction. Despite the fact that an inexpensive spatially selective detector (microchannel plate + phosphor screen) was being used, the detection limits, isotope-ratio precision, and precision rivaled that of far more costly and less versatile instruments. In addition, we showed that use of constant-momentum acceleration (CMA) in time-of-flight mass spectrometry (TOFMS) yields improved resolution over conventional constant-energy acceleration. This realization allows TOFMS to be used in two alternating modes: conventional and CMA, with the former providing broad mass coverage and the latter enhanced resolution over a narrower mass range.

Coordination Chemistry Derived Materials Featuring Nanoscale Porosity and Selective Chemical Separation

Institution: Northwestern University
Point of Contact: Joseph Hupp
Email: j-hupp@northwestern.edu
Principal Investigator: Joseph Hupp
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The project research objectives are to design, understand, and utilize new materials having nanoscale porosity – specifically, new metal-organic frameworks (MOFs) – to achieve energy-efficient separations of technologically relevant or DOE-mission-relevant chemical mixtures, especially mixtures of gases and/or vapors. Achieving these objectives has entailed the development of new tools for computational modeling and new methods for synthesizing MOFs, especially MOFs that are difficult or impossible to access via conventional methods.

FY 2014 HIGHLIGHTS

Although an enormous variety of MOF compounds has been reported, many MOFs that could be highly effective as selective sorbents appear impossible to access via conventional synthesis methods. With this problem in mind, we have focused on three new or emerging MOF synthesis strategies, AIM, SALE, and SALI. AIM (Atomic-Layer-Deposition In MOFs) is an example of a broader set of approaches that can be classified as post-synthesis modification. SALE and SALI (solvent-assisted-ligand-incorporation) are examples of a set of synthesis approaches that can be viewed as building-block-replacement approaches. AIM: This new synthesis technique provides a way of creating uniform arrays of metal-oxide, mixed-metal-oxide, and metal-sulfide clusters. Our intent is to use these clusters to accomplish selective binding and separation of mixtures of small molecules. We have recently demonstrated the experimental feasibility of AIM with the platform MOF, NU-1000. SALE: In several recent reports we have shown that otherwise synthetically inaccessible MOF materials can be accessed by first building structural analogues and then subjecting the materials to solvent-assisted-linker-exchange (SALE). We are just beginning to explore the implications of SALE for synthesis of new materials for chemical separations. SALI: Closely related to SALE (i.e. exchange of structural ligands) is solvent-assisted incorporation of desired nonstructural ligands. Using the platform MOF, NU-1000, as a test case, we have found that a wide variety of pore-modifying ligands can be controllably installed, including ligands whose incorporation via direct synthesis methods is not possible. Examples include pendant-catechols (metal-ion binding sites), organic acids, organic bases, thiols, fluorocarbons, “click”-susceptible azide or acetylide functionalities, amino acids, and oligopeptides. Our intent is to systematically alter the affinity of MOF channels for selected molecular components of chemical mixtures.

Molecular-Level Investigation of Diffusion Behaviors within Cylindrical Nanoscale Pores

Institution: Kansas State University
Point of Contact: Takashi Ito
Email: ito@ksu.edu
Principal Investigator: Takashi Ito
Sr. Investigator(s): Daniel Higgins; Kansas State University
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 1 Undergraduate(s)
Funding: \$240,000 (2014)

PROGRAM SCOPE

The goal of this project is to develop a quantitative molecular-level understanding of mass transport mechanisms within solution-filled nanoporous media. Cylindrical nanopores having well-defined sizes and surface properties are obtained from self-organized materials such as surfactant-templated mesoporous silica (STMS) and cylinder-forming block copolymers (CFBCP), and are employed as model systems. Mass transport is investigated using single-molecule fluorescence techniques including single

molecule tracking (SMT) and fluorescence correlation spectroscopy (FCS) as well as ensemble techniques such as fluorescence recovery after photobleaching (FRAP). These two types of methods are used to measure identical materials for directly comparing between single-molecule and ensemble behavior. The direct comparison is expected to reveal key molecular-level processes governing the rate and selectivity of molecular permeation through nanoporous media employed in chemical separations and catalysis, and as membrane separators in fuel cells and batteries. The comprehensive understanding that will result from these studies will facilitate the engineering of nanoporous media optimized for energy-related applications. In addition, we are pursuing new experimental approaches as means to overcome certain fundamental limitations of existing fluorescence techniques used for mass transport measurements. Previously, we developed a simple, quantitative method (orthogonal regression analysis) to quantify the orientation and order of nanopores by tracking the one-dimensional motions exhibited by single molecules diffusing within them. We applied it for assessing microscale domains with differently oriented nanopores in STMS films and also for revealing flow-induced alignment and diffusion pathways in rod-shaped block copolymer micelles. We have also developed a new polarization-dependent SMT method to quantify the wobbling motions of single molecules confined within nanoscale pores.

FY 2014 HIGHLIGHTS

During FY2014, we investigated elongation, alignment and guided electrophoretic migration of individual fluorescently-labeled double-stranded DNA molecules within flow-aligned surfactant mesophases (H. Xu, *et al.*, J. Phys. Chem. B 2014, 118, 4151.). This work demonstrated that the DNA molecules could be elongated parallel to the cylindrical micelles comprising the (near-surface) mesophase and that the micelles guided DNA migration. The effects of probe molecule charge on single-molecule diffusion within hexagonal STMS nanopores filled with cationic (R. Kumarasinghe, *et al.*, in prep.) and uncharged surfactants (S. C. Park, *et al.*, in prep.) were explored. The results show that the dimensionality and rate of motion are both charge dependent. The flow-induced alignment of CFBCP microdomains was investigated via the diffusion behavior of single molecules within the microdomains (K.-H. Tran-Ba, *et al.*, J. Phys. Chem. B. 2014, 118, 11406.). The results showed that alignment occurred by a shear mechanism and that micrometer sized grains limited long-range mass transport. Measurements of diffusion phenomena at both the ensemble and single-molecule levels in identical areas of nanostructured materials using FRAP and SMT (K.-H. Tran-Ba, *et al.*, in prep.) were demonstrated. Taken together, the ensemble and single-molecule results afford detailed data on the continuity of diffusion pathways. We have developed a new algorithm, trajectory-profile-guided tracking, that permits better assignment of one-dimensional single-molecule diffusion trajectories (K. C. Robben, *et al.*, Anal. Chem. 2014, 86, 10820.). Finally, we contributed invited review articles that comprehensively discussed analytical applications of block copolymer monoliths comprising microdomains (T. Ito, Chem.–Asian J. 2014, 9, 2708.) and single-molecule studies of morphology and mass transport dynamics within nanostructured materials (D. A. Higgins, *et al.*, Annu. Rev. Anal. Chem., submitted.).

The Physics and Chemistry of Cluster-Based Catalyst Systems

Institution: Central Michigan University
Point of Contact: Koblar Jackson
Email: jacks1ka@cmich.edu
Principal Investigator: Koblar Jackson
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$316,274 (2014-2016)

PROGRAM SCOPE

We are carrying out theoretical/computational research that explores the physical and chemical properties of atomic clusters. Clusters are small clumps of matter containing from tens to hundreds of atoms and cluster science is a new frontier in the study of materials, spawning new ideas such as clusters as “superatoms” with an entirely new chemistry. Cluster properties are determined by an intricate interplay of factors related to their small size and can vary dramatically with the addition or deletion of even a few atoms. This sensitive size dependence creates the possibility of tailoring cluster properties for specific applications such as catalysis. The overall goal of our research is to use first-principles computational methods based on density functional theory (DFT) to gain an improved understanding of the properties of clusters, particularly those that are important for applications. The project has two main thrust areas: i) investigating the reactivity of metal and mixed-metal clusters that could be useful as catalysts; and ii) studying the polarizability of clusters as a function of the number of atoms in order to understand the evolution of electronic properties in matter at the smallest length scales.

FY 2014 HIGHLIGHTS

Our research resulted in three published papers. The first describes the chemical interaction between hydrogen molecules and palladium clusters. Dissociative adsorption occurs without barrier on these clusters. The second paper traces the evolution of cluster polarizabilities in Na clusters. We show that the charge transfer-type polarization is comparable to the bulk per atom value in clusters as small as 10 atoms. The final paper applies a new, linear response-based formalism that partitions the polarizability into atomic contributions to long-chain polymer molecules. Finite difference approaches cannot be applied to these systems.

- H₂ reactions on Palladium clusters. A. Pelzer, K. A. Jackson, and J. Jellinek, *J. Phys. Chem A*, v117, 10407 (2013).
- Investigating the metallic behavior of Na clusters using site specific polarizabilities. L. Ma, K. A. Jackson, M. Yang, J. Jellinek, and M. Horoi, *Phys. Rev. B* v89, 035429 (2014).
- Site-specific polarizabilities from analytic linear response theory. J. E. Peralta, V. Barone, and K. A. Jackson, *Chem. Phys. Lett.* v608, 24 (2014).

EARLY CAREER: Graphene Membranes with Tunable Nanometer-Scale Pores

Institution: Massachusetts Institute of Technology
Point of Contact: Rohit Karnik
Email: karnik@mit.edu
Principal Investigator: Rohit Karnik
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Graphene, a one-atom thick membrane of hexagonally bonded carbon atoms, is one of the strongest materials known and is impervious to the diffusion of even helium gas. The potential for creation of tunable nanometer-scale pores in graphene, combined with its other properties, make it a promising

material for improving selectivity, permeability, and energy efficiency in a diverse range of membrane separation and sensing applications. The objective of this work is to systematically study the effect of ion irradiation, nitrogen doping, and chemical oxidation to create tunable, nanometer-scale pores in single and multilayer graphene membranes, and elucidate the transport characteristics of the resulting membranes. High-resolution imaging will be used to study the pore structures and transport measurements will be performed on large-area membranes as well as on single pores. The study will result in fundamental understanding of the relationship between fabrication methods, pore structures, and transport properties of graphene membranes, which may lead to significant advances in a wide range of separations applications.

FY 2014 HIGHLIGHTS

Development of leakage-sealing methods enabled measurements of water flux and solute transport across nanoporous monolayer graphene for the first time. The estimated flux of water through graphene pores was consistent with theoretical studies in the literature. Furthermore, the study demonstrated the ability of a single layer of graphene to filter out solutes (multivalent salts and small molecules). The filtration behavior was consistent with convection-diffusion model of mass transport across graphene pores, given the observed pore size distribution in graphene. Complementary to these studies with large area graphene membranes, studies of ionic conductance through isolated pores in graphene revealed ion-selective behavior and stochastic switching. A transport model was developed that accounted for electrostatic and ion hydration interactions. The model could quantitatively match the observed ionic conductance behaviors of isolated graphene nanopores.

Precisely tunable high performance carbon molecular sieve membranes for energy intensive separations

Institution: Georgia Institute of Technology
Point of Contact: William Koros
Email: wjk@chbe.gatech.edu
Principal Investigator: William Koros
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$120,000 (2014)

PROGRAM SCOPE

This project focuses on advanced carbon molecular sieve (CMS) membrane materials to dramatically reduce the energy intensity of gas separations. Polymer precursor dense films are being pyrolyzed to form materials with attractive properties. Fundamentally, we are seeking to show that constraining translational, rotational and vibrational degrees of freedom of the rejected components in the activated state reduce diffusion coefficients of the rejected component. Our preliminary experimental work supports the validity of this hypothesis and opens the way to progress toward economical advanced membrane materials. Besides the fundamental significance of the work, these findings also have enormous practical importance, since the work shows the way to develop processes for separating gas pairs at a greatly reduced energy cost. The polyimide precursor materials being study include trade-offs in segmental flexibility and packing, which allow structure-property insights to allow tunability for both smaller penetrant pairs like CO₂/CH₄ as well as the larger olefin-paraffin penetrants. These insights should provide the needed fundamental tools to tune ultra-micropore distributions to enable separations across the full spectrum of key gases needed for the next half century. Complementary studies, involving x-ray, thermogravimetric analysis assisted by mass spectrometry, Fourier transform

infrared spectroscopy and Raman spectroscopy will be used to gain additional fundamental insights into evolution of structures during the systematic formation work.

FY 2014 HIGHLIGHTS

Our earlier DOE BES work identified a so-called “entropic selectivity” principle that enables high performance membrane separation of the O₂/N₂ pair. Under our current DOE BES support, we have shown the validity of entropic selectivity as also crucially important for energy efficient separations of the N₂/CH₄ and the C₂H₄/C₂H₆ pairs. Both of these pairs are important in the hydrocarbon processing motivating the resurgence of the US economy. The CO₂/CH₄ case is another important gas pair related to enhanced oil production, which we are exploring to further assess our entropic selectivity factor analysis. Slit-like pores in CMS membranes enable such entropic selectivity factors to reduce overall energy intensity for all of above separations, which are currently done by highly energy intensive thermally-driven processes. Besides our theoretical work, our group has synthesized actual CMS membranes that demonstrate this special selectivity property. This work showed that CMS materials can undergo rapid physical aging, which is analogous to that observed with simple glassy polymers. Fortunately, under actual operating conditions we discovered that the aging in CMS materials is not a serious impediment to their practical use. Despite the ability to “live with aging”, during the past year, our group has begun exploring ways to slow down or even quench this aging process. We have already shown that selective trace level chemical treatments, which do not seriously impact the intrinsic productivity and selectivity of the CMS materials, are useful for control of the physical aging. This anti-aging work is ongoing, and will be pursued in the next grant period if the project is renewed.

The Dynamics and Thermodynamics of Gaseous Macro-ions

Institution: Purdue University
Point of Contact: Scott McLuckey
Email: mcluckey@purdue.edu
Principal Investigator: Scott McLuckey
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

The overall objectives of this research effort are to expand the range of informative chemistries of gaseous polyatomic ions and their complexes within the context of a mass spectrometry experiment and to provide a deeper understanding of the factors that affect ionic reactions. The specific objectives of the project include study of the selective covalent bond in tandem mass spectrometry via ion/ion chemistry, which promises to greatly enhance the utility of structural characterization by tandem mass spectrometry, the study of ion/ion reactions involving non-covalently bound complex ions with emphasis on hydrated ions, and the spectroscopy of ions derived from energy relevant molecules, such as lignins.

FY 2014 HIGHLIGHTS

Cold Ion Spectroscopy and Photodissociation: We have made significant progress in our gas-phase ion spectroscopy collaboration with Professor Tim Zwiernicki in our department. We have constructed a triple quadrupole instrument with an ion optical axis that employs a multi-pole cold trap with a recirculating

liquid helium refrigeration system. This brings ions down to roughly 10 K so that we can generate high resolution infra-red spectra on conformation selected ions via an action spectroscopy approach. The instrument has been constructed and is generating data. We have collected both IR and UV spectra of well-studied systems, such as protonated tryptophan, and have begun generating data on ions derived from lignins, which are of interest to the bio-fuels community. Our first paper describing the lignin work has been submitted to the Journal of Physical Chemistry A. Selective Metal Ion Removal via Ion/Ion Reactions. We began a project this year involving the use of anions of superacids as ion/ion reagents in collaboration with Prof. Christopher Reed of UC Riverside. These ions have the interesting characteristic of being selective for metal ion removal when there is a mixture of metal ions and protons whereas virtually all other anions that we have used in the past are highly selective for proton removal. This interesting behavior is intimately linked with the low proton affinities of super acid anions. A paper is currently in press with the Journal of the American Society for Mass Spectrometry.

Imaging of Conformational Changes

Institution: Colorado, University of
Point of Contact: Josef Michl
Email: michl@eefus.colorado.edu
Principal Investigator: Josef Michl
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our ultimate objective is to develop methods for the detection and control of rotary conformational changes for single molecules in real time. In the initial funding period differential barrier height imaging (DBHI) and tip-enhanced resonance Raman spectroscopy (TERS) have been combined in a new instrument with the potential to make correlated maps of Raman band intensities and polarizations for molecules undergoing or having undergone electric-field induced conformational change. Tailor-made molecular rotors needed for the investigation have been prepared by standard methods of covalent synthesis, and new methods, developed by us, that substantially reduce the complication of the standard synthesis by using self-assembly. In several stages we will move from making a correlated map of the tunneling current, the DBHI plot and the static Raman spectra of single surface-mounted molecules to collecting dynamic Raman spectra of molecular rotors undergoing rotational conformational changes induced by the tip electric field. Raman spectroscopy is expected to quantify rotational conformational motion with up to 10-ns resolution in the dynamic investigations proposed here, and potential future ones with ps-time resolution. We believe this research will have represented a significant contribution to understanding of surface-enhanced Raman spectroscopy and single-molecule spectroscopic detection, both strong interests of the Separations and Analysis program of the Chemical Sciences, Geosciences and Biosciences Division, and towards the synthesis of solid-state materials with tailored properties from designed precursors, a strong interest of the Catalysis and Chemical Transformations program, also in the Chemical Sciences, Geosciences and Biosciences Division.

FY 2014 HIGHLIGHTS

Our target molecular rotor is a prismatic frame supporting a carbostyryl rotator. To avoid the standard covalent multistep synthesis of this compound, a two-step synthesis based on the convergent process of metal-ion-directed self-assembly was developed. To test the key covalent stabilization step, Pt(+)-N to

Pt-C conversion, simple squares were synthesized and confirmed by X-ray diffraction. The initial choice of trimethylphosphine as a ligand on Pt unfortunately permits a facile isomerization of the cis isomer into the trans isomer before covalent stabilization. A simple remedy was found by using a bridging diphosphine across two sites, preventing the rearrangement to the trans form. A model system containing a carbostyryl rotor derivative coupled by an axle to three fatty acid chains was synthesized to test for its TERS feasibility. This compound forms LB films neat or in dilution with stearic acid but segregates into islands. Ellipsometric, polarized FTIR, and UV-vis spectroscopic investigations of these rotor films showed that the rotor axle was unsuitably tilted. Further, the rotor was found to undergo dimerization in ambient light in the film. DBHI investigations on a series of rotors mounted on Au(111) were completed. A UV-TERS demonstration using a LB film of DiA was performed by excitation of a Co STM tip with 364 nm light and confirms that cobalt has a LSPR. This is the first time UV-TERS has been demonstrated with a Co tip. The near-field wavelength-dependent EM enhancement for a pair of cobalt spheroids was calculated using the discrete dipole scattering method. Two identical Co spheroids with a short axis of 40 nm and a 5 : 1 aspect ratio were placed perpendicularly separated by a 1 nm gap. A maximum enhancement factor >30 for the LSPR at 400 nm was found. A molecular dynamics simulation of molecular rotors driven by a rotating electric field or by a flow of gas was completed and provided insight into the nature of friction in molecular rotors.

The Flotation Chemistry of Nonsulfide Minerals

Institution: Utah, University of
Point of Contact: Jan Miller
Email: jan.miller@utah.edu
Principal Investigator: Jan Miller
Sr. Investigator(s): Xuming Wang; Utah, University of
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$480,000 (2014-2017)

PROGRAM SCOPE

Particulate separations are of considerable significance in many areas of technology ranging from pharmaceuticals and microelectronics, to mining and construction materials. In addition, particulate separation technology is of critical importance in the environmental area, for example the development of advanced water treatment processes for the 21st century will rely on more efficient particulate separation techniques. One such particulate separation process of considerable importance is the flotation separation process. The primary goal of this research program on flotation chemistry is to provide a basis for improved flotation separation efficiency in nonsulfide mineral systems by establishing the fundamental features of interfacial water structure, particle interactions, and collector (surfactant) adsorption reactions associated with the hydrophobic surface state and developing appropriate surface chemistry control strategies. Sum Frequency Vibrational Spectroscopy (SFVS), Molecular Dynamics Simulations (MDS), and Atomic Force Microscopy (AFM) are being used to accomplish this goal. These advanced experimental techniques together with more traditional experimental methods are providing crucial information concerning the interfacial surface state and collector adsorption phenomena in selected nonsulfide mineral systems, including, but not limited to, the flotation chemistry of phyllosilicate, soluble salt, and rare earth minerals in an effort to develop improved technology for the recovery of such strategic materials from our mineral resources.

FY 2014 HIGHLIGHTS

Flotation research activities in 2014 include the surface chemistry of layered silicate minerals and the rare earth mineral bastnaesite. Also, the spectroscopy of film rupture/bubble attachment is in progress. A significant achievement in the surface chemistry of phyllosilicates (layered silicates) has been accomplished. Namely, the experimental procedure for the isolation and preparation of the 30 nm thick edge surfaces of 300 nm anisotropic kaolinite particles has been successfully developed and the results published in JCIS, 420, pp. 35-40 (2014). These kaolinite edge surfaces have been characterized by AFM surface force measurements and the surface charge/surface potential calculated for the first time. Now, with these results, the interaction of such nano clay particles will be simulated in quantitative detail. Bastnaesite is a RE fluorocarbonate ($Ce,LaFCO_3$), and is an important domestic resource for RE production. Consequently, surface chemistry aspects of bastnaesite flotation with octyl hydroxamate collector are being studied. Advanced experimental techniques including collector adsorption experiments, sum frequency vibrational spectroscopy (SFVS) and molecular dynamic simulations (MDS) have been accomplished. The adsorption features as well as the corresponding hydrophobic surface state at low levels of hydroxamate adsorption had not been described. Finally, the presence of a water exclusion zone at hydrophobic surfaces has been established by MDS, X-ray reflectivity and SFVS. Further, it has been shown that the van der Waals (vdW) force between a bubble and such a hydrophobic surface is not repulsive as suggested in the literature. For example, even when the water exclusion zone is just 2 Å in thickness, an attractive vdW force is calculated and observed. As the thickness of the water exclusion zone increases, the calculated attractive vdW force increases, and helps to explain the nature of short-range and long-range hydrophobic forces.

Energetics of Nanomaterials

Institution: California-Davis, University of
Point of Contact: Alexandra Navrotsky
Email: anavrotsky@ucdavis.edu
Principal Investigator: Alexandra Navrotsky
Sr. Investigator(s): Brian Woodfield; Brigham Young University
Juliana Boerio-Goates; Brigham Young University
Nancy Ross; Virginia Polytechnic Inst. and State U.
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Nanomaterials differ in structure, reactivity, and thermodynamic properties from materials in the bulk. The focus of this project is the thermodynamics of nanomaterials, with synergy among three research groups: Brian Woodfield and Juliana Boreio Goates at Brigham Young University bringing expertise in nanoparticle synthesis and low temperature heat capacity measurements, Alexandra Navrotsky at University of California Davis bringing unique capabilities in high temperature calorimetry and the measurement of enthalpies of formation and surface energies, and Nancy Ross at Virginia Tech engaging in neutron scattering studies. Together this group seeks understanding of the systematics of surface energies and the hydration of nanoparticle surfaces and their effects on stability and reactivity. Current work has shown that different structures have systematically different surface energies, leading to crossover in thermodynamic stability of polymorphs at the nanoscale, and to substantial changes in the position of phase boundaries for dehydration and oxidation-reduction reactions. Such systematics are explored, with an emphasis on redox reactions and hydration. Studies of surface energies in spinel and

perovskite structures are performed and a useful set of surface energies for calculating nanoscale diagrams will be assembled. The details of structure and energetics of hydration layers are probed.

FY 2014 HIGHLIGHTS

Studies of bulk and nanophase spinels in the cobalt manganese oxide and iron manganese oxide systems confirm that the surface energies of all spinels in the systems are similar; thus the heat of mixing does not depend on particle size. The mixing energetics have been measured and modeled. The work is being prepared for publication. To explore new directions in nanoparticle energetics, which are highlighted in a submitted renewal proposal, we have studied several hybrid organic inorganic systems and their adsorption energetics of water and carbon dioxide.

Hyperthin Membranes for Gas Separations

Institution: Lehigh University
Point of Contact: Steven Regen
Email: slr0@lehigh.edu
Principal Investigator: Steven Regen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$465,000 (2014-2017)

PROGRAM SCOPE

This research focuses on the design, synthesis and characterization of hyperthin (< 100 nm) polymeric membranes based on polyelectrolyte multilayer (PEM) formation and Langmuir-Blodgett (LB) deposition. This work builds upon two recent discoveries: (i) unexpectedly high CO₂/N₂ permeation selectivities that have been found for PEMs made from two commonly used polyelectrolytes, and permeances that were two to three times greater for structurally matched analogs, and (ii) A 7 nm-thick Langmuir-Blodgett bilayer derived a polymeric surfactant (POMTMA) plus poly(acrylic acid) having a H₂/CO₂ selectivity of 200 that reached the “upper bound”². This research will explore the scope of structural matching of polyelectrolytes as it relates to its influence on the permeation properties of

resulting PEMs. Specifically, the consequences of hydrogen bonding, the position of the pendant ions along the polymer backbone, and polymer tacticity on the barrier properties of PEMs will be determined with respect to H₂, CO₂ and N₂. Related studies will test the feasibility of introducing uniform micropores into PEMs to produce relatively fast selective gas transport. Finally, the influence that covalent crosslinking has on the permeation properties and robustness of PEMs and ionically crosslinked, all-polymer-based-LB bilayers will be examined. At a fundamental level, the concept of structural matching is entirely new in the PEM area. As further advances are made with hyperthin PEMs as membrane materials, sensors, protective coatings, etc., the results of this research should provide valuable insight into what possibilities may exist for further development through structural matching.

FY 2014 HIGHLIGHTS

Polyelectrolyte multilayers derived from poly(diallyldimethylammonium chloride) and poly(sodium 4-styrene sulfonate) have been deposited onto poly[1-(trimethylsilyl)-1-propyne] (PTMSP) with anchoring layers formed by Langmuir-Blodgett and self-assembly methods. Using gas permeation selectivity as a basis for judging the efficacy of each anchoring method, we have found that similar CO₂/N₂ selectivities (ranging from 110-140) could be achieved by both methods, and that their permeances were also similar. Although LB anchors require fewer layers of polyelectrolyte to reach this level of selectivity, the greater ease associated with self-assembly, and its applicability to curved, high surface area supports (e.g., PTMSP-coated hollow fibers), encourages its use with PTMSP in creating new membrane materials for the practical separation of gases.

Developing Ion Mobility-Mass Spectrometry for Structural Characterization of Complex Molecular Systems

Institution: Texas A&M University
Point of Contact: David Russell
Email: russell@chem.tamu.edu
Principal Investigator: David Russell
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Our research focuses on developing mass spectrometry-based approaches for determining the structure(s) of molecules and molecule complexes and how structure influences reactivity. Our studies employ a variety of cutting-edge mass spectrometry instrument types and structural probes, ranging from ion-neutral and ion-surface collisions, e.g., collision-induced dissociation and surface-induced dissociation and electronic excitation, including electron-capture and electron-transfer dissociation. These structural probes are combined with ion mobility-mass spectrometry (IM-MS), which separates ions on the basis of size-to-charge. There is natural synergy between size- and m/z-based separation and resulting structural information, and the ability to experimentally determine the heterogeneity (structural diversity) of the ion population, which affords separation of isomeric species. Molecular dynamics (MD) simulations are integral to IM-based structure determination, i.e., structure is not derived from first principles. Consequently, a significant component of our research involves computation and informatics. During the last two years we have used IM-MS and MD simulations to understand the structure of water, viz. ions of the type H⁺(H₂O)_n, where n ranges from 0 to >100, and

similar hydrates of polar molecules, $[M + H]^+ \cdot (H_2O)_n$. These focus on understanding how water influences the structure of the M as well as how M influences the structure of water.

FY 2014 HIGHLIGHTS

Our most important accomplishment this year has been in developing a more thorough understanding of the effects of water on conformational preference and dynamics of peptide using cryogenic (80 K)-ion mobility-mass spectrometry (cryo-IM-MS). Cryogenic-IM-MS makes possible novel investigations of ionic water clusters and hydrated polar molecules. In the course of these studies we have provided new insights on the structure of hydrated protons and hydronium ions, specifically how the structures of the hydrated species change with the extent of hydration. We have also shown how hydration affects the structures of hydrated peptides as well as how this experiment can be utilized for “kinetic trapping” of specific conformers for systems where multiple conformations are energetically possible. Five publications in high impact journals have been derived from these studies. We have also developed new IM-MS approaches for deconvolution of complex tandem MS spectra, and we have demonstrated the utility of these approaches through collaborations with biological and materials chemists, which amply illustrate the broader impact of the research. This work clearly illustrates that IM-MS is rapidly evolving as one of the most versatile and information-rich mass spectrometry-based analytical techniques. In many of the challenging areas of 21st century chemical research, the needs for rapid, high-throughput, ultra-high sensitivity analytical techniques continue to grow. Such experimental capabilities are now spilling over into diverse areas including catalysis and nano-catalysis, polymer/materials science, petroleomics, esp. bio-mass/biofuels and renewable energy.

EARLY CAREER: A Physicochemical Method for Separating Rare Earths: Addressing an Impending Shortfall

Institution: Pennsylvania, University of
Point of Contact: Eric Schelter
Email: schelter@sas.upenn.edu
Principal Investigator: Eric Schelter
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The broad aim of this project is to develop and apply fundamental chemistry to the separation of mixtures of rare earth metals. We are developing coordination chemistry of rare earth metal cations, including La–Pr, Tb, and Dy in an effort to connect meaningful chemical properties that can be used for elemental separations with their distinctive electronic structure characteristics. Our hypothesis for the project is that electron-hole coupling (electronic configurational mixing) in molecular complexes of certain lanthanide metals with redox active ligands can be used to manifest chemical distinctiveness and affect separations. The study of such effects also expands the basic knowledge of f-element chemistry and electronic structure. New redox active nitroxide ligands are proposed to both bind the rare earth cations and to observe electronic/magnetic coupling and redox chemistry between metal 4f electrons and ligand electron-holes. We expect that the redox active ligands will affect selective complexation of specific rare earth metal cations in mixture depending on the electronic characteristics of the ligands. The electronic structure effects discovered will be used as design principles for tailored extractants for

use in liquid-liquid extraction or other separations techniques for superior performance over extractant schemes currently in use.

FY 2014 HIGHLIGHTS

Our efforts to study metal-ligand redox have been applied to two processes in the rare earth metals supply chain. We have isolated a cerium(IV) hydroxamate complex in the context of beneficiation of rare earths ores. Beneficiation by froth floatation is the first step for claiming rare earths from ores. Crushed rare earth mineral solids are separated from waste materials through surface chemistry of organic 'collectors,' such as hydroxamates. Our analysis of the Ce-hydroxamate complex showed a strong preference for the cerium(IV) state. These results indicated that engineering models of beneficiation must include redox chemistry, which we expect will contribute to improved efficiency in this critical process. We have also leveraged computations to study metal redox processes. An experimental/computationally-predicted correlation of the redox properties for 15 cerium complexes has been achieved. Starting from crystal structures, density functional theory was applied to compute energies for the compounds in both multiple redox forms. Comparison the results with the experimentally measured values produced an excellent correlation with a range of more than 2.5 V. We expect this approach will find broad application in separations, including the design of chemical systems for lanthanide/actinide separations. Multi-dentate nitroxide ligands have been synthesized and their coordination chemistry with the lanthanides launched. A tripodal ligand framework was expected to provide a binding pocket for controlled coordination chemistry within an open coordination site. We have achieved the synthesis of a tripodal nitroxide ligand: $((2\text{-tBuNOH})\text{C}_6\text{H}_4\text{CH}_2)_3\text{N}$ (H_3TriNO_x), and its coordination to a rare earth cation to form complexes: $\text{RE}(\text{THF})(\text{TriNO}_x)$ RE = rare earth metal. The $\text{RE}(\text{THF})(\text{TriNO}_x)$ complexes have unusual isomeric- and solubility-properties. We have leveraged these observations to affect simple separations of pairs of rare earth ions, an approach that was recently patented.

Surface Functionality and Reactivity Using Single-Molecule Probes

Institution: Colorado, University of
Point of Contact: Daniel Schwartz
Email: Daniel.Schwartz@colorado.edu
Principal Investigator: Daniel Schwartz
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$216,664 (2014)

PROGRAM SCOPE

The goal of this project is to develop and employ real-time imaging methods that use individual reactant/adsorbate molecules as probes of surface chemical functionality (particularly non-covalent interactions) and reactivity. Our approach is based on observations of individual molecules using total internal reflection fluorescence microscopy (TIRFM), including high-resolution spectral methods involving resonance energy transfer. Methods like these will be necessary for the development and characterization – and especially the mechanistic understanding – of patterned and/or self-organized nanomaterials as well as of advanced catalysts that modify the environment of the active site (using non-covalent interactions) to improve reactivity, selectivity, and longevity.

FY 2014 HIGHLIGHTS

We have developed methods to study heterogeneous surface properties using the dynamic behavior of multiple probe molecules that respond to different chemical surface properties. Using diffusion, adsorption rate, and residence time from both probes allows the use of an unsupervised 6D Gaussian mixture model to identify data clusters corresponding to individual surface chemistries, which can then be mapped back onto the surface spatially. We also connected single-molecule dynamic observations directly with retention times in reversed phase liquid chromatography (RPLC). Using the dynamic behavior of individual probe molecules we identified strong surface binding sites. The adsorption and desorption kinetics on these sites were heterogeneous and positively correlated, suggesting a broad underlying distribution of site binding energies. Using the stochastic model of chromatography, we showed that single-molecule kinetic results were consistent with the empirical trend observed in actual RPLC experiments as a function of the solvent composition. This approach to identifying and quantifying adsorption sites should be useful for designing better chromatographic separations and for identifying the role of heterogeneous surface chemistry in molecular dynamics. In the conventional picture of surface diffusion, a molecule sticks to a surface and moves continuously following a two-dimensional random walk. However, in recent experiments, we observed stop-and-go hopping across the surface with a diverse group of molecules. The molecules underwent periods of confined 2D diffusion punctuated by occasional long 3-dimensional flights. These trajectories, similar to “forager dynamics” well-known in biology, represent a highly efficient search process. This conceptual understanding also enabled new insights into polymer surface dynamics. These findings may enable new approaches to control or direct molecular motion at interfaces.

New Approaches for Metabolomics by Mass Spectrometry

Institution: George Washington University
Point of Contact: Akos Vertes
Email: vertes@gwu.edu
Principal Investigator: Akos Vertes
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$330,000 (2013-2014)

PROGRAM SCOPE

Small molecules constitute a large part of the world around us, including fossil and some renewable energy sources. Solar energy harvested by plants and bacteria is converted into energy rich small molecules on a massive scale. Some of the worst contaminants of the environment and compounds of interest for national security also fall in the category of small molecules. The development of large scale metabolomic analysis methods lags behind the state of the art established for genomics and proteomics. This is commonly attributed to the diversity of molecular classes included in a metabolome. Unlike nucleic acids and proteins, metabolites do not have standard building blocks, and, as a result, their molecular properties exhibit a wide spectrum. This impedes the development of dedicated separation and spectroscopic methods. Mass spectrometry (MS) is used as a quantitative analytical tool with extensive metabolite coverage. Although various MS-based techniques are emerging for metabolomics, many of these approaches include extensive sample preparation that make large scale studies resource intensive and slow. New ionization methods are redefining the range of analytical problems that can be solved using MS. This program aims to develop new approaches for the direct analysis of small molecules in unprocessed samples, as well as push the limits of ultratrace analysis in volume limited

complex samples. These projects will result in techniques that enable metabolomics investigations with enhanced molecular coverage, as well as the study of cellular response to external perturbation. We established a new analytical platform, laser ablation electrospray ionization (LAESI) in combination with ion mobility separation (IMS) and MS, for the direct study of metabolic changes in cells and tissues following external perturbation.

FY 2014 HIGHLIGHTS

During the reporting period we demonstrated the utility of LAESI-IMS-MS to directly identify metabolites and lipids in genetically modified energy harvesting green alga (*Chlamydomonas reinhardtii*) under altered light conditions. To determine the turnover rate of secondary metabolites, lipids and peptides, we introduced pulse-chase experiments based on stable isotope labeling in combination with LAESI-IMS-MS. Increased lipid yields were observed in genetically modified strains of *C. reinhardtii*. Wild type (WT) and several mutants of *C. reinhardtii* were raised in tris-acetate phosphate (TAP) medium. Compared to the WT, an impaired starch pathway mutant showed a higher production of triacylglycerol (TAG) and digalactosyldiacylglycerol (DGDG) lipids under both light and dark conditions. LAESI-IMS-MS showed the presence of particular TAGs in both conditions, proving this to be an efficient technique for rapid lipid identification. To explore the turnover rates of the abundant diacylglyceryl-N,N,N-trimethylhomoserines (DGTS) in *C. reinhardtii*, it was cultured in ¹⁵N-labeled TAP (pulse phase). For the chase phase the ¹⁵N-labeled TAP was replaced with ¹⁴N-TAP. At several time points, analysis was conducted to discern turnover rates and half-lives of nitrogen containing biomolecules, e.g., essential lipids. LAESI-MS in combination with stable isotope pulse-chase experiments promises to provide a rapid assessment of metabolic conversion rates in complex biological systems. Extended molecular coverage in direct analysis of biological samples, e.g., the model plant *Arabidopsis thaliana*, was achieved by collecting both positive and negative ion LAESI-IMS-MS spectra and by introducing reactive components into the electrospray. In negative ion mode LAESI-IMS-MS for the analysis of *A. thaliana* leaves, small metabolites, glucosinolates (plant defense compounds), phosphatidylglycerols and triglycerides were simultaneously detected.

Computer Simulation of Proton Transport in Fuel Cell Membranes

Institution: Chicago, University of
Point of Contact: Gregory Voth
Email: gavoith@uchicago.edu
Principal Investigator: Gregory Voth
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This project involves a unique multiscale computer simulation methodology for studying proton solvation and transport in proton exchange membranes (PEMs) for fuel cell applications. A key component of the project is a novel atomistic molecular dynamics (MD) simulation approach called the Self-Consistent Iterative Multi-State Empirical Valence Bond (SCI-MS-EVB) method, which has provided, for the first time, an atomistic simulation capability to study excess proton solvation and transport in PEM, including the critical Grotthuss shuttling process (hopping transport) and vehicular transport (classical Einstein diffusion) on the same footing. Several significant advances of the SCI-MS-EVB approach have been made to improve efficiency and will be extended in the future, including a force-

matching method to derive accurate SCI-MS-EVB model parameters from *ab initio* molecular dynamics (AIMD) simulations. These algorithmic advances and enhanced code scalability have further allowed the SCI-MS-EVB simulations to access increasingly large system sizes and long simulation times. Key results obtained during the past funding period have revealed the remarkably complex behavior of the proton solvation and transport in the hydrophilic domains of Nafion™, including an unusual and unexpected anti-correlation between vehicular transport and hopping transport which increases with decreasing PEM hydration levels. The water properties in various proposed Nafion morphological models have been investigated in large-scale MD studies in order to understand how proton transport is influenced by both hydration and morphology. Novel mesoscopic-scale simulations of proton transport in PEMs have also been developed, with key extension proposed, that include a multiscale bridging of the atomistic SCI-MS-EVB data to mesoscopic proton transport modeling coupled to complex PEM morphology.

FY 2014 HIGHLIGHTS

To understand the fundamental mechanism of proton transport within perfluorosulfonic acid (PFSA) membranes, we have utilized extensive large scale SCI-MS-EVB simulations to examine two PFSA materials, Hyflon and the 3M membrane, at different hydration levels. Specific interactions between the sulfonate groups of the polymer side chains and the hydrated protons were found to have a relatively limited influence on the proton transport. Instead, proton swapping between the close hydration layers of the sulfonates was the primary mechanism for the proton transport. The hydrated excess protons are essentially always within two solvation shells of the sulfonate groups. When the solvation shells of neighboring sulfonate groups can overlap substantially, the depth of the potential energy well of individual sulfonates becomes less important. The hydrated excess proton can transfer to an adjacent, overlapping potential well, if and there is an adjacent sulfonate group. The larger water clusters and more flexible side chain of the 3M membrane allow for an enhancement of this swapping mechanism compared to Hyflon. These results have been made possible by recent advances in our SCI-MS-EVB approach, which is a unique computational methodology. It has also been found that the caging effects for the proton transport in the PFSA materials lasts up to at least 1 ns and so the required time scale for a proper calculation of the proton self-diffusion constant cannot be shorter than around 10 ns. This finding demonstrates that multiple SCI-MS-EVB trajectories of at least several nanoseconds long are needed in order to fully characterize the long-time behavior of proton transport in PFSAs, well beyond the current capabilities of *ab initio* molecular dynamics simulation.

Subnanometer Spatial Resolution Chemical Imaging

Institution:	California-Los Angeles, University of
Point of Contact:	Paul Weiss
Email:	psw@cnsi.ucla.edu
Principal Investigator:	Paul Weiss
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding:	\$630,000 (2014-2017)

PROGRAM SCOPE

We develop submolecular-resolution spectroscopic imaging in the visible, near-visible, and vibrational infrared ranges. These scanning tunneling microscopes (STMs) are used for chemical imaging in order to measure structure, function, and spectroscopy simultaneously. By combining these measurements we

will develop enabling tools to elucidate the nanoscale rules of function at the ultimate limits of miniaturization.

FY 2014 HIGHLIGHTS

We have induced (the first recorded) cooperative motion in precisely assembled one-molecule-wide lines of azobenzene-functionalized molecules. This motion has been induced both with ultraviolet (UV) photons in “broadcast” mode and locally with electrons of substantially lower energy, supplied by the STM probe tip. New capabilities were developed in order to induce this cooperative motion. First, we developed the means to assemble one-dimensional lines of functional molecules along domain boundaries in self-assembled monolayers. After our initial observation that this was possible, we were able to make these one-dimensional lines dominate the assembly of the functional molecules by processing the co-assembled films. We also developed the means to record the motion with both spatial isolation and spectral isolation, with scanning tunneling microscopy and plasmonic-substrate-enhanced Raman spectroscopy. In combination with theoretical calculations and spectroscopic simulations, we were determined that electron delocalization along the chains is critical to cooperative function in this case and were able to determine the mechanism(s) of isomerization.

Chemical Imaging with Cluster Ion Beams and Lasers

Institution: Pennsylvania State University
Point of Contact: Nicholas Winograd
Email: nxw@psu.edu
Principal Investigator: Nicholas Winograd
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$177,231 (2014)

PROGRAM SCOPE

This research effort with the Department of Energy is focused upon the use of cluster ion bombardment of surfaces, followed by laser photoionization of desorbed neutral molecules, for molecule-specific imaging experiments. This unique strategy allows the chemical identification of small molecules in the near surface region of a solid to be mapped with a lateral resolution of a few hundred nanometers, and a depth resolution of about 10 nm. The basic idea is to utilize an energetic cluster ion beam, consisting of C₆₀ or Ar₄₀₀₀ molecules, that is focused to a well-defined point on the target. During the energy deposition process, both the neutral and ionized molecules are desorbed from the surface. This research is aimed toward finding novel ways to ionize the neutral molecules using suitable a suitable light source to enhance the sensitivity to allow improved imaging and to produce as little photo-induced fragmentation as possible. The photoionized molecular ions are detected by time-of-flight mass spectrometry, and an image is created by scanning the ion beam over an appropriate area. The overarching goal is to broaden the scope of mass spectrometry imaging experiments through techniques aimed to improve molecular desorption efficiency and instrumental sensitivity.

FY 2014 HIGHLIGHTS

Prior DOE-funded research has led us to utilize high field femtosecond IR pulsed laser radiation for the most efficient photoionization of sputtered molecules. The use of IR radiation is important in order to reduce photo-fragmentation by increasing the probability of ionization via a tunneling mechanism rather

than by multiphoton excitation. A unique laser system has been implemented in the laboratory, which produces 40 fs pulses throughout the near IR (1200 nm – 2000 nm) with a peak power density approaching 1 petawatt, and a pulse repetition rate of 1 kHz. Protocols have been developed for maximizing the ionization efficiency by systematically varying laser intensity, wavelength and polarization. During FY 2014, our group has focused upon the demonstration of this strategy using a wide variety of target molecules, and to determine whether this approach does indeed improve the sensitivity of the mass spectrometry measurements. The results have been quite spectacular since we have been able to efficiently photoionize molecules up to molecular weights of nearly m/z 1000, a result not yet obtained using any other laser photoionization approach. Moreover, we have demonstrated that the method is useful for a broad range of molecules including long chain fatty acids, cholesterol and other sterols, aromatic hydrocarbons, sugars, and a variety of metal-organic compounds. Molecule-specific images have been obtained from biological tissue sections and from single algae cells. The algae studies are quite interesting since we find localization of hydrocarbons (squalene in particular) within globules produced inside the cell. With this information and the enhanced sensitivity of our imaging approach, we can better speculate about how these cells produce hydrocarbons, and hence, how their energy production might be improved. The results have been published in a series of 3 papers in Analytical Chemistry and in The Journal of Physical Chemistry.

DOE National Laboratories

Fundamental Studies of Novel Separations

Institution: Oak Ridge National Laboratory
Point of Contact: Phillip Britt
Email: britt@ornl.gov
Principal Investigator: Sheng Dai
Sr. Investigator(s): Shannon Mahurin; Oak Ridge National Laboratory
De-en Jiang; Oak Ridge National Laboratory
Students: 6 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$825,000 (2014)

PROGRAM SCOPE

The overall goal of this project is to investigate fundamental issues of gas separations by nanostructured architectures and unconventional media that selectively bind and/or transport target molecular species via tailored interactions. To achieve this goal, we will pursue three specific aims: (1) How do the molecular structures of ionic liquids (ILs) dictate separations in gas/ionic liquid systems to achieve high selectivity and fast diffusivity? (2) How do the porosity and nitrogen functionality of carbonaceous materials control gas adsorption and diffusion for advanced separations? (3) How can porous carbon and ionic liquids be rationally integrated to create advanced separation materials with controlled porosity and functionality, fast transport, and high selectivity? A combination of synthesis, characterization, testing and modeling will be employed to answer these questions. More specifically, we will explore how the molecular structure and functionality of ILs and/or combinations of ILs impact both gas solubility and diffusivity. Through improved understanding of the impact of gas/IL and cation/anion interactions and the effect of these interactions on solubility and diffusivity, we will improve our ability to design liquid membrane systems with enhanced permeability and permselectivity. We will explore novel methods to control both the surface functionality and porosity of carbon membranes to further elucidate the precise mechanisms that control gas adsorption and transport. Finally, we will take advantage of the unique properties of porous materials and ILs to create porous

liquid systems that will enhance both gas diffusivity and permselectivity in integrated membrane systems. Though we primarily focus on CO₂/N₂ separation, this work will be applicable to other species and also in developing advanced separation media which hold the key to future chemical separations in energy production and utilization, environmental remediation, and carbon capture.

FY 2014 HIGHLIGHTS

A porous, triazine and carbazole bifunctionalized task-specific polymer was synthesized via a facile Friedel–Crafts reaction. The resultant porous framework exhibited excellent CO₂ uptake (4.1 mmol/g at 273 K and 1 bar) and good CO₂/N₂ adsorption selectivity. The synthesis of hierarchical macro-, meso-, and micro-porous polymeric molecular sieve membranes was demonstrated using a one-step, *in situ* cross-linking process based on the Kirkendall effect. The porous polystyrene membranes exhibited high permeability and selectivity promising for gas separations. A CO₂-philic amidoxime functional group was grafted onto a porous carbon framework for the selective capture and removal of carbon dioxide. The presence of the amidoxime group enhanced CO₂/N₂ selectivity due to a stronger interaction of CO₂ with the functional group. Free-standing mesoporous carbon-graphitic carbon nanocomposite membranes with controllable pore size (7.3-11.3 nm) were synthesized by the “brick-and-mortar” method, in which carbon black (CB) serves as the “bricks” and soft-templated phenolic resin-based mesoporous carbon (MC) serves as the “mortar”. Immobilization of ionic liquids in the carbon gave highly stable supported ionic liquid membranes at more than 10 atm transmembrane pressure. Mesoporous carbons were prepared via spinodal decomposition of non-amphiphilic linear polyethylene glycol with phloroglucinol–formaldehyde resin under refluxing acidic ethanol conditions. By shifting the molecular weight and the concentration of the polyethylene glycol, both mesopore size and volume could be tuned.

Chemical Analysis

Funding: \$853,000 (2014)

PROGRAM SCOPE

The goal of our research is to obtain a fundamental understanding of the physical phenomena underlying chemical analysis of molecules and small particles in complex, heterogeneous environments. To achieve this goal we develop unique mass spectrometry instrumentation for studying ion-surface collisions and for comprehensive physical and chemical characterization of small particles. These one-of-a-kind experimental tools are used to address analytical challenges of interest to catalysis, energy storage, materials science, and environmental science. Specifically, our experiments probe physical and chemical phenomena underlying collisions of ions with surfaces. Surface induced dissociation provides important information on the binding energies in complex molecules of interest to self-assembly, photovoltaics, and light harvesting. Our fundamental studies established preparatory mass spectrometry as a unique tool for the highly selective preparation of novel materials. We also develop nanospray desorption electrospray ionization– a new ambient ionization technique for sensitive chemical analysis of complex mixtures. Our experimental capabilities enable multidimensional characterization of a of

individual small particles in-situ and in real-time. Simultaneous measurements of particle, size, composition, density, shape, phase, and fractal dimension transformed the way complex organic particles are viewed and treated by models. Specifically, we demonstrated that evaporation rates of mixed organic particles are orders of magnitude slower than predicted by broadly accepted models indicating these particles are semi-solids. Using the newly developed methods to characterize particle morphology, we demonstrated the multi-layered structure of complex organic particles. Unique software packages were developed for visualization and interpretation of the large experimental datasets without loss of detailed information that is inherent to multidimensional individual particle data.

FY 2014 HIGHLIGHTS

Surface-induced dissociation experiments enabled the first experimental determination of the ligand binding energies in small triphenylphosphine-ligated cationic gold clusters. We demonstrated that clusters with high ligand binding energies are observed with enhanced abundance in the initial stages of nucleation in solution. These results are important to controlling solution-phase nucleation and growth of nanoparticles of interest to catalysis, molecular electronics, and sensing. We also developed a new temperature-controlled flow reactor for studying nanoparticle formation in solution using mass spectrometry, which will enable future studies of the structures and stability of intermediates produced during batch synthesis. Our soft-landing experiments focused on charge retention by native dications and anions on well-characterized organic surfaces. Fundamental understanding of charge retention is essential for the controlled preparation of catalytically active substrates using ion soft-landing. Our studies of phenomena pertinent to the non-equilibrium formation, properties, and transformations of complex organic-containing particles, focused on understanding diffusion in nanoparticles, characterization of particle morphology, and evaporation kinetics of size-selected nanoparticles at different relative humidity. Imaging of particles with multifaceted shapes and morphologies provided important information on the relationship between nanoparticle shapes, physicochemical properties, and dynamics in different flow regimes. In addition, we continued the development of new approaches for visualization and analysis of large multidimensional data. Specifically, we implemented a novel approach to incremental correlation clustering of large datasets with visual feedback, and new interactive visual analytics software designed to explore and visualize complex, multidimensional data in a geo-spatial context.

Principles of Chemical Recognition and Transport in Extractive Separations

Institution: Oak Ridge National Laboratory
Point of Contact: Phillip Britt
Email: brittpf@ornl.gov
Principal Investigator: Bruce Moyer
Sr. Investigator(s): Radu Custelcean; Oak Ridge National Laboratory
Laetitia H. Delmau; Oak Ridge National Laboratory
Ben Hay; Oak Ridge National Laboratory
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$1,135,000 (2014)

PROGRAM SCOPE

This program strives to provide new understanding of the theoretical, synthetic, structural, and thermodynamic principles of molecular recognition leading to unprecedented selectivity and control of

ion binding in separations such as liquid-liquid extraction and crystallization. The major line of inquiry deals with the design of fully functional ion receptors that can completely accommodate the coordination and charge-neutralization requirements for separation of ions, ion pairs, or ion aggregates, whether the recognition occurs with discrete molecular receptors or small molecular units that function by self-assembly. Three specific aims deal with computer-aided molecular design to guide the discovery of molecular structures with controlled functionality; self-assembly of small molecular units with multiple ions to form predetermined structures; and cooperativity effects in the selective separation of ions and ion pairs. Specific progress is being made with new anion-binding motifs based on new guanidinium, urea, and calixpyrrole platforms, and when these are combined with cation-binding groups, the resulting ditopic structures self-assemble with ion-pairs in high-order assemblies. Resulting transformative understanding of the theoretical, structural, and thermodynamic principles underlying ion recognition will strongly benefit DOE's energy, environmental, and national-security missions.

FY 2014 HIGHLIGHTS

Research results in FY 2014 reflect an advancing understanding of fully functional receptors for selective separation of ions in extractive systems. Most newsworthy was the first demonstration of a pseudobicyclic guanidinium receptor for binding oxoanions. The guanidinium group has long been a key building block in the design of oxoanion receptors, but its flexibility has led researchers to employ a difficult-to-prepare bicyclic guanidinium structure for preorganization. To explore whether alternative pseudobicyclic analogs could be found, N,N'-bispyridylguanidine was successfully synthesized, and an X-ray crystal structure demonstrated the 2:1 symmetrical binding of sulfate by the hypothesized pseudobicyclic guanidinium form. In another major accomplishment, the use of an anion receptor, meso-octamethylcalix[4]pyrrole (C₄P), to alter the selectivity of liquid-liquid cation exchange was demonstrated for the first time, and a crystal structure confirmed the hypothesized binding of the lipophilic anion of the alkylphenol cation exchanger by C₄P. To improve the solubility of C₄P in organic solvents, the template synthesis of a tetrahexyl derivative was accomplished in a single pot, and the new more lipophilic derivative serendipitously exhibited 100-fold greater selectivity for sulfate vs. chloride in an anion-exchange system. Extraction of sulfate by two bispyrrole-strapped C₄P anion receptors provided by collaborator J. L. Sessler at UT-Austin was also elucidated. In preparation for ion-pair extraction studies of Fr⁺ ion using C₄P, the Gibbs energies of partitioning of Fr⁺ between water and the solvents 1,2-dichloroethane and o-nitrophenyl octyl ether were determined for the first time. The molecular design of ion-pair architectures, including helicates and higher-order assemblies such as cubes and tetrahedra was completed, and preliminary results were obtained for the self-assembly of one of the targeted structures in solution.

Laser Materials Interactions (Ablation)

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov
Principal Investigator: Rick Russo
Sr. Investigator(s): Xianglei Mao; Lawrence Berkeley National Laboratory
Vassilia Zorba; Lawrence Berkeley National Laboratory
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$340,000 (2014)

PROGRAM SCOPE

Traditional chemical analysis involves outdated laborious acid dissolution procedures that are harmful to personnel and the environment. In contrast, laser based chemical analysis offers a clean (green) advanced capability that mainly utilizes light energy. The research in this BES program focuses on understanding and developing laser ablation for direct solid sample chemical analysis; laser ablation offers real-time analysis without sample preparation or consumables, provides nanometer spatial scale imaging and analysis, and can be utilized for every application, for example energy, environmental, forensics, nonproliferation and almost every industrial application. Laser ablation chemical analysis can and will become a mainstream capability for society by expanding our knowledge of fundamental processes; establishing underlying principles for using laser energy to measure the chemistry of a sample. This research emphasizes the study of laser ablation for elemental and isotopic analysis at atmospheric pressure. Goals are to understand fundamental principles related to the efficiency of coupling laser energy into the sample, energy transfer, thermal and shock removal of sample constituents during ablation, effect of ionized plasma shielding, the influence of the surface plasma on ablation, and particle formation. The research also addresses laser plasma chemistry as the fundamental basis for formation of chemical species in the plasma plume that ultimately influence the precision and accuracy of analysis. Time-resolving underlying non-linear ablation processes and assigning mechanisms to describe the measured chemistry in the plasma and of the aerosol form the basis of this research program.

FY 2014 HIGHLIGHTS

Our recent breakthrough in this laser ablation chemical analysis technology was the discovery of molecular signatures in the optical surface plasma (induced by the laser ablation event) that amplify spectral isotope splitting; molecular bands provide isotope signatures with orders of magnitude spectral splitting compared to atomic and ionic lines. Our new technology was named LAMIS for Laser Ablation Molecular Isotopic Spectroscopy. LAMIS provides new capabilities for studying laser ablation processes and as a new technology for real time isotopic analysis without a mass spectrometer. The LAMIS technology has won several awards including twice being recognized as best published papers in Spectrochimica Acta B. Using isotopically spiked samples, we measured the spatial and temporal formation of molecular species in the plasma, and related these data to the underlying high temperature and pressure ablation of the sample. These new data allow us to tailor the ablation process for enhancing the sensitivity, accuracy and precision of analysis. We demonstrated LAMIS as a new isotope analysis technology with precision approaching that of thermal ionization mass spectrometry (TIMS) for boron isotope ratio measurements. The LAMIS data were recorded at atmospheric pressure in two minutes whereas the TIMS data required vacuum, sample preparation and almost two hours. To date, we have demonstrated LAMIS for U, Sr, W, H/D and C. Precision is dependent on the number of laser pulses; we have achieved <0.1% precision using 1000 laser pulses (two minutes). LAMIS is gaining recognition by the analytical scientific community as one of the most significant capabilities presented in atomic spectroscopy.

Chemical Analysis of Nanodomains

Institution: Ames Laboratory
Point of Contact: Cynthia Jenks
Email: cjenks@ameslab.gov

Sr. Investigator(s): Jacob Petrich; Ames Laboratory

Ning Fang; Ames Laboratory
Javier Vela; Ames Laboratory

Students: 2 Postdoctoral Fellow(s), 11 Graduate(s), 0 Undergraduate(s)
Funding: \$582,000 (2014)

PROGRAM SCOPE

Many important phenomena occur on a spatial scale that is smaller than can be probed noninvasively by conventional optical techniques. Understanding these nanoscale phenomena is fundamental to the DOE mission of developing new and revolutionary clean energy technologies. Using the combined tools of time-resolved stimulated emission depletion (fluorescence) microscopy, scanning angle (SA) Raman microscopy, time-resolved spectroscopies, and skills in materials synthesis, the Chemical Analysis of Nanodomains program develops and characterizes distinct and widely applicable strategies for preparing nanomaterials and films of nanomaterials having improved performance in solar cells. The objective of the research is the analysis of the next generation of solar-cell materials that will one day outperform existing commercial technologies in terms of efficiency, stability, and cost. The specific aims are to: (1) develop and elucidate the photophysical, photochemical, and stability behavior displayed by organometal halide perovskite and germanium nanomaterials; (2) develop SA Raman spectroscopy to extract axial chemical information about films consisting of two or more species with distinct layers or phases; (3) develop a fundamental understanding of the diffusion properties within a polymer film containing defined structural characteristics; and (4) identify the structural features responsible for performance decay and enhancement in organometal halide perovskite and germanium solar cells. As outlined in the BESAC report, "New Science for a Secure and Sustainable Energy Future," this work fills a need for the development of teams "to close gaps between needs and capabilities in synthesis [and] characterization ... of advanced materials," and develop tools that probe materials and chemical processes with unprecedented resolution, where the compositions and dynamics need to be non-invasively measured on the nanoscale, and particularly for analyses in complex environments.

FY 2014 HIGHLIGHTS

Stimulated Emission Depletion (STED) Imaging: This program quantitatively addressed how to increase the validity of measured lifetimes by STED without compromising the subdiffraction spatial resolution, which is the inherent benefit of the technique. The important conclusion of this work is time binning can be applied to increase the number of photons in the peak channel without affecting the lifetime values.

SA Raman Spectroscopy: A second-generation, fully automated, low angular spread and uncertainty, visible excitation SA Raman spectrometer was developed. SA Raman spectra of a diblock copolymer were collected with a signal-to-noise ratio of 30 using a 0.25 s acquisition. The instrument was subsequently used to study bulk heterojunction photostability of organic photovoltaic films containing a polymer donor and a fullerene-derivative acceptor. This information can enable more photostable devices, with the end goal of providing organic photovoltaic films suitable for a range of applications. A complementary technique for thin film analyses at a gold interface called Fourier transform plasmon waveguide resonance was also demonstrated; and the location of a buried interface between two polymers was measured by SA Raman spectroscopy with approximately 10 nm precision—orders of magnitude better than confocal Raman spectroscopy.

Nanomaterials: The program has used high-resolution superlocalization imaging to reveal the nature and photocatalytic properties of surface reactive sites on single CdS-Au hybrid nanocatalysts. The results from this study bear enormous potential impact on the development of better visible light photocatalysts for solar-to-chemical energy conversion. A simple synthesis for controlled size and

morphology $\text{CH}_3\text{NH}_3\text{PbI}_3$ and $\text{CH}_3\text{NH}_3\text{PbBr}_3$ perovskites was developed. $\text{CH}_3\text{NH}_3\text{PbI}_3$ nanocrystals with several distinct morphologies behave as nonblinking and photostable single particle emitters at room temperature, and may be useful in energy capture devices.

Improving Chemical Separations through Understanding of Weak Interactions

Institution: Oak Ridge National Laboratory
Point of Contact: Phillip Britt
Email: brittpf@ornl.gov
Principal Investigator: Andrew G. Stack
Sr. Investigator(s): Ariel A. Chialvo; Oak Ridge National Laboratory
J. Michael Simonson; Oak Ridge National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$388,000 (2014)

PROGRAM SCOPE

The goal of this research is to achieve a predictive understanding of the molecular-level interactions in solution that drive the affinity and selectivity between target ions and receptors in chemical separations. Theoretical and experimental efforts will be aimed toward understanding the specific contributions of solvation environment to selectivity in extractive separations. Determining local structure in solution will provide the experimental basis for new understanding of changes in entropy in solvation and binding; molecular-level modeling of solvation and binding interactions will strengthen predictive capabilities for anion extraction; and detailed investigations of the liquid-liquid interface will provide new insights into interfacial effects on extractive separations. To accomplish these specific aims we will take advantage of available and emerging capabilities in neutron scattering and computational sciences at ORNL. Success in this research will enhance the molecular-level predictability of extractive separations, extending the current capabilities from separate quantum mechanical considerations of individual ion-receptor interactions and structural determinations in ordered solids, to a bridging understanding of the important effects of solvent rearrangement on extractive separations. These new capabilities will contribute directly to DOE missions in energy production and utilization, environmental remediation, and to national and energy security.

FY 2014 HIGHLIGHTS

The goal of this program is to develop a general method to measure the hydration structure of aqueous oxyanions using neutron diffraction with isotopic substitution (NDIS) with accompanying classical molecular dynamics (MD) simulations. Previously, the hydration structure of aqueous nitrate ion was confirmed by using nitrogen isotopes, and preliminary data for oxygen isotope substitution was collected. Using MD simulations, a technique to rapidly predict the total scattering for each sample was developed and implemented. It was determined that the difference in scattering signal between the naturally abundant and isotopically enriched samples should be $\sim 0.2\%$, whereas actual measured differences were much larger (3-4%). Once the sources of errors were determined (hydrogen contamination, small concentration differences and sample holder diameter), new methods were developed to remove these prior to the experiment as well mitigate them “on-the-fly” during the course of the experiment. Most hydrogen contamination was eliminated by performing all sample preparation inside a glove box. Small amounts of hydrogen contamination (likely from salts used to create stock solutions), sample thickness and concentration differences were mitigated by titrating with a solution of slightly more concentrated similar concentration and isotopic enrichment, with small amounts of

hydrogen added. This method development effort has significantly paid off, as we just recently made the best measurements of oxygen substituted NDIS we have ever performed. The results show that aqueous nitrate ion does not contain a strong coordination shell of ordered water compared to chloride ion. This is rationalized by the small hydration free energy of nitrate (~300 kJ/mol) compared to e.g., aqueous sulfate ion (~1100 kJ/mol) and that this free energy is spread out over a larger anion compared to chloride (also ~300 kJ/mol). The corresponding MD simulation work on the nitrate system has also been completed.

Spatially Resolved Material Characterization at Interfaces

Institution: Oak Ridge National Laboratory
Point of Contact: Phillip Britt
Email: brittpf@ornl.gov
Principal Investigator: Gary Van Berkel
Sr. Investigator(s): Vilmos Kertesz; Oak Ridge National Laboratory
Olga Ovchinnikova; Oak Ridge National Laboratory
Benjamin L. Doughty; Oak Ridge National Laboratory
Yingzhong Ma; Oak Ridge National Laboratory
Students: 5 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,669,000 (2014)

PROGRAM SCOPE

The overarching goal of this research is to surpass the existing analytical capability for nanometer scale spatially resolved material characterization at interfaces under ambient conditions. This is being accomplished through a distinctive merger of advanced spectroscopic and ultrafast time-resolved imaging, scanning probe microscopy, and mass spectrometry. There are two synergistic subtasks in this proposal. In Subtask 1, research is focused on enabling and advancing the ability of ambient surface sampling/ionization mass spectrometry, in combination with other imaging modalities, to study and characterize with submicrometer spatial resolution (100- 1000 nm) molecular and elemental constituents of material interfaces under real world conditions. In Subtask 2, research is focused on utilizing optical spectroscopic methods with high spatial and temporal resolution to provide an understanding of the ultrafast energy flow and chemical reactions in nanostructures and selected functional nanostructure assemblies by imaging individual nanoparticles and nanostructures with chemical contrast, nanoscale spatial resolution, and femtosecond time resolution. Combinations of techniques that capitalize on both optical spectroscopy and mass spectrometry will provide deeper chemical understanding of interfaces than could either discipline alone. Mass spectrometry operates on the molecular level, while our optical techniques probe nanostructures and their assemblies. The new techniques and tools developed under the umbrella of this research proposal to study and characterize a surface, with submicrometer spatial resolution with the ability to specifically identify a wide range of elements, molecular compounds from small molecules to large macromolecules, and functional domains, over a variety of time scales, will be of great utility in the advancement of the DOE mission (including solar energy utilization, energy storage, fuel cells, and catalysis).

FY 2014 HIGHLIGHTS

The mass spectrometry (MS) subtask focused on new concepts for surface sampling/ionization and enhanced material transport and ionization efficiency. A controlled-resonant surface tapping-mode scanning probe electrospray ionization MS imaging platform was shown to provide 35 μm spatial

resolution. It also provided a simple, hands-off means to control the surface to probe liquid microjunction for direct liquid extraction. A transmission geometry laser ablation system combined with a liquid vortex capture probe was implemented for MS imaging enabling a 6 μm spatial resolution. We also advanced a hybrid atmospheric pressure atomic force microscopy/MS imaging system utilizing nano-thermal analysis probes for thermal desorption surface sampling with subsequent atmospheric pressure chemical ionization and mass analysis. The ability to correlate topographic images of a surface and mass spectral chemical images of the same surface, both with nanometer scale resolution was demonstrated. Work within the optical spectroscopy subtask focused on the key electronic excited-state processes in several molecular and polymeric systems, including phlorins, pristine and deuterated P3HTs as well as their thin film blends with PCBM. Extensive effort was taken to develop two femtosecond pump-probe microscopic imaging apparatuses for quantitative assessment of complex electronic excited-state phenomena in spatially heterogeneous systems. The first one is based on an 82 MHz femtosecond oscillator, and its utilization of a white-light continuum probe, offers not only broad spectral range but also can be extended for coherent Raman and electronic four-wave mixing imaging. The second one employs a 250 kHz regenerate amplifier system offers remarkably broader spectral tunability, higher pulse energy and wider applicability than those achievable with the first apparatus. The lower repetition rate makes the second platform particularly suitable for examining long-lived excited state processes.

Electronically Wired Semiconductor Nanoparticles: Toward Vectoral Electron Transport in Hybrid Materials

Institution: Arizona, University of
Point of Contact: Neal Armstrong
Email: nra@email.arizona.edu
Principal Investigator: Neal Armstrong
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

We are focused on the development of new semiconductor nanomaterials which are prototypical for systems that may be ultimately used to photoelectrochemically produce fuels from sunlight, and in understanding how the introduction of catalytic sites (e.g. metallic tips on a semiconductor nanorod) can alter the band edge energies (E_{VB}/E_{CB}) and the dynamics of electron transfer to/from these nanomaterials

FY 2014 HIGHLIGHTS

We have demonstrated new approaches to a) the characterization of valence band energies using photoemission spectroscopies, which for the first time fully take into account local vacuum level shifts (due to the dipolar nature of the NR), and b) conduction band energies (E_{CB}) using waveguide-based spectroelectrochemical approaches to determine the potentials (versus vacuum) for electron injection into the NC (nanocrystal) or NR (nanorod). Both approaches show significant shifts in band edge energies, and the rates of electron transfer (ET), when NCs and NRs are decorated with metallic and oxide catalytic sites at the NR tip. Even small Au nano-tips on CdSe NRs, where the metallic component is less than 1% of the total atomic content of the NR, introduces shifts in E_{VB} and E_{CB} which are predicted to alter efficiencies of photoelectrochemically driven water splitting and related formation pathways toward solar fuels.

EARLY CAREER: Molecular and Structural Probes of Defect States in Quantum Dots for Solar Photoconversion

Institution: Pennsylvania State University
Point of Contact: John Asbury
Email: jasbury@psu.edu
Principal Investigator: John Asbury
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 3 Undergraduate(s)
Funding: \$144,000 (2014)

PROGRAM SCOPE

This project investigates fundamental problems associated with charge photogeneration and transport in emerging solution processed photovoltaic systems. In traditional inorganic semiconductors such as crystalline silicon, the density of charge traps and defects can be reduced sufficiently to permit the electrical transport length to exceed the thickness of material needed to absorb all photons with energy greater than the bandgap of the semiconductor. Emerging solution processed photovoltaic layers composed of organic molecules, colloidal nanocrystals or organo-halide perovskites offer alternate routes to high throughput manufacture that exceed the capacity of crystalline silicon by many orders of magnitude. However, these chemical systems have struggled to achieve defect densities and photochemical stability that are comparable to traditional inorganic semiconductors. In this project, the molecular origins of charge traps and defects are examined in emerging solution processed inorganic systems for solar to electric photoconversion. Charge traps and defects are minority species and so cannot be examined with traditional characterization tools such as X-ray diffraction or electron microscopy that report majority chemical species. Novel infrared electro-optical spectroscopies are developed that permit the introduction of charge carriers into photovoltaic chemical systems that then equilibrate with electronic states at the band edges providing a means to selectively examine charge traps. The infrared spectroscopy permits structurally specific examination of the underlying molecular structures that give rise to these states. The problem of how complex intermolecular interactions in the solid state influence the formation of charge traps and defects is also being investigated by hypothesis based variation of ligand-nanocrystal interactions in colloidal nanocrystals and composition dependent crystallization of organo-halide perovskite photovoltaic systems.

FY 2014 HIGHLIGHTS

This project had earlier demonstrated the ability to tune the density and energetic distribution of charge traps and recombination centers in photovoltaic systems composed of dense arrays of colloidal nanocrystals by systematic variation of ligand-nanocrystal interactions. Collaboration with the Sargent group at University of Toronto revealed that these variations gave rise to a twenty-fold increase in the mobility-lifetime products of the photovoltaic layers with corresponding increases in the solar to electric power conversion efficiencies. One recent effort in this project has focused on overcoming the solubility limitation of ligand exchanged nanocrystals to enable fundamental studies of how ligand-nanocrystal interactions influence the electronic structure and charge transport properties of the systems. This approach involved suspending ligand exchanged nanocrystals in inert polystyrene matrices as a means to prevent inter-particle transport and enable examination of the electronic structure of isolated nanocrystals. Another effort focused on extending the infrared electro-optical spectroscopy techniques to examine molecular species involved in the formation of charge traps and recombination centers in organo-halide perovskite absorbers. Initial work in this direction has used transient infrared spectroscopy to reveal that hydrogen bonded N-H and O-H moieties associated with organic cations in the perovskite phase provide structurally specific probes of the interaction of photogenerated charge carriers with the photovoltaic layer. In future work, this capability will be used to examine the structural origins of charge trapping and photodegradation of organo-halide perovskite systems.

Nano-Structured Electrocatalysts for Conversion of Solar Energy to Fuels

Institution: Texas-Austin, University of
Point of Contact: Allen Bard
Email: ajbard@mail.utexas.edu
Principal Investigator: Allen Bard

Sr. Investigator(s): Charles Mullins; Texas-Austin, University of
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Objectives: We seek advances in the discovery, design, development, fabrication, testing, and fundamental understanding of stable, high-performing, nano-structured materials for solar photoelectrochemical (PEC) production of hydrogen. Practical, sustainable, and scalable solutions will require low-cost, high-availability, stable materials. **Description of the Project:** The project will focus on the discovery and characterization of new nanostructured semiconductor photo-materials and electrocatalysts for PEC systems for production of hydrogen. The morphology of the photo-material is important just as is its compositional make-up; both interactively determine optical and charge-transport characteristics. We will continue and expand the search for new material compositions (including the effects of dopants) and synthesize films of candidate photo-materials for physical and photoelectrochemical characterization. We will also study the performance of amorphous silicon triple junction photovoltaic cells with electrocatalytic and protective coatings. This work is proposed as fundamental research. **Methods:** We will synthesize films of candidate photo-materials by one or more of several synthesis methods, including electrodeposition, chemical spray pyrolysis, drop-casting, reactive ballistic deposition, hydrothermal synthesis, and coatings applied via atomic layer deposition. **Potential Impact:** The development of photocatalytic solar energy conversion as a sustainable, scalable alternative to other forms of energy would provide plentiful renewable energy for the world, whose energy use is projected to double by 2050. As an important chemical feedstock, solar hydrogen could displace at least some production from steam reforming of natural gas, comparatively without emissions of carbon dioxide or sulfur.

FY 2014 HIGHLIGHTS

Over the last year we have conducted several studies of electrocatalysts and nanostructured photomaterials for the production of fuels (especially hydrogen) from solar energy. We have also performed studies of the magnitude and mechanism of electronic conduction in pure and doped bismuth vanadate. This work has resulted in more than one dozen archival journal articles containing the results of these studies. **Future Plans:** We will continue to study Surface Interrogation-Scanning ElectroChemical Microscopy of photomaterials and electrocatalysts searching for photogenerated intermediates. We will also continue to investigate the behavior of semiconductor composites. Finally, we will continue working on the development and characterization of electrocatalysts for both OER and HER and the effect of photomaterial support on electrocatalytic behavior.

Carbon Dioxide Reduction to Organics in an Aqueous Photoelectrochemical Environment: the Impact of Semiconductor Energetics and Aromatic Amine Reaction Dynamics

Funding: \$190,000 (2014)

PROGRAM SCOPE

Work during FY 2014 involved the interaction of aromatic amines with p-GaP for the photocatalytic reduction of CO₂ and the synthesis and characterization of new p-type metal oxide semiconductors as photocathodes for the reduction of either CO₂ or H₂O. Mechanistic studies focused on the p-GaP/pyridinium system where a strong dependence on crystal face employed, (111) vs. (100), was detected. We also found a strong potential dependence (formate vs. methanol) on the GaP (100) surface when lutidinium was the catalyst. This finding is contrary to the expected (ideal) behavior of a semiconductor/electrolyte interface and implies a key role for a density of surface states that moderates charge transfer specifically to formate. Separately, we synthesized and characterized the Mg doped delafossite, p-CuFeO₂ and evaluated it as a photocathode for the reduction of CO₂ in aqueous electrolyte. This layered material, has a measured band gap of 1.36 eV with a conduction band edge at 1.1 V vs. SCE. This material selectively reduces CO₂ to formate without the need for a dissolved cocatalyst. Under the conditions we have employed CO₂ is converted to formate at ~800 mV of underpotential. Based on this system we synthesized the analogous delafossite, p-CuRhO₂. We determined a band gap of 1.9 eV. This material was found to be surprisingly inept at reducing CO₂. Rather, it efficiently splits water at zero bias! Further, the material was found to be self-healing at basic pH in the presence of air. Faradaic efficiencies for H₂ production reach 80%, with good electrode stability. This novel system is one of the few photoelectrochemical systems that successfully splits water without external bias under insolation.

FY 2014 HIGHLIGHTS

- Determined that the aromatic amine catalyzed reduction of CO₂ at a p-Gap photocathode has unexpected surface and potential dependences.
- Synthesized a new photocathode material, Mg-doped p-CuFeO₂ and demonstrated the ability of this material to efficiently reduce CO₂ to formate using visible light.
- Synthesized a new photocathode material, p-CuRhO₂ and demonstrated the ability of this material to efficiently split water at zero bias under visible light irradiation.

Semiconductor-Electrocatalyst Contacts: Theory, Experiment, and Applications to Solar Water Photoelectrolysis

Institution: Oregon, University of
Point of Contact: Shannon Boettcher
Email: swb@uoregon.edu
Principal Investigator: Shannon Boettcher
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$157,000 (2014)

PROGRAM SCOPE

Semiconductor photoelectrodes coated with electrocatalysts are key components of photoelectrochemical (PEC) energy conversion and storage systems. Despite an intense effort aimed at optimizing these materials, there has been little systematic work focused on the semiconductor-electrocatalyst (SC-EC) interface. The SC-EC interface is important because it is responsible for collecting the photoexcited electron-hole pairs generated in the semiconductor. The objectives of this research are to: (1) Understand the rate-/performance-limiting processes at SC-EC interfaces using computer

simulations to predict PEC J-E response as a function of materials parameters. (2) Fabricate and study model systems using single-crystal photoelectrodes to verify predictions and determine how the rates of SC-EC electron/hole transfer and the SC-EC interface energetics vary for different catalyst architectures. The catalyst architectures that will be studied include dense crystalline oxide films, redox-active ion-permeable oxide/hydroxide films, and monolayers of robust inorganic polyoxometalate molecular catalysts. (3) Uncover the interface/catalyst design-principles critical to improving PEC water-splitting photoanodes. This work focused on SC-EC interfaces will therefore fill key knowledge gaps in the understanding of solar-water-splitting using catalyst-modified semiconductor photoelectrodes. This will enable the design of improved materials systems that are practically relevant because they provide a mechanism to directly convert and store solar energy in the form of hydrogen gas, a renewable chemical fuel.

FY 2014 HIGHLIGHTS

We developed a new experimental technique, dual-electrode photoelectrochemistry allowing for direct electrical measurement of the semiconductor-catalyst interface in solar water splitting devices. We also developed the first theory of the semiconductor-catalyst interface and applied the theory through numerical simulation to predict interfacial charge transfer properties of the semiconductor-catalyst junction. We discovered that porous, ion-permeable, redox-active catalysts such as Ni-(Fe) oxyhydroxides form so-called “adaptive” junctions where the effective interfacial barrier height to electron transfer depends on the charge state of the catalyst. This is in sharp contrast to interface properties of dense catalysts, which we found form buried junctions that could be described by simple equivalent electrical circuits. These results elucidated a design principle for catalyzed photoelectrodes - high-performance photoelectrodes with direct semiconductor-catalyst junctions use soft deposition techniques that yield ion-permeable catalysts.

Modular Nanoscale and Biomimetic Assemblies for Photocatalytic Hydrogen Generation

Institution: Rochester, University of
Point of Contact: Kara Bren

Principal Investigator: Kara Bren
Sr. Investigator(s): Todd Krauss; Rochester, University of
Richard Eisenberg; Rochester, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$240,000 (2014)

PROGRAM SCOPE

The conversion of solar energy into chemically stored energy is a crucial component of efforts to develop solar energy resources in the U.S. and to lessen our dependence on fossil fuels. The primary objective of this project is the development of a multicomponent assembly to convert visible light energy into chemically stored energy in the form of hydrogen (H₂). The proposed photochemical hydrogen production assembly possesses a modular design. The separation of components enables rapid progress through parallel development of individual modules. The three modular components are: 1) a light-absorbing and charge-transfer module consisting of semiconductor quantum dots, 2) a non-porous carbon nanotube membrane that rapidly transfers electrons and protons to a proton-reducing catalyst and separates the light-harvesting and proton-reducing components; and 3) a proton-reducing catalyst in the form of a coordination complex or a metalloprotein that incorporates earth-abundant

metals. Numerous methods are being employed from the fields of biology, chemistry, optics, and materials science and engineering for the development, fabrication, characterization, and testing of the assemblies and their separate components. The experimental methods and techniques required for the project include protein engineering, atomic force microscopy, absorption and fluorescence spectroscopy, time-resolved optical spectroscopy, chemical vapor deposition, optical lithography, current-voltage spectroscopy, synthetic chemistry, electrochemistry, and kinetics studies.

FY 2014 HIGHLIGHTS

A major leap forward in the light-driven generation of H₂ from aqueous protons was taken with the construction of a system in which the light absorber or photosensitizer consists of water-solubilized CdSe quantum dots and the catalyst is an *in situ* formed Ni complex. Activity and robustness are impressive with turnover numbers approaching 1,000,000, activity maintained over 15 days, and a quantum yield for H₂ of 36% with 520-nm light. The activities of a series of catalysts have been assessed with the CdSe photosensitizer. Several specific classes of catalysts were examined including bis-dithiolene complexes of Co and Ni and related derivatives. These complexes possess redox-active ligands that are valuable for assembling two protons and two electrons into H₂ at the catalyst center. A new class of catalysts for H₂ evolution developed consists of artificial hydrogenases based on proteins and porphyrin-peptide assemblies. Electrocatalytic H₂ evolution was accomplished using a water-soluble cobalt porphyrin peptide, CoMP11-Ac, with a turnover number of over 20,000 at nearly quantitative Faradaic yield, at pH 7.0, in the presence of air. Regarding the charge-transfer module, freestanding vertically aligned carbon nanotube membranes have been synthesized and their electron conductivity and proton transport properties characterized. These membranes were used in an integrated system with colloidal CdSe quantum dots to generate photocurrents. The nanotubes were found to have excellent transport properties, directing both electrons and protons over micron distances in a macroscopically directional manner. Materials with these properties are of interest in solar fuel and fuel cell technologies.

Oxomanganese Catalysts for Solar Fuel Production

Institution: Yale University
Point of Contact: Gary Brudvig
Email: gary.brudvig@yale.edu
Principal Investigator: Gary Brudvig
Sr. Investigator(s): Victor Batista; Yale University
Robert Crabtree; Yale University
Charles Schmittenmaer; Yale University
Students: 2 Postdoctoral Fellow(s), 11 Graduate(s), 0 Undergraduate(s)
Funding: \$580,000 (2014)

PROGRAM SCOPE

This project involves close cooperation of our four research groups in the Chemistry Department at Yale University. The goals are to integrate water-splitting catalysts that we have developed with sensitized metal oxide nanoparticles to construct solar-driven photocatalytic cells, and also to investigate how to achieve the advances in efficiency necessary to make photocatalytic water oxidation an economically viable solar fuel resource. In prior work, we have developed new methods for surface attachment of molecular components and catalysts to metal oxide nanoparticles with oxidation-resistant anchors and

linkers that are stable in water and have verified interfacial electron transfer. The specific objectives of the proposed research program are:

- (1) to attach water-oxidation catalysts to mesoporous metal oxide films using anchors,
- (2) to develop photosensitizers that are stable during catalytic turnover, give rapid electron injection upon visible-light excitation, and suppress detrimental recombination while permitting visible light absorption for solar fuel formation,
- (3) to develop structure-activity relationships for charge and energy transfer essential for photocatalysis as characterized by spectroscopic, synthetic and computational methods.
- (4) to couple water-oxidation catalysis to photon-driven single-electron transfer at a photoanode, and
- (5) to couple catalysts for hydrogen production to photochemical water-oxidation in a photoelectrochemical cell.

FY 2014 HIGHLIGHTS

Several new approaches have been developed to attach molecular components and catalysts to metal oxide surfaces and to optimize interfacial electron transfer. By using a modular assembly method, we constructed T-shaped assemblies with a molecular dye bound to a metal oxide surface via an anchoring group attached to pyridine which is axially bound to a high-potential zinc porphyrin. We find that a hydroxamate anchoring group has the best combination of stability and electronic coupling for photoexcited electron injection from a molecular dye into the metal oxide conduction band. We also designed a porphyrin-based model system to examine the use of lateral intermolecular hole transfer as an efficient means to increase transport of holes to a water-oxidation catalyst. Measurement of the hole-hopping kinetics by using transient absorption spectroscopy shows that each hop occurs in 25 ns, enabling efficient hole harvesting for multielectron photoelectrocatalytic applications. In order to enhance the directionality of interfacial electron transfer, we developed a computational screening methodology for systematic search of molecular frameworks with intrinsic electronic rectification. We find that N-phenylbenzamide derivatives are very promising scaffolds to build molecular rectifiers for energy-harvesting purposes.

Graphene Charge Transfer and Chemical Reactions

Institution: Columbia University
Point of Contact: Louis Brus
Email: leb26@columbia.edu
Principal Investigator: Louis Brus
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This project focuses on the special electronic and optical properties of graphene with adsorbed molecular species. Graphene makes an excellent substrate for current collection in nanostructured photovoltaic designs. Graphene is almost transparent, and can be used as a solar cell window. It also has no surface states, and thus current is efficiently transported over long distances. Progress in graphene synthesis indicates that there will soon be practical methods for making large pieces of graphene for devices. We now need to understand exactly what happens to both ground state and electronically excited molecules and quantum dots near graphene, if we are going to use them to absorb light in a nano-structured photovoltaic device using graphene to collect photocurrent. We also need to

understand how to shift the graphene Fermi level, to optimize the kinetics of electron transfer to graphene. And we need to learn how to convert local graphene areas to semiconductor structure, to make useful spatially patterned graphenes. In this project we work on several basic science experiments related to these goals.

FY 2014 HIGHLIGHTS

We finished a detailed study of gaseous Br₂ adsorption and charge transfer on graphene, combining *in situ* Raman spectroscopy and density functional theory (DFT).

Radiation and Photochemistry in the Condensed Phase and at Interfaces

Prashant Kamat; Notre Dame, University of
Jay LaVerne; Notre Dame, University of
Sylwia Ptasinska; Notre Dame, University of
Students: 8 Postdoctoral Fellow(s), 14 Graduate(s), 16 Undergraduate(s)
Funding: \$5,035,000 (2014)

PROGRAM SCOPE

Research at the Notre Dame Radiation Laboratory builds on a long history of significant accomplishment in basic radiation chemistry, impacting fields ranging from nuclear power generation to medical physics, and a world-renowned program in solar energy conversion. A first thrust focuses on homogeneous solutions, often under extreme conditions, integrating both experimental and computational investigations into the physicochemical processes underlying energy deposition and transport in radiolysis and exploring the spectroscopy, structure and reactions of the radicals produced. The second targets radiation processes in heterogeneous environments and tackles the fundamental chemistry of radiation-induced effects at interfaces, probing not only how the interface modifies the radiation chemistry but also how the interface itself is affected. The mechanistic information obtained underpins applications in a wide range of energy and environmental industries. Fundamental radiation science relevant to nuclear energy applications is logically distributed between these two endeavors. Our efforts in solar energy aim to elucidate capture and conversion of light energy by mesoscale architectures, striving to overcome factors currently limiting high overall efficiency. Excited state dynamics in semiconductor quantum dots, carbon nanostructures, and organic semiconductors are probed and new multifunctional hybrid assemblies are identified to optimize photoinduced charge separations. Advances in the biochemical arena employ both ultrafast imaging of charge and energy flow in biosystems and the unique contributions radiation chemistry can make to a detailed understanding of the interaction of ionizing radiation with the components of such systems. This includes radiation damage at synchrotrons during macromolecular crystallography, radiation interactions with biomolecules, particularly the effect of low-energy electrons, and radiolytic oxidation of amino acids, peptides, and alkaloids.

FY 2014 HIGHLIGHTS

Quantum diffusion of atomic hydrogen isotopes was characterized in water using pulse radiolysis/electron paramagnetic resonance over a large temperature range. Deep-UV time-resolved resonance Raman measurements of key inorganic transients in water determined radical structures in solution. Femtosecond transient absorption spectroscopy revealed both long-range Förster and short-range Dexter energy transfer between CdSe quantum dots linked to a squaraine dye and showed mechanistic variation with dot size. Measured excited state dynamics at the band edge of an organo-lead halide perovskite, successfully modeled by Burstein-Moss band filling theory, uncovered promising hole conductor candidates for reaching high efficiencies. Near ambient pressure X-ray photoelectron spectroscopy demonstrated strong water dissociation on a GaAs surface with simultaneous oxygenation and hydroxylation of surface Ga atoms as water pressure increased at room temperature and a growth of As oxides, mainly with rising temperature. The oxidation extent depends strongly on the morphology of the samples. The yields of molecular hydrogen were measured as a function of water loading for irradiated components of resins, widely used for separations and filtering throughout the nuclear industry. A new dissociative electron attachment apparatus provided well-calibrated measurements on isotopically-labeled gas phase N-methylformamide, an initial step toward a better understanding of ionizing radiation effects on amino acids, peptides, and proteins. Thermodynamic thresholds for the observed fragmentations were evaluated using extensive computational quantum chemistry calculations. Optical properties of Frenkel excitons in self-assembled porphyrin tubular aggregates, an analog for natural photosynthetic antennae, were systematically measured by ultrafast optical spectroscopy and modeled by stochastic techniques. Nonradiative pathways induced by traps and defects to dominate the relaxation process.

Low Power Upconversion for Solar Fuels Photochemistry

Institution: North Carolina State University
Point of Contact: Felix Castellano
Email: fncastel@ncsu.edu
Principal Investigator: Felix Castellano
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$368,771 (2014-2015)

PROGRAM SCOPE

The original proposal concept related to the development of earth abundant and ideally water soluble/compatible sensitizers and acceptors suitable to drive photochemical upconversion photochemistry in aqueous environments. If successful, upconversion phenomena would be made compatible with solar fuels photochemistry and low energy photons would promote/activate energetically demanding reactions. Initially, this work focused on the development of new classes of photosensitizers incorporating earth abundant metals such as tin and copper to produce Sn(IV) porphyrins and Cu(I) metal-to-ligand charge transfer (MLCT) chromophores, respectively. Similar research lines intend to develop water soluble Ru(II) and Ir(III) MLCT chromophores for possible incorporation as photosensitizers in both upconversion and solar fuels photochemistry. Another related research line seeks to integrate various combinations of donors and acceptors into soft materials enabling photochemical upconversion photochemistry in encapsulated media suspended in aqueous environments.

FY 2014 HIGHLIGHTS

Copper(I) diimine complexes have metal-to-ligand charge transfer (MLCT) absorptive properties similar to $[\text{Ru}(\text{bpy})_3]^{2+}$, without the deactivating ligand field states found in other first row transition metal complexes. However, upon excitation, Cu(I) diimine complexes undergo a significant structural rearrangement, leading to excited states possessing large pseudo-Stokes shifts and very short lifetimes, thereby limiting their usefulness as photosensitizers. Methyl groups in the 3,8-positions of the phenanthroline ligand, combined with bulky sec-butyl groups in the 2,9-positions cooperatively restrict the degree of structural distortion in the Cu(I) MLCT excited state thereby extending its lifetime to the microseconds time scale. This increase in sensitizer lifetime translates to improved performance in sensitized photon upconversion compositions with several anthracene derivatives as triplet acceptors. The newly synthesized cyclometalated coordination compound bathophenanthroline disulfonate-bis-(5-methyl-2-(4-fluoro-phenyl)-pyridine)-iridium(III), displays unique, concentration-dependent photophysics in water, resulting from the formation of complex macromolecular self-assembled structures. The photoluminescence quantum yield and excited state lifetime of this complex markedly increase with increasing chromophore concentration until it achieves a saturation limit. The self-assembly process is clearly evident from simple bubble degassing experiments, which completely remove the chromophores from the aqueous solution in the form of photoluminescent bubbles. Dynamic light scattering experiments suggest the formation of two aggregate structures distinguishable by their hydrodynamic radii. This unique combination of molecular design elements may represent a novel way to control sensitizer structure while enhancing the associated photophysical properties in aqueous media.

Physical Chemistry of Reaction Dynamics in Ionic Liquids

Institution: New Jersey-Rutgers, State University of
Point of Contact: Edward Castner
Email: ecastner@rci.rutgers.edu
Principal Investigator: Edward Castner
Sr. Investigator(s): David Blank; Minnesota, University of
Claudio Margulis; Iowa, University of
Mark Maroncelli; Pennsylvania State University
James Wishart; Brookhaven National Laboratory
Students: 7 Postdoctoral Fellow(s), 7 Graduate(s), 3 Undergraduate(s)
Funding: \$849,000 (2014)

PROGRAM SCOPE

Ionic liquids are complex fluids that display domain-like structure on the nanometer scale, often exhibiting multiple disordered phases as well as dynamic heterogeneity on the femtosecond to nanosecond time scales. They are emerging as important components in several energy technologies that involve charge transfer and the transport of molecules and charge. This project addresses basic research needs in understanding how emergent aspects of ionic liquids result from individual ion properties and how this knowledge can be used to control transport and charge transfer processes that are important for energy-related applications. This work is part of a five-institution collaboration to achieve a fundamental understanding of charge transfer and transport in ionic liquids, involving the following P.I.s: Blank (Minnesota), Castner (Rutgers), Margulis (Iowa), Maroncelli (Penn State) and Wishart (Brookhaven). Solvated electrons in ionic liquids are studied by ultrafast pulse radiolysis at BNL and transient absorption spectroscopy at Minnesota, together with theoretical work at Iowa.

Mechanisms and dynamics of photo-induced charge separation are studied at Penn State, Rutgers and BNL. Structural studies by the Rutgers group are carried out using synchrotron X-ray experiments at the APS and using 2D-NMR methods. Theoretical studies at Iowa focus on electrons and holes, tracer diffusion of both neutral and charged species, and bulk structural properties of ionic liquids. Work at BNL focuses on pulse radiolysis and flash photolysis studies of diffusion and electron transfer phenomena in ionic liquids, including pressure dependent studies. Another focus at BNL and Rutgers is the design and synthesis of specific ILs for these investigations. The effects of local ionic liquid composition and structure (e.g., the scales of the polar and nonpolar domains within the ionic liquid) on the energetics and dynamics of charge transfer is a particular focus.

FY 2014 HIGHLIGHTS

Theoretical work on ionic liquids (ILs) in the Margulis group progressed on three fronts. Collaborations with the Blank and Wishart groups focused on quantum dynamics of excess electrons and holes in ILs. Experiments in the Blank group concentrated on dynamics of electron detachment, cooling, localization and reactivity in a series of ILs with varying cation sizes, complementing radiolysis studies at BNL by the Wishart group. The Margulis and Maroncelli groups collaborate on understanding mechanisms for neutral vs. charged tracer diffusion in ILs. Margulis group collaborations with the Castner group focused on quantitative comparisons of IL structure from X-ray scattering with molecular simulations. The Castner group complements the X-ray and simulation studies with 2D-NMR studies of specific solute interactions with the IL anions and cations. Time-resolved optical spectroscopy studies of photo-induced charge separation and solvation in ILs have continued in the Maroncelli, Castner and Wishart groups. The Maroncelli group results included studies of solvation and local friction in both neat ILs and in mixtures of ILs with polar solvents such as water and acetonitrile; extensive computer simulations are underway to model the experimental results. Complementary work in the Castner and Wishart groups has focused on both intramolecular and bimolecular photo-induced charge-transfer as a function of cation variation in the ILs. Novel reactive ILs are being used with either anions or cations that serve as electron donors. The Wishart group and collaborators also studied cations with either benzyl- or methylcyclohexyl- moieties, observing that the benzyl-substituted cations have much lower viscosities. The Wishart and Castner groups study reactive N,N-dimethylamino-N'-alkylpyridinium cations that are moderate electron-donors, while cyanate-containing anions are exploited as strong electron donors.

Electrochemical Synthesis of Polycrystalline Semiconductor Electrodes with Optimum Compositions and Morphologies for Use in Solar Fuel Production

Institution: Wisconsin-Madison, University of
Point of Contact: Kyoung-Shin Choi
Email: kschoi@chem.wisc.edu
Principal Investigator: Kyoung-Shin Choi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$390,000 (2014-2015)

PROGRAM SCOPE

The overall objective of our project is to bring about a marked advancement in the construction, understanding, and available variety of inexpensive polycrystalline semiconductor electrodes for use in solar fuel production by exploiting electrochemical synthesis methods. Electrochemical synthesis can offer a new level of precision and freedom in controlling both the compositions and the interfacial

morphologies of the photoelectrodes. We will establish electrochemical synthesis conditions to produce several highly promising semiconductor systems (e.g. Bi_2S_3 , CuBi_2O_4 , LaFeO_3) with optimum compositions and morphologies to maximize their solar-to-fuel conversion efficiencies. This will significantly broaden our choice of photoelectrodes that can be used to assemble efficient PECs while generating multiple sets of new understanding and insights, which will generally increase our fundamental understanding of semiconductor photoelectrochemistry.

FY 2014 HIGHLIGHTS

We established electrochemical synthesis conditions to produce CuBi_2O_4 as high quality, high surface area electrodes and identified that p-type CuBi_2O_4 is one of the most promising oxide photocathodes. CuBi_2O_4 has a band gap of 1.5-1.8 eV, and, therefore, it can utilize significant portion of visible light. We confirmed that the conduction band edge of CuBi_2O_4 is sufficiently negative to utilize photoexcited electrons for H_2 production. Furthermore, the valence band and flatband potential of CuBi_2O_4 are located at a much more positive potential than those of p-type Si, which is currently considered the most promising photocathode. As a result, it can provide a photovoltage (i.e. the difference between thermodynamic reduction potential of water and photocurrent onset potential) of up to 1.15 V for H_2 evolution. Owing to its early photocurrent onset, CuBi_2O_4 generated a photocurrent density of 1 mA/cm^2 at a potential as positive as 0.8 V vs. RHE. These features make CuBi_2O_4 one of the most promising photocathode systems. We will further improve the efficiency and stability of CuBi_2O_4 for use in solar H_2 production.

Ground and Excited State Structures of Sensitizer Dyes Adsorbed on Semiconductor Nanoparticles

Institution: New York-Buffalo, State University of
Point of Contact: Philip Coppens
Email: coppens@buffalo.edu
Principal Investigator: Philip Coppens
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$199,000 (2014)

PROGRAM SCOPE

The Project consists of synthesis of novel polyoxotitanate clusters, crystallization of homodisperse nanoparticles of the new species, measurement of their spectra and electrochemical properties, parallel theoretical calculations. Although a large number of sensitized polyoxotitanate clusters have been reported, detailed information on the electrochemical properties of fully structurally defined nanoparticles and their relation to physical and electronic properties is lacking. Such information is essential for the design of photovoltaic cells of increased efficiency. To address this structure gap we have synthesized a series of transition-metal doped polyoxotitanate nanoparticles, determined their structure and calculated their electronic properties. The clusters prepared include manganese-doped $\text{Ti}_{28}\text{MnO}_{38}(\text{OEt})_{40}\text{H}_2$, $\text{Ti}_{14}\text{MnO}_{16}(\text{OEt})_{28}\text{H}_2$, $[(\text{Ti}_{13}\text{Mn}_4\text{O}_{16}[\text{MeC}(\text{CH}_2\text{O})_3]_4(\text{OEt})_{12}\text{Br}_4)]_\infty$, a series of Ti_{11} cluster of composition $\text{Ti}_{11}(\text{XY})\text{O}_{14}(\text{O}^i\text{Pr})_{17}$ with X= Co, Mn and Fe, and Y= Cl, Br and I. Especially for the Mn and Fe complexes a significant reduction of the bandgap is observed, leading to light-absorption and photo-induced electron injection in the visible region. The work is continuing.

FY 2014 HIGHLIGHTS

Of particular interest are a series of nano particles of which $Ti_{17}O_{28}(O'Pr)_{16}[Fe-phen]_2$ (phenanthroline) (1) and $Ti_{11}(FeBr)O_{14}(O'Pr)_{17}$ are the prototypes. Complex (1) is a member of a doped-functionalized series of nanoclusters in which the phenanthroline is attached to the transition metal atom located on the nanoparticle surface. The visible solution spectrum of the Fe complex (1) shows a series of absorption bands in the 400-900 nm region. Theoretical calculations show the bands in increasing wavelength order to correspond to metal-to-core charge transfer (MCCT), metal-to-ligand charge transfer (MLCT) and d-d metal-atom transitions. Exposure of a thin solid layer of the complex in a photoelectrochemical cell and comparison with theoretical results shows that electron injection in the anode of the cell after photoexcitation occurs from both the titanium oxide particle and from the organic phenanthroline ligand, the latter a result not observed previously. In collaboration with researches at Yale University the femtosecond dynamics of hole injection from the ligand 4-nitrophenyl-acetylacetonate into Ti_{17} nanoparticles was calculated and confirmed by electrochemistry and EPR. The reported experimental and theoretical analysis demonstrates for the first time the feasibility of p-type sensitization of TiO_2 .

Applications to Adaptive Quantum Control to Research Questions in Solar Energy Conversion

Institution: Colorado, University of
Point of Contact: Niels Damrauer
Email: niels.damrauer@colorado.edu
Principal Investigator: Niels Damrauer
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$161,500 (2014)

PROGRAM SCOPE

This work explores several photoactive systems at the heart of third generation solar energy conversion strategies. Such strategies aim to increase the upper thermodynamic limit for conversion of sunlight to electrical power or chemical potential. We seek to develop advanced spectroscopic tools and to couple these to new chemical systems as well as modified material systems in order to interrogate fundamental photoconversion processes. A basic understanding of mechanism will permit new molecular or material designs in the future. A primary interrogation tool that is used and developed consists of advanced coherent control spectroscopies such as adaptive pulse shaping. In one area of research we have proposed new tunable bichromophoric molecules supporting singlet fission, to understand the role of specific nuclear motions and electronic coupling pathways for altering photoreactivity and mechanism. Singlet fission is a process by which a single electronic excitation in a molecule or material consisting of coupled chromophoric units is converted to separate electronic excitations on distinct chromophores. With such systems we aim to establish, using adaptive pulse shaping control strategies as well as electronic structure and parameterized theoretical methods, a rigorous understanding of how shaped fields couple to vibrational motions and how these motions perturb electronic properties and affect photoconversion dynamics. These molecules will also allow us make inroads into the development of molecular systems that support singlet fission for eventual utilization in low-cost dye-sensitized or disordered multicomponent thin film solar cells. In a second area of research we aim to consider how thin-film morphology impacts singlet fission yield for polycrystalline tetracene and how a systematic increase of pulse shape complexity affects controllability and illuminates control mechanisms.

FY 2014 HIGHLIGHTS

In 2014 we have been engaged in (a.) synthetic efforts, (b.) troubleshooting ultrafast laser pulse shaping experiments, and (c.) the development of new theoretical/computational tools to quantify molecular electronic properties relevant for singlet fission (SF). In synthesis (a.) we established a working route to generate reasonable quantities of an oxidized dimeric species built via several cyclo-addition and oxidation reactions. With a related model system we identified and optimized conditions for a final reduction step that produces the chromophores of interest. We have put these two facets together and have synthesized the target SF dimer. We have also synthesized a monomeric model system. We are optimizing yields and will then report this and begin photophysical explorations. In the context of pulse-shaping (b.) we have struggled with a loss of control of SF yields in polycrystalline tetracene (Tc) samples that had previously shown response to shaped laser pulses. In searching for root causes we have rebuilt and refined numerous aspects of the general experimental setup and have traced the problem to the pulse-shaper itself and how it impacts the spatial mode of the laser beam. We are currently working with a key part manufacturer to rectify the problem. In collaboration with researchers at NREL we have developed protocols for growth of polycrystalline Tc thin films with control over crystallite size and polymorph type. These efforts are tied to our pulse-shaping control efforts. In our theoretical/computational efforts (c.) we have developed, in collaboration with Subotnik's group at U. Penn, tools for facile determination of SF electronic coupling. These tools are applicable to molecular systems and we have used them to explore the dimer system currently being synthesized. We have explored how molecular vibrations impact this electronic coupling – so called non-Condon effects. This work was published in the Journal of Physical Chemistry A.

Development of Earth-Abundant Transition Metal Catalysts for Water Oxidation

Institution: Boston University
Point of Contact: Linda Doerrer
Email: doerrer@bu.edu
Principal Investigator: Linda Doerrer
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

The current global energy demands for low-cost, clean, and sustainable energy sources have prompted many groups to investigate earth-abundant transition metal complexes as potential catalysts for water oxidation. Our group is investigating complexes with C-F ligand bonds instead of oxidatively susceptible C-H bonds in their scaffold. The chelating bidentate perfluoropinacolate (pinF)²⁻ was proposed as a ligand for air-stable and oxidatively robust complexes that can support highly electrophilic moieties as active species in a water oxidation cycle. This oxygen-donating ligand is virtually unique in the studies of small molecule-based, homogeneous water oxidation catalysts, which generally have nitrogen-donor atoms from the ligands. Oxygen donor systems are particularly important to investigate because the most effective biological and heterogeneous water oxidation systems have metal bound to oxygen. Therefore detailed mechanistic studies to iteratively improve catalysis will be most effective with such a system.

FY 2014 HIGHLIGHTS

Our work has been successful in several important areas: (i) synthesis of a large and flexible family of water-soluble, late transition metal, perfluoropinacolate (pinF) compounds, (ii) structural characterization of five-coordinate water adducts for Co and Ni, (iii) demonstration of homogeneous electrochemical water oxidation catalysis by the $[\text{Co}(\text{OH}_x)(\text{pinF})_2]^{n-}$ system,⁷ (iv) development of new strategy for inhibition of heterogeneous MO_x formation by using the complex ligand as the buffer, (v) comparative spectroscopic and electrochemical studies of the $[\text{Ni}(\text{OH}_x)(\text{pinF})_2]^{n-}$ system, and (vi) discovery of water and nitrate reduction catalysis from $[\text{Cu}(\text{pinF})_2]^{2-}$. The (pinF) chemistry has provided an important framework for studying the mechanism of homogeneous water oxidation catalysis. By investigating this reaction in both the Co and Ni systems, with both experimental and computational work, we now have pH-dependent data that show the important redox energy changes as a function of acidity or basicity. We also have structural data that show how the ligand environment (coordination geometry) changes as a function of oxidation state, including a highly unusual square-planar Co(III) complex from a complementary study in organic media. Our work this past year has been particularly successful in showing a system whose ligand properties of metal chelation are a unique method for the suppression of MO_x formation. Data have shown the pH dependence of precipitate dissolution, consistent with the proposed ligand role. Further studies with Cu species have shown that the pinF system is not only robust to oxidation, but also to reduction. There is great interest to develop systems that are competent in water oxidation and reduction, in a wide pH range to tolerate the protons produced or removed respectively. The demonstration of water reduction with a Cu complex, suggests that the same ligand might be used in both redox processes.

Theoretical Studies of Photoactive Molecular Systems: Electron Transfer, Energy Transport, and Optical Spectroscopy

Institution: Columbia University
Point of Contact: Richard Friesner
Email: rich@chem.columbia.edu
Principal Investigator: Richard Friesner
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$180,500 (2014)

PROGRAM SCOPE

This project is aimed at the development of computational methods for modeling solar energy conversion systems, and application of those methods to important solar energy conversion systems. Methods development is currently focused on quantum chemical calculations, specifically density functional theory, with a focus on the determination of redox potentials, pK_a s, energies of different electronic states, spin splittings, and reaction barriers, for organic and transition metal containing systems. The methods development is performed primarily using small organic molecules and organometallic complexes containing a single metal; however, the calculations have to be scaled up to a large cluster model, containing ~300-500 atoms (many of which are transition metals), requiring parallelization of the code in order to get reasonable time to solution. The calculations are performed in continuum solvent (as opposed to vacuum) which is essential in obtaining realistic results for energetics that can be compared with experimental data. The principal application for this granting period has been to understand the functioning of the Gratzel cell, particularly the states relevant to electron

trapping and transport, and the mechanism of hopping transport enabling electrons to move from the site of light excitation to the electrode. Significant progress has been made, as is discussed below.

FY 2014 HIGHLIGHTS

Firstly, we have applied our localized orbital DFT corrections for first row transition metals (DBLOC) to the calculation of pK_a s of hexaquo metal complexes. Standard DFT methods make very serious errors in predicting the pK_a s of these systems, as large as 5-10 pK_a units. Yet the deprotonation of water when attached to a first row transition metal is a key step in catalytic water splitting by such systems. The DBLOC method, employing parameters taken from prior optimization efforts, reduces the average error in our data set from 5.7 pK_a units to 0.9 pK_a units, which is likely close to experimental error. Secondly, we have studied our model for the Gratzel cell under conditions in which hydrogen ions, rather than lithium, are the dominant small ion in the cell solution environment. We find that the hydrogen ions form quasi-covalent bonds with oxygen atoms in the titanium dioxide, leading to greater trap depths and hence higher barriers to electron hopping as compared to lithium. These results are in good agreement with experimental measurements of the trap depth when hydrogen ions are the dominant species, as well as the observed slower rate of electron transport (due to higher activation barriers for electron hopping) under these conditions. Finally, in work as yet unpublished, we have been performing large scale comparisons of our methods with alternative approaches such as the M06-2X density functional, building an anatase (rather than rutile)based model of the titanium dioxide nanoparticle, and are getting ready to model catalytic water splitting reactions at the titanium dioxide surface.

Model Dyes for Study of Electron Transfer Processes at Metal Oxide Semiconductor Interfaces

Institution: New Jersey-Rutgers, State University of
Point of Contact: Elena Galoppini
Email: galoppin@rutgers.edu
Principal Investigator: Elena Galoppini
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$171,000 (2014)

PROGRAM SCOPE

The objective of this research program is the design, synthesis, and photophysical study of organic and inorganic chromophore-spacer-anchor model compounds to control and study photoinduced heterogeneous charge transfer processes at the interface between organic chromophores and nanostructured metal oxide semiconductors (TiO_2 and ZnO). We proposed to develop model compounds to study the following: a) the correlation between open circuit photovoltages and charge transfer reactions; b) the influence of a tunable dipole built in the spacer unit on the energy level alignment of the chromophore; c) the mechanisms of iodide oxidation including recombination of injected electrons with oxidized iodide species. To achieve these objectives, we proposed three types of chromophore-spacer-anchor model compounds:

- The synthesis through click-chemistry of a novel class of homoleptic complexes of Ru(II) (Star complexes), that are designed to prevent close contact of the Ru center to the semiconductor by the highly symmetric arrangement of rigid linkers on the ligands.
- The development of rigid-rod chromophores with built-in dipoles in the linker to be aligned parallel or antiparallel to single crystal TiO_2 and ZnO surfaces. Changes in the dipole will shift the molecule

energy level relative to the metal oxide conduction and valence bands, while changes in the functionalization of the chromophore will result in changes primarily in the HOMO-LUMO gap.

- The synthesis and study of N₃-type rigid-rod complexes to understand the factors that control V_{oc} and dye regeneration processes with the Meyer group. The compounds were designed to have enhanced solubility, enhanced light harvesting in the near-IR, and the MLCT excited state localized on a remote bpy ligand.

FY 2014 HIGHLIGHTS

1. Tuning Energy Level Alignment At Organic/Semiconductor Interfaces Using a Built-In Dipole in Chromophore–Bridge–Anchor Compounds S. Rangan, A. Batarseh, K. P. Chitre, A. Kopecky, E. Galoppini, R. A. Bartynski *J. Phys. Chem. C* 2014 118, 12923-12928 DOI: 10.1021/jp502917c
2. Homoleptic “Star” Ru(II) Polypyridyl Complexes: Shielded Chromophores to Study Charge-Transfer at the Sensitizer-TiO₂ Interface P.G. Johansson, Y. Zhang, G.J. Meyer and E. Galoppini, *Inorg. Chem.*, 2013, 52, 7947–7957 DOI: 10.1021/ic4004565
3. Distance Dependent Electron Transfer at TiO₂ Interfaces Sensitized with Phenylene Ethynylene Bridged Ru^{II}-Isothiocyanate Compounds P. G. Johansson, A. Kopecky, E. Galoppini, G. J. Meyer *J. Am. Chem. Soc.*, 2013, 135, 8331–8341. DOI: 10.1021/ja402193f

Monodispersed Design of Zinc-Oxide Nanoparticle-Dye Dyads and Triads

Institution: Minnesota, University of
Point of Contact: Wayne Gladfelter

Funding: \$90,000 (2014)

PROGRAM SCOPE

The primary processes underpinning conversion of light to electrical and/or chemical potential in dye sensitized solar cells comprise a basic competition between the available fates of electrons displaced from equilibrium by the absorption of light. Our continuing development of well-defined dye-metal oxide nanocrystal colloidal dispersions in solution has enabled us to isolate the individual steps of energy conversion and study them in detail. Although the performance of zinc oxide in assembled devices lags that of the more ubiquitous titanium dioxide, the synthetic control of morphology and nanocrystal radius in zinc oxide offers some significant advantages in the current context of detailed, fundamental investigations. When the nanocrystal radii are below ~6 nm, the effects of quantum-confinement alter the band gap and density of states; both of which are expected to play an important role in determining the initial rate of charge injection from the excited state of the attached dyes. From an experimentally important perspective, tight synthetic control over size distributions results in well-defined samples that are optically transparent and easily refreshed. The following projects are being pursued:

- Synthesize new classes of molecular sensitizers that are optimized for charge injection into zinc oxide nanocrystals.
- Investigate the influence of energetic alignment and electronic structure on forward and reverse charge transfer.

- Investigate the influence of the dye binding group and nanocrystal capping chemistry on charge transfer rates.
- Study the dynamics and reactivity of reduced zinc oxide nanocrystals. With dyes bound to their surface, probe the intermediate in the dye sensitization process and evaluate the potential to drive multi-electron chemistry with visible light on such a platform.

FY 2014 HIGHLIGHTS

A comprehensive study of a series of thiophene oligomer based dye sensitizers was completed. The work combined theory and experiment to investigate how tuning the absorption spectrum by extending electronic delocalization via systematic addition of thiophene units influenced charge transfer character and excited state lifetimes. A cyanoacrylic acid group was incorporated for binding to ZnO nanocrystal electron acceptors. Compared to the commonly employed carboxylic acid, the additional electron withdrawing character in the cyanoacrylic acid was successful at maintaining a bias for excited state electron density near the interface even as the size of the oligomer was increased moving the center of mass farther away from the surface. The excited state lifetimes were extended relative to bare thiophenes, and the rate of excited state charge injection into ZnO NCs remained constant with increase in oligomer size. In addition, the binding group was varied on a terthiophene chromophore to quantify its impact on excited state electron transfer rates. Several new inorganic dyes with large excited state reduction potentials (> -1.0 V) were synthesized and their solution surface chemistry with ZnO nanocrystals was investigated. The known compound, $[\text{Bu}_4\text{N}]_4[\text{Pt}_2(\text{P}_2\text{O}_5\text{H}_2)_4]$ was synthesized and solution based Stern-Volmer experiments with ZnO nanocrystals showed that the phosphorescence of the longer-lived triplet state was quenched. Three binuclear iridium (I) compounds bearing bridging pyrazolate ligands were synthesized. Each pyrazolate ligand has a carboxylic acid functional group that allowed binding to the ZnO nanocrystals. All complexes displayed both singlet and triplet emission, and Stern-Volmer experiments again established that the triplet state phosphorescence was quenched by ZnO nanocrystals.

Organic Macromolecular Materials for Efficient Transport Properties in Light-Energy Conversion Applications

Institution:	Michigan, University of
Point of Contact:	Theodore Goodson III
Email:	tgoodson@umich.edu
Principal Investigator:	Theodore Goodson III
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$330,000 (2014-2015)

PROGRAM SCOPE

Organic materials have great potential for the purpose of inexpensive artificial light-harvesting and energy conversion devices. However, there is still much to be understood regarding the molecular-level mechanisms of solar energy capture and conversion of organic systems in the condensed phase. The focus of this investigation is to probe the fundamental excitation mechanisms in novel organic systems. In this approach, close attention is given to the mechanism and efficiency of a multipath energy transport process in different geometrical organic systems with strong interchromophore coupling. With different steady-state and time-resolved spectroscopic methods as well as with nonlinear microscopy we will characterize the mechanism of energy transport and the relative strength of intra-molecular

interactions in the novel organic macromolecular system. These macromolecules possess unique qualities which might help obtain a better understanding of exciton transport in organic light conversion devices leading to superior efficiencies. The potential impact of this work is the development of a new approach for long range excitation transport and efficient light harvesting in organic macromolecules of different topologies through a deeper understanding of the mechanisms involved in multipath multidimensional energy transport. The experimental methods will be combined with electronic structure calculations as well as phenomenological dynamical calculations. The outcome of the proposed investigations will be a basic understanding and design criteria for long-range excitation harvesting and transport in organic macromolecular systems which will have high impact in the photo-physics, materials chemistry and materials device design areas of solar energy conversion field.

FY 2014 HIGHLIGHTS

New low band gap electron-accepting polymers PNSW, PNTPD, PNPDI and PECN containing thieno[2',3':5',6']pyrido[3,4-g]thieno[3,2-c]isoquinoline-5,11(4H,10H)-dione (TPTI) and fluorine-dicyclopentathiophene dimalononitrile (FDCPT-CN) were investigated. These polymers are based on repeating units of thienothiophene (TT) and benzodithiophene (BDT), and one of the most efficient solar cell materials (PTB-7). The polymers had HOMO levels of -5.73 to -5.15 eV and low bandgaps in the range of 1.47 to 2.45 eV. Fluorescence upconversion studies on the polymers showed longer lifetimes of 1.6 and 2.4 ns for PNSW and PNTPD respectively while PNPDI and PECN showed very fast decays within 353 fs and 110 fs. Two-photon absorption investigation of the polymers showed that the absorption cross sections are in the region of $1.0\text{-}6.4 \times 10^4$ GM per monomer. The electronic structure calculations of the polymers indicated that the LUMO is localized on the electron-withdrawing co-monomers while the HOMO was localized on the more-electron-donating co-monomers. As the difference between the electron affinities of the co-monomers in the polymers decreased, the HOMO and LUMO is more distributed throughout the monomers. Polymers having alternating electron-withdrawing and electron-donating monomers experience enhanced dipole moments necessary for efficient solar cell applications. Also the synthesis of a carbazole bridged porphyrin dimer system which possesses a 90° orientation change between porphyrin units and the single-product four dimer macrocycle, were investigated. Subsequent characterization of the two-photon absorption and ultrafast emission lifetimes of these systems indicates a very strong coupling between constituent dimers in the assembled macrocycle structure. Excitonic coupling through the slipped co-facial arrangement created by imidazolyl-to-zinc interaction was shown to play a critical role in solar cell performance.

Supramolecular Structures for Photochemical Energy Conversion

Funding: \$237,000 (2014)

PROGRAM SCOPE

Fundamental principles of artificial photosynthesis are being investigated. Artificial photosynthesis is the design, preparation, and study of solar energy conversion systems that are based on the chemistry and

physics of the natural photosynthetic process. Several aspects of the basic science underlying artificial photosynthesis are under study. One involves the design, synthesis, and characterization of new classes of polymers based on porphyrins. These are electrically conducting polymers that absorb visible light and undergo photoinduced electron transfer to generate charge-separated states. They may be useful in new types of solar photovoltaic cells and other optoelectronic applications, in sensors for various purposes, and in molecule-based electronics. A second part of the study involves the fundamental properties of carotenoid polyenes that may be important in artificial photosynthesis. In natural photosynthesis, carotenes act as antenna chromophores and as photoprotective agents. Both functions involve the interactions between carotenoids and cyclic tetrapyrroles such as chlorophyll and porphyrins. Model carotenoid-tetrapyrrole constructs are being synthesized, and their photochemistry is being investigated using transient spectroscopic techniques. These studies are generating fundamental information that is useful in both artificial photosynthesis research and in understanding the functions of carotenoids in natural photosynthesis. Additional investigations involve various aspects of the photochemistry of porphyrins and similar materials that are important for artificial photosynthesis.

FY 2014 HIGHLIGHTS

This year a report was published on the design, preparation and photophysical study of a new soluble, semiconducting porphyrin polymer. This new class of materials may be useful in solar cells for electricity generation, and in other sensing and optoelectronic applications. New dyad molecules consisting of carotenes and phthalocyanines were prepared. Their study revealed unusual electronic (excitonic) interactions between the two chromophores. Additional investigations showed the details of the exchange of both singlet and triplet excitation energy between carotenes and porphyrins or phthalocyanines. These findings will contribute to our understanding of carotenoid antenna and photoprotective functions as seen in natural and artificial photosynthesis. In other studies, we have developed new chemical methods for binding semiconducting polymers and small molecule sensitizers to metal oxides in order to use them in photovoltaic applications. These results showed improved efficiency and stability in investigational solar cells using silatrane-based binding linkages as compared to the more commonly used carboxylates. Finally, complex organic molecules were prepared and sent to collaborators at the National Renewable Energy Laboratory for use in investigations of the fundamental chemistry underlying organic solar cell function.

EARLY CAREER: Molecular and Material Approaches to Overcome Kinetic and Energetic Constraints in Dye-Sensitized Solar Cells

Institution: Michigan State University
Point of Contact: Thomas Hamann

Principal Investigator: Thomas Hamann
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$160,704 (2014)

PROGRAM SCOPE

The general goal of this project is to understand the effect of the dye-sensitized solar cell, DSSC, components – redox shuttle, photoanode, sensitizer, and solvent – on key electron-transfer and electron-transport processes. The interdependent kinetics of these processes – charge injection, dye regeneration, recombination, and charge transport – determine the internal quantum yield of DSSCs.

We are performing a series of systematic investigations of each process as a function of the relevant component in order to develop general structure/function relationships. This knowledge will ultimately allow us to design new molecules and materials capable of overcoming the kinetic and energetic constraints of current generation DSSCs. We are currently primarily interested in understanding the physical underpinning of dye regeneration and recombination reactions. We have synthesized a series of outersphere one-electron redox shuttles with varying potential and reorganization energy to learn what properties of a redox shuttle will allow efficient dye regeneration with minimal driving force and recombination losses. The photoanode material plays a critical role as the electron donor in recombination to both the sensitizer and redox shuttle. A detailed understanding of recombination as a function of material property is therefore vital in choosing a material that is compatible with a given sensitizer / redox shuttle. Another question we are therefore addressing is how the properties of photoanode material, such as surface state density, conduction band energy, and electron mobility, affect the recombination kinetics.

FY 2014 HIGHLIGHTS

We have developed a new spectroelectrochemical method determine the conduction band energy of nanostructured mesoporous semiconductor electrodes by quantifying the Burstein-Moss shift as a function of potential and correlating this with the increased free electron absorbance. We have performed a series of measurements with nanoparticle, NP, TiO₂ in contact with a variety of solvents which allows us to develop a detailed picture of recombination of TiO₂ electrons in terms of Marcus-Theory. In parallel we have synthesized alternative anode materials, including NP SrTiO₃. Work is ongoing to measure the conduction band energy and trap state density of these materials, and measure recombination rates to a series of redox shuttles which will allow us to take an important step of elucidating the details of electron transfer from metal oxide semiconductor NP electrodes and develop general structure-function relationships. In addition, we have performed an extensive series of measurements of the charge collection and regeneration efficiencies of DSSCs employing [Co(ttcn)₂]^{3+/2+} and [Co(bpy)₃]^{3+/2+} redox shuttles in combination with several sensitizers on TiO₂ electrodes, with and without alumina blocking layers. The experiments have consisted of comparisons of the detailed absorption and incident photon to current efficiency, IPCE, measurements from back and front side illumination directions, as well as electrochemical impedance spectroscopy measurements. We have found that [Co(ttcn)₂]²⁺ is capable of quantitative regeneration with minimal driving force loss, while [Co(bpy)₃]²⁺ is not. Recombination to [Co(ttcn)₂]³⁺ limits the diffusion length and thus overall efficiency, which is not the case for [Co(bpy)₃]³⁺ however. Modulation of the recombination kinetics through application of alumina barrier layers offers a method to overcome the differential kinetics. These measurements are now being extended to include the alternative photoanode materials described above.

Solar Energy-Driven Multi-Electron-Transfer Catalysts for Water Splitting: Robust and Carbon-Free Nano-Triads

Institution: Emory University
Point of Contact: Craig Livingston Hill
Email: chill@emory.edu
Principal Investigator: Craig Livingston Hill
Sr. Investigator(s):
Students: 4 Postdoctoral Fellow(s), 10 Graduate(s), 2 Undergraduate(s)
Funding: \$308,000 (2014)

PROGRAM SCOPE

The funded project has 5 interlocking fundamental research goals that address core challenges in solar fuel production: (1) Development of oxidatively, thermally and hydrolytically robust, very fast, yet tunable water oxidation catalysts (WOCs). The focus has been on polyoxometalate (POM) WOCs because they are carbon-free, hence oxidatively stable, thermally stable and hydrolytically stable over pH ranges that depend on the metal composition and structure of the POM. Yet unlike metal oxides, they are molecular, thus their structural and electronic properties can be readily studied by spectroscopic, single-crystal diffraction, electroanalytic and computational methods. (2) Chromophore development. (a) New classes of molecular, yet carbon-free photosensitizers (PS) are under investigation, (b) complexes between these PS and POM WOCs are under study. (3) Immobilization of POMs on photoelectrode surfaces. (a) electrostatic, (b) hydrophobic, and (c) covalent immobilization protocols are targeted. (4) Measuring the rates of charge separation and recombination kinetics in our unique multi-component nanostructures. The dynamics in POM-containing dyadic and triadic systems are under investigation. (5) Development of computational methods for POM-based photoelectrocatalysts. (a) A discrete variable representation of an effective mass Hamiltonian has been applied to exciton wavefunctions in quantum confined nanostructures, and (b) hybrid quantum mechanical approaches probe electron transfer in heteronanostructures.

FY 2014 HIGHLIGHTS

This program produced 14 publications over the last year making it as productive as any year for the Emory team thus far.

- 1) Catalyst development. New POM WOCs were designed, in part with computational input, and characterized by spectroscopic, diffraction, electroanalytic and computational methods, including $[\text{Co}_4(\text{H}_2\text{O})_2(\text{PW}_9\text{O}_{34})]^{10-}$, an extraordinarily fast WOC yet one that is very resistant to degradation by air, water and heat. A new class of heterogeneous POM-based WOCs compatible with pH 14 has just been developed (unpublished).
- 2) Chromophore development. The spectroscopic and dynamic properties of a large class of carbon-free (POM) chromophores were characterized. Metal-to-polyoxometalate charge transfer lifetimes were understood as a function of heterometal location within the POM unit.
- 3) Immobilization of POMs on photoelectrode surfaces. Electrostatic methods for POM immobilization were improved and some POM-PS photoelectrodes proved to be very robust. Hydrophobic methods for POM immobilization were improved. An apparatus for collecting meaningful early-time kinetic data in homogeneous catalytic water oxidation with a sacrificial oxidant was reported.
- 4) Measuring the rates of charge separation and recombination kinetics in our nanostructures. The recombination dynamics in irradiated hematite and BiVO_4 semiconductors with and without surface immobilized molecular WOCs have been measured (recent, unpublished work).
- 5) Development of computational methods for POM-based photoelectrocatalysts. An infinite order discrete variable representation of an effective mass Hamiltonian has been applied to exciton wavefunctions in quantum confined nanostructures. Electronic structures of new POM catalysts have been elucidated.

Fundamental Studies of Energy-and Hole/Electron-Transfer in Hydroporphyrin Architectures

Institution: Washington University, St. Louis
Point of Contact: Dewey Holten
Email: holten@wustl.edu
Principal Investigator: Dewey Holten
Sr. Investigator(s): David Bocian; California-Riverside, University of
Jonathan Lindsey; North Carolina State University
Christine Kirmaier; Washington University, St. Louis
James Diers; California-Riverside, University of
Students: 2 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$620,964 (2014)

PROGRAM SCOPE

The long-term objective of the this highly collaborative research program is to design, synthesize, and characterize tetrapyrrole-based molecular architectures that absorb sunlight, funnel energy, and separate charge with high efficiency and in a manner compatible with current and future solar-energy conversion schemes. The synthetic tetrapyrroles include porphyrins and hydroporphyrins; the latter classes of molecules encompass analogues of the naturally occurring chlorophylls and bacteriochlorophylls (e.g., chlorins, bacteriochlorins, and their derivatives). The studies include (i) gaining a deep understanding of the spectral and electronic properties of bacteriochlorins, especially absorption deeper in the photon rich near-infrared region, (2) achieve panchromatic absorption (broad spectral coverage) while preserving a long, viable long-lived excited singlet state, (3) determination of the rates of ground-state hole/electron transfer between hydro(porphyrins) as a function of electronic and structural design parameters, and (4) construction of integrated architectures that incorporate all the above-noted elements and others to explore the viability of the component parts and processes under application-oriented conditions. The attainment of the goals of the research program requires the close interplay of molecular design and synthesis (Lindsey group), static and time-resolved optical spectroscopic measurements (Holten and Kirmaier group), and electrochemical, electron paramagnetic resonance, resonance Raman, and infrared studies, as well as density functional theory calculations (Bocian group). Collectively, the studies will provide fundamental insights into molecular properties, interactions, and processes relevant to the design of molecular architectures for solar-energy conversion. The accomplishment of these goals is only possible through a highly synergistic program that encompasses molecular design, synthesis, and in-depth characterization.

FY 2014 HIGHLIGHTS

The collaborative research during the reporting period has led to the following advances:

- 1) Synthesis, photophysical and electronic-structural characterization of hydroporphyrins that absorb across the red and near-infrared spectral regions.
- 2) Photophysical and molecular-orbital characterization of panchromatic absorbers that consist of a porphyrin and one to four tightly coupled perylenes.
- 3) Studies of electronic and vibrational properties of hydroporphyrins on surfaces.
- 4) Synthesis and initial characterization of single-unit and multi-component building blocks of an integrated molecular architecture for light-harvesting, energy transfer, and charge separation. Collectively these studies advance our understanding of the design, synthesis and characterization of tetrapyrrole chromophores and arrays for use in molecular architectures for solar energy conversion.

Transition Metal Building Blocks and Assemblies for Photocatalytic Fuel Production

Institution: Chicago, University of
Point of Contact: Michael Hopkins
Email: mhopkins@uchicago.edu
Principal Investigator: Michael Hopkins
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$90,000 (2014)

PROGRAM SCOPE

One of the major scientific and technical challenges of this century is to develop chemical means to store solar energy in the form of fuels. This research program aims to address fundamental questions that underlie the conversion of carbon dioxide to a solar fuel using homogeneous molecular systems. Central to the approaches being pursued is the development of homogeneous systems that catalytically extract the reducing equivalents from dihydrogen, which is a renewable reductant that can be sourced to water, instead of from conventional sacrificial reagents that vitiate solar energy storage. Two main lines of research are being pursued. One effort focuses on understanding the general principles that govern how light-absorbing molecules interact with independent dihydrogen-oxidation and carbon-dioxide-reduction catalysts to produce a functional cycle for driving the energy-storing reverse water-gas-shift reaction with light. The second effort centers on developing the dihydrogen activation chemistry of tungsten–alkylidyne chromophores, which are among the most powerful excited-state reducing agents known and can be incorporated into light-absorbing, catalyst-containing assemblies.

FY 2014 HIGHLIGHTS

We demonstrated that a homogeneous chromophore/two-catalyst system containing hydrogen oxidation and carbon-dioxide reduction precatalysts can be photochemically converted to a catalytically active state, with the energy for this conversion being provided by a low-energy photon. The photochemical mechanism by which this system operates was designed (and found) to be light-induced inter-catalyst electron transfer, as established by transient-absorption spectroscopy. The resulting system is thermodynamically capable of driving the solar-energy-storing reverse water gas shift reaction, and remains in the active state following excitation for sufficient time for the subsequent substrate-transforming steps to take place. It was discovered that the metal-mediated coupling product of carbon dioxide and ethylene is liberated from the metal center through chemical oxidation using bromine, providing functionalized organic anhydrides. This transformation is relevant to the potential catalytic solar-driven production of acrylic acid (a commodity chemical produced on a massive scale) from carbon dioxide and ethylene. A family of tungsten–alkylidyne containing phenylene-ethynylene molecular wires with controllable optical and photophysical properties was designed and characterized. These chromophores contain both a hydrogen-activating center and a linker for connection to carbon-dioxide (and other) reduction catalysts. Analysis of the electronic structures of the compounds as a function of wire length indicated that the degree of electronic coupling between the metal center and the wire could be rationally controlled through variation of the metal and supporting ligands.

Fundamental Studies of Light-induced Charge Transfer, Energy Transfer, and Energy Conversion with Supramolecular Systems

Institution: Northwestern University
Point of Contact: Joseph Hupp
Email: j-hupp@northwestern.edu
Principal Investigator: Joseph Hupp
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$171,000 (2014)

PROGRAM SCOPE

This project seeks to exploit supramolecular chemistry: a) to interrogate and understand fundamental aspects of light-induced charge transfer and energy transfer, and b) to construct solar energy conversion systems that make use of unique assembly motifs to address key conversion efficiency issues. The project focuses specifically on developing, investigating, and understanding at a fundamental-science level the behavior of promising new light harvesters and redox shuttles in dye-sensitized solar cell (DSC) and DSC-like environments. These new light harvesters include metal-organic frameworks.

FY 2014 HIGHLIGHTS

Given that energy (exciton) migration in natural photosynthesis primarily occurs in highly ordered porphyrin-like pigments (chlorophylls), equally highly ordered porphyrin-based metal-organic frameworks (MOFs) might be expected to exhibit similar behavior, thereby facilitating antenna-like light-harvesting and positioning such materials for use in solar energy conversion schemes. We recently demonstrated that directional, long-distance energy migration, culminating in hole transfer to a molecular partner, can be achieved within an intentionally designed MOF. In FY2014 we showed that: a) hybrid structures comprising MOFs and quantum dots can broaden the spectrum for light harvesting, with the dots serving as antennae for MOFs, b) spatially oriented MOFs, containing multiple light harvesters can be assembled in automated fashion on surfaces with a precision for thickness approaching the dimensions of a single molecular subunit, c) antenna behavior can be observed by appropriately positioning the various chromophores within surface-supported MOFs, d) chromophoric MOFs can be installed on transparent electrodes via the automated synthesis technique, via solvothermal synthesis, and via electrophoretic deposition of pre-assembled MOFs, e) chromophoric sites within these MOFs can be addressed electrochemically, and f) rates of charge hopping between sites, an essential process for conversion of sunlight to electricity via light-absorbing molecules (MOF linkers), can be measured and modulated.

Study of Multiple Exciton Generation with New Multi-Dimensional Spectroscopies

Institution: Colorado, University of
Point of Contact: David Jonas
Email: david.jonas@colorado.edu
Principal Investigator: David Jonas
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$190,000 (2014)

PROGRAM SCOPE

One approach to high efficiency third generation photovoltaics involves generation of multiple electron-hole pairs (excitons) from a single photon. Novel spectroscopic methods will be developed and applied to probe quantum dot electronic structure, multiple exciton generation, and competing processes in quantum dots synthesized under air-free conditions with controlled surface modifications. Femtosecond two-dimensional Fourier transform spectroscopy will be extended across the short-wave infrared where high efficiency third generation photovoltaics must have their bandgap. We will record two-dimensional spectra to study quantum dot electronic structure and dynamics that have previously been hidden under broad linear absorption lineshapes arising from the distribution of quantum dot sizes. Two-dimensional spectroscopy will also be used to probe the interactions between carriers (electrons and holes) involved in carrier multiplication and the electron-phonon couplings that dissipate energy and compete with carrier multiplication. The Auger recombination process that reverses the beneficial effects of carrier multiplication will be studied using absolutely calibrated pump-probe signals. The overall goal is to determine the carrier multiplication mechanism so that factors influencing the yield can be identified and controlled. More broadly, the novel spectroscopic approaches to be developed and applied here hold great promise as selective probes of the coupling needed for carrier multiplication in third generation photovoltaics. By the end of the project, we aim to develop sufficient mechanistic understanding of the carrier multiplication process in a few semiconductor quantum dots that its potential for third generation photovoltaics can be properly evaluated. The potential impacts include an ability to rationally select quantum dot materials for third generation photovoltaics and non-contact tests for processes that inhibit quantum dot carrier multiplication.

FY 2014 HIGHLIGHTS

We have developed an oxygen free synthesis of lead sulfide quantum dots in the sense that none of the precursors, solvents, or ligands contain oxygen atoms, and all can be rigorously de-oxygenated and dried. The oxygen-free PbS quantum dots have a size distribution comparable to the best obtained in the literature, and their photoluminescence quantum yield is measured at a respectable 30%. We have also developed an ultra-high vacuum level spinning sample cell that is compatible with the interferometric stability required for two-dimensional spectroscopy and allows excitation of a fresh sample for every laser shot. We demonstrated that the oxygen-free quantum dots have a stable absorption spectrum, in solution, for over two weeks of optical experiments inside this new sample cell. We have also developed an exceptionally broadband, actively stabilized interferometer for two-dimensional femtosecond spectroscopy in the short-wave infrared, and extended the bandwidth through interlaced sampling. Two-dimensional femtosecond spectra have been recorded for a number of less-stable lead chalcogenide quantum dot samples (including chlorine passivated dots that are air-stable for months in the solid state, but not stable for more than two days in solution). These two-dimensional spectra reveal the bi-exciton binding energy, which measures coupling between excited carriers, the decoherence time, which measures carrier-phonon coupling, and relaxation times of fine structure normally hidden under the one-dimensional spectrum. We have also measured Auger recombination for hot carrier excitation of 6.2 nm diameter colloidal indium arsenide quantum dots using degenerate transient absorption spectroscopy. The hot bi-exciton signal contains all of the hot single exciton dynamics, plus a new 26 ps timescale attributed to Auger recombination.

Spectroscopy, Photophysics and Charge Transfer Dynamics in Advanced II-VI Semiconductor Nanostructures

Institution: California-Merced, University of
Point of Contact: David Kelley
Email: dfkelley@ucmerced.edu
Principal Investigator: David Kelley
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$152,000 (2014)

PROGRAM SCOPE

This project focuses on how the composition and morphology of pure and alloyed II-VI semiconductor heterostructures control their spectroscopic and dynamical properties. This research uses a combination of synthesis development, electron microscopy, time-resolved electronic spectroscopy and modeling calculations to study these nanostructures, and examines the extent to which morphology, compression due to lattice mismatch and alloy effects can be used to tune the electron and hole energies and the spectroscopic properties of II-VI heterojunctions. It also uses synthesis, optical spectroscopy and HRTEM to examine the role of lattice mismatch and hence lattice strain in producing interfacial defects, and the extent to which defect formation can be prevented by controlling the composition profile through the particles and across the interfaces. In addition, the project involves the study the magnitude of the surface roughness in core/shell nanostructures and the role of shell thickness variability on the inhomogeneity of interfacial charge transfer rates.

FY 2014 HIGHLIGHTS

We have recently published experimental results and computational model calculations that lead to a few very simple conclusions about the morphology of CdSe/CdS core/shell quantum dots. We have shown that smooth shell growth is thermodynamically favored during the initial deposition of CdS shell on a CdSe core. As shell deposition proceeds the lattice strain energy increases. At some point, depending on the core size and shell thickness, the strain energy density becomes sufficiently great (27 eV or 0.59 eV/nm^2) that the shell undergoes reconstruction to a higher surface area, lower strain morphology. This typically creates defects and thereby lowers the luminescence QY. Shell reconstruction is an activated process and if the shell is deposited at a sufficiently low temperature, much higher strain energies will be obtained before the shell undergoes reconstruction. This is desirable for making well passivated, highly luminescent CdSe/CdS particles.

Next-Generation Semiconductors for Solar Photoelectrolysis

Institution: New York-Stony Brook, State University of
Point of Contact: Peter Khalifah
Email: kpete@bnl.gov
Principal Investigator: Peter Khalifah
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$141,000 (2014)

PROGRAM SCOPE

The objective of this research is to gain a better understanding of the chemical and physical processes occurring at the surface of and within the bulk of pyrochlore family semiconductor oxides, enabling the design of systems with high quantum efficiencies for visible-light-driven solar water splitting. Pyrochlore family semiconductor oxides provide an active, robust, and tunable direct band gap semiconductors with band gaps between 2 and 4 eV that can be used to understand and eliminate the barriers to efficient visible light water splitting. The novel thin film and single crystal growths of some complex oxide pyrochlore phases which show promise for visible light water splitting will be carried out. These samples will be characterized to obtain accurate measurements of their light absorption and their electronic conduction, providing the insights required to improve their ability to harvest the energy of sunlight to produce hydrogen fuel.

Water splitting chemical reactions occur at a surface, either of the semiconductor or of an attached co-catalyst, and specific chemical sites participate in this reaction. The single crystal and epitaxial film pyrochlore family semiconductor surfaces will allow surface species to be probed by a wide variety of surface science techniques, offering insights into chemical reaction mechanisms and chemical intermediates through these collaborative experiments. Both direct and collaborative studies will be done of semiconductor surface structure. Electrochemical and photoelectrochemical methods will be used to evaluate the efficiency of these materials for carrying out water splitting reactions.

FY 2014 HIGHLIGHTS

No FY14 Highlights provided.

Establishing the Role of the Electrode Surface in Solar-Driven Pyridine-Catalyzed CO₂ Reduction

Institution: Princeton University
Point of Contact: Bruce Koel
Email: bkoel@princeton.edu
Principal Investigator: Bruce Koel
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$615,000 (2014-2016)

PROGRAM SCOPE

This research applies to the generation of chemical fuels by solar-driven CO₂ reduction. Our work studies catalysts that can be used to efficiently carry out this process, with a goal of increasing both the rate and selectivity of fuel production. In particular, we are investigating the pyridine (C₅H₅N) catalyzed conversion of CO₂ to methanol, which when used in a photoelectrochemical cell employing a p-type gallium phosphide (GaP) photocathode, is the most efficient recorded photoelectrocatalytic system for methanol fuel generation. However, despite considerable electrochemical characterization and theoretical consideration, there is currently no consensus on the mechanism by which pyridine catalyzes CO₂-to-methanol conversion, and this limits the pace of continued optimization of catalysts for solar-driven CO₂ reduction. In our research, we use a surface science approach to establish a molecular-level understanding of the reaction mechanism and specifically probe the role of the semiconductor electrode surface in pyridine-catalyzed CO₂ reduction. We will characterize the atomic and electronic structure of GaP single crystal surfaces, beginning with studies of GaP(110), and identify active sites for reactions with hydrogen, water, and pyridine using a powerful array of surface analytical tools. This will answer

basic questions regarding the structure of these adsorbates on the surface, as well as provide a foundation for the more complex chemistry studied subsequently. Surface-bound intermediates, as well as their thermal stabilities in the dark and illuminated conditions, will be characterized. Their reaction with CO₂ and other compounds along the CO₂-to-methanol pathway, including formic acid and formaldehyde, on the GaP surface will be investigated to develop a fundamental framework for understanding this catalysis and advancing catalyst development.

FY 2014 HIGHLIGHTS

Our initial experiments involved high-resolution electron energy loss spectroscopy (HREELS) and high-resolution X-ray photoelectron spectroscopy (XPS) and ambient pressure photoelectron spectroscopy (AP-PES) studies to characterize GaP(110) and the interaction of H₂O and pyridine with the GaP(110) surface. We observed a partially dissociated water layer consisting of adsorbed H₂O and surface-bound OH and H species. Current work is exploring the role of these species in the mechanism of CO₂ electroreduction. Pyridine is molecularly adsorbed and interacts with GaP(110) via a dative bond between the N lone pair and surface Ga atoms. These baseline measurements provide a foundation for the more complex chemistry that we are presently investigating. Future studies will entail low-temperature STM studies of the adsorption sites and geometries of pyridine and CO₂ on GaP(110) and *in situ* measurements of ultrafast transient spectroscopy, which probes carrier dynamics during charge transfer to adsorbates involved in CO₂ reduction. We have also established collaboration with E. A. Carter's group at Princeton to provide theoretical insights for our experiments. Their DFT calculations explore adsorption configurations of a partially dissociated layer of H₂O on GaP(110) and adsorption sites and molecular geometries of relevant molecular catalysts on GaP(110).

Photophysics & Photoinduced Charge Transport in Single Walled Carbon Nanotubes

Institution: Rochester, University of
Point of Contact: Todd Krauss
Email: krauss@chem.rochester.edu
Principal Investigator: Todd Krauss
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$129,000 (2014)

PROGRAM SCOPE

This proposal addresses the general use of novel nanometer scale materials to solve fundamental impediments to further developing cheap and efficient solar energy through studies of the photophysical and photoinduced charge transport properties of single walled carbon nanotubes. For example, more efficient solar cells based on carbon nanotubes, which would be inexpensive, could lower overall solar energy costs such that they can potentially compete with the costs of energy from carbon-based fuels. These proposed studies will result in a deep understanding of the fundamental optical physics of this novel nanoscale material, and perhaps may lead to the development of new technologies based on nanotube photonics. For example, carbon nanotubes are attractive materials for potential use as efficient nanometer scale energy conduits, since they are able to transport charge long distances with minimal energy loss. In this project time-integrated and time-resolved photoluminescence from long nanotubes under electrochemical control will be used to better characterize and thus further understand the photophysics of single walled carbon nanotubes. In particular, these spectroelectrochemistry studies will be used to obtain the reduction and oxidation

potential of individual nanotubes, unknown at present. In a second project, ultrafast pulses will be used to generate (and detect) many electron-hole pairs in single-walled carbon nanotubes through single photon multiple exciton generation processes. The generation of more than one electron-hole pair (i.e. exciton) from a single photon is a simple way to enhance solar cell conversion efficiencies since in this process excess electron and hole kinetic energy is converted into another electron-hole pair. The fate of those multiple excitons is also very important and will be a focus of this project.

FY 2014 HIGHLIGHTS

Using spectroelectrochemistry on the single nanotube (NT) level we found the photoluminescence (PL) of individual NTs was quenched at positive and negative potentials, as electrons or holes filled the conduction or valence band energy levels, respectively. However, the onset of the PL quenching varied significantly from NT to NT, by upwards of hundreds of meV. Thus, we concluded that the same type of NT can have reduction or oxidation potentials that vary by hundreds of meV depending on its surroundings. We proposed that differences in the local environment of the individual NTs lead to a shift of the Fermi energy, resulting in a distribution of the oxidation and reduction potentials. It is currently not understood why NTs have PL quantum efficiencies that are at best a few percent. To get a deeper understanding of NT PL we studied PL from NTs wrapped in derivatives of polyfluorene polymers (PFOs) at temperatures between 77 and 300 K. We have focused on a sideband in the PL spectrum about 140 meV to the red of the main excitonic PL peak due to a photon mediated transition (called the K-momentum dark exciton or KDE peak). The coupling of a phonon to the nominally “dark” exciton transition was thought to take place through emission of a D-band phonon, but these conclusions were drawn from studies that were only on a single chiral NT species (i.e. (6,5) NTs only). We have found that the KDE peak actually disappears at low temperature, suggesting that the KDE transition involves absorption and not emission of phonons, and we are formulating a theory of the involvement of phonons in NT PL consistent with our observations. We also set up a single molecule confocal microscope that can operate at low temperatures down to 4 K. We have begun experiments to use single molecule spectroscopy at temperatures between 10 and 300 K to better understand the nature of the trion emission from NTs, and thus important charged particle interactions in NTs.

Light-Driven Charge Separation in Face-To-Face Donor-Spacer-Acceptor Supramolecular Systems

Institution: Northwestern University
Point of Contact: Frederick Lewis
Email: fdl@northwestern.edu
Principal Investigator: Frederick Lewis
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014-2015)

PROGRAM SCOPE

Optimization of the efficiency of photoinduced charge separation provides one of the fundamental challenges to the utilization of solar energy. The DNA conjugates developed in our laboratory provide versatile model systems for the study of the basic processes which determine the efficiency of multistep photoinduced charge separation and for the optimization of this process. The chronology of photoinduced charge separation in DNA hairpins modified with electron acceptor chromophores can be divided into three stages. In the first stage, which occurs within the first few ps, an exciplex or radical ion pair involving the chromophore and adjacent base pair is formed either via excitation of the

chromophore followed by charge transfer or direct excitation of a charge-transfer transition. Following this initial stage, spatial separation of the radical ion pair occurs on the ps-ns time scale to yield a charge-separated radical ion pair. Finally, the hole on the base pairs can migrate via an incoherent random walk until it reaches a trap site. Whereas the overall process can be described in broad outline, the details of the two initial stages remain incompletely understood in the case of hole (positive charge) transport and largely uninvestigated in the case of electron transport. It is the objective of this project to investigate several specific aspects of the charge separation process in DNA. The effect of driving force and the separation of the chromophore and base pair by an insulating cyclohexane-derived base pair on the initial charge separation process will be investigated. Special attention will be paid to the injection and transport of electrons in novel donor-bridge-acceptor systems designed for this application. The effect of cation radical or anion radical confinement on a finite number of identical bases will also be investigated.

FY 2014 HIGHLIGHTS

Several organic chromophores as electron acceptors or donors have been investigated in studies of DNA electron transport during FY 2014. 4,4'-Dimethylaminobenzophenone (Michler's ketone) is best known as a triplet sensitizer, but can also serve as an electron acceptor or donor by virtue of the charge-transfer character of its excited state. Hairpins possessing a Michler's ketone linker undergo fast singlet state charge separation and charge recombination with an adjacent purine base, attributed to well-stacked ground state conformations, and intersystem crossing to the triplet state, attributed to poorly-stacked ground state conformations. The failure of the triplet to undergo electron transfer reactions on the 7 ns time scale of our measurements is attributed to the low triplet energy and reduction potential of the twisted triplet state. Naphthalenediimide (NDI) is a powerful singlet state electron acceptor. Both the initial charge injection and subsequent charge separation processes for NDI hairpins are more rapid than those for hairpins with linkers that are weaker acceptors such as stilbenedicarboxamide (SA) or PDI. In addition to investigating the driving force dependence of the dynamics of charge separation, we are also investigating the effect of inserting a pair of cyclohexane (CX) base analogs between the chromophores and first A-T or G-C base pair. The CX base pair serves as a tunneling barrier for hole injection. 4,4'-Dialkoxystilbenes are strong electron donors capable of injecting electrons into adjacent pyrimidine bases. We have recently completed an investigation of the dynamics of electron injection and charge recombination for natural purines and several halogenated purines and find that T₁Un sequences (FU = 5-fluorouracil) provide the highest yields and longest lifetimes for the formation of charge separated states.

Investigations of the Fundamental Interfacial Chemistry and Physics of Functionalized Zn₃P₂, WS₂, and Partially Metalized Semiconductor Surfaces

Institution: California Institute of Technology
Point of Contact: Nathan Lewis
Email: nslewis@caltech.edu
Principal Investigator: Nathan Lewis
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$209,000 (2014)

PROGRAM SCOPE

This project focuses on developing an understanding of, and control over, the behavior at interfaces between semiconductors and liquid electrolytes in photoelectrochemical systems that convert solar energy to either electricity or fuels. The behavior of photoelectrochemical systems depends on an interplay between often competing factors, including the morphology, surface-state density, interfacial charge transport, and electrocatalytic properties of semiconductor/liquid interfaces. In this project, an understanding of these factors is being developed through fundamental studies of the surface and interfacial phenomena of promising non-traditional semiconductor systems, such as transition-metal chalcogenides, and through studies of electron-transfer and charge-equilibration processes of traditional semiconductors in contact with discontinuous phases with distinct interfacial chemistries. The goal of this work is to increase the viability of the studied systems for use in photoelectrochemical energy-conversion devices and to guide future explorations and improvements into the surface properties of other non-traditional semiconductors.

FY 2014 HIGHLIGHTS

Layered transition-metal chalcogenides, such as molybdenum disulfide and tungsten diselenide, are attractive non-traditional semiconductors for use in solar energy-conversion devices. The crystal structures of these materials consist of layers – each layer consisting of a sheet of metal atoms between two sheets of chalcogen atoms, with adjacent layers held together by van der Waals interactions. The surface of the crystals is characterized by chemically stable chalcogen-terminated terraces terminated by edge sites which provide a pathway for degradation and performance losses. We have synthesized crystals of p-type tungsten diselenide by chemical-vapor transport and fabricated photocathodes from the crystals. *In situ* laser-beam-induced current (LBIC) microscopy was used to map the photocurrent produced by illuminated photocathodes in contact with an aqueous solution containing a fast, one-electron redox couple. We also applied the LBIC technique to studies of photocathodes in contact with sulfuric acid, with and without platinum deposited on the surface. For the case of bare tungsten diselenide photocathodes, we found that edge sites correlate with a decrease in photocurrent, supporting the hypothesis that edges act as carrier-recombination centers. However, we also found that different terraces can have significantly different photoactivity, and that the presence of low-performing terraces may be more detrimental to the performance of a device than macroscopic edges. For the case of photocathodes in acid under conditions of hydrogen evolution, the *in situ* LBIC study and a post-measurement scanning electron microscopy (SEM) analysis showed that areas of high photoconversion efficiencies directly correlated with the presence of the platinum catalyst in those areas. These studies have provided a detailed picture of the photoconversion processes on transition-metal chalcogenide electrodes.

Colloidal Type II Nanorod Based Triad/Antenna Complexes for Solar-Fuel Conversion

Institution: Emory University
Point of Contact: Tianquan Lian
Email: tlian@emory.edu
Principal Investigator: Tianquan Lian
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 4 Graduate(s), 2 Undergraduate(s)
Funding: \$184,146 (2014)

PROGRAM SCOPE

The long-term goal of the proposed project is to prepare and investigate novel colloidal semiconductor nanostructure assemblies for efficient solar-to-fuel conversion. These assemblies, consisting of light harvesting antennas and charge separation triads, are capable of efficient photon absorption, charge separation, charge accumulation, and catalysis under solar flux. The colloidal inorganic triads, based on epitaxially grown type II hetero-nanorods (NR) with attached hydrogen evolution catalysts (such as CdSe-CdS-Pt), have built-in directional charge separation and tunable optical, electronic and catalytic properties. The design and improvement of such photocatalytic triad/ antenna complexes requires a fundamental understanding of the photophysics and charge transfer properties of the NR triads. The first objective of the proposed plan is to investigate single and multiple exciton relaxation as well as single and multiple charge separation and recombination dynamics in NR based dyads and triads by transient absorption spectroscopy. The initial studies are focused on CdSe-CdS and CdSe-CdS-Pt quasi-type II NR dyads and triads and related materials, examining how exciton relaxation and charge separation properties depend on the constituent materials and their dimensions. In addition to guiding the design and optimization of these materials, the proposed study will also provide a fundamental understanding of whether and how the one-dimensional (1-D) excitonic structures in the NRs affect their exciton relaxation and dissociation dynamics compared to the much better understood 0-D excitons in quantum dots (QDs). The second objective of the proposed plan is to investigate the interaction mechanism between plasmons in the metal tip with the semiconductor domain in semiconductor-metal heterostructures. Using CdS-Au and CdSe-Au as model systems, this study investigates the key parameters that control the efficiency of plasmon induced hot electron transfer.

FY 2014 HIGHLIGHTS

We completed three projects from Oct 1, 2013 to September 30, 2014. 1) Auger-assisted electron transfer from Quantum dots. In an effort to test theoretical models for describing ET from excitonic nanomaterials, we investigated electron transfer in QD-molecular complexes. We showed that the rate of photoinduced electron transfer from QDs to molecular acceptors increased at increasing driving force. We accounted for this unusual driving force dependence by proposing an Auger-assisted electron transfer model, in which the transfer of the electron can be coupled to the excitation of the hole. Because Auger-type processes occur in most quantum confined nanomaterials, we believe that the Auger assisted ET model should be generally applicable for describing exciton dissociation in other nanomaterials. 2) Plasmon induced hot electron transfer in CdS-Au nanorods. In this paper, we demonstrate that the optical excitation of either the Au tip and CdS NR can lead to charge separation across the semiconductor-metal interface. This finding suggests the possibility of further optimization of plasmon induced hot electron injection efficiency through controlling the size and shape of the plasmonic and excitonic domains for potential light harvesting applications. 3) Hole removal limits H₂ generation quantum efficiency in CdSe-CdS-Pt and CdS-Pt nanorods. Semiconductor-metal nano-heterostructures are promising materials for solar-to-fuel conversion because they allow rational integration of an light absorber, hole acceptor, and electron acceptor or catalyst in an all-inorganic triadic heterostructure. To provide design principles of such triadic nanorods, we examined the photocatalytic H₂ generation quantum efficiency and the rates of elementary charge separation and recombination steps of CdSe/CdS-Pt and CdS-Pt nanorods. We showed that hole transfer is a key efficiency-limiting step.

Fundamental Studies of Energy- and Hole/Electron-Transfer in Hydroporphyrin Architectures

Institution: North Carolina State University
Point of Contact: Jonathan Lindsey
Email: jslindse@ncsu.edu
Principal Investigator: Jonathan Lindsey
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The long-term objective of the this highly collaborative research program is to design, synthesize, and characterize tetrapyrrole-based molecular architectures that absorb sunlight, funnel energy, and separate charge with high efficiency and in a manner compatible with current and future solar-energy conversion schemes. The synthetic tetrapyrroles include porphyrins and hydroporphyrins; the latter classes of molecules encompass analogues of the naturally occurring chlorophylls and bacteriochlorophylls (e.g., chlorins, bacteriochlorins, and their derivatives). The studies include (i) gaining a deep understanding of the spectral and electronic properties of bacteriochlorins, especially absorption deeper in the photon rich near-infrared region, (2) achieve panchromatic absorption (broad spectral coverage) while preserving a long, viable long-lived excited singlet state, (3) determination of the rates of ground-state hole/electron transfer between hydro(porphyrins) as a function of electronic and structural design parameters, and (4) construction of integrated architectures that incorporate all the above-noted elements and others to explore the viability of the component parts and processes under application-oriented conditions. The attainment of the goals of the research program requires the close interplay of molecular design and synthesis (Lindsey group), static and time-resolved optical spectroscopic measurements (Holten and Kirmaier group), and electrochemical, electron paramagnetic resonance, resonance Raman, and infrared studies, as well as density functional theory calculations (Bocian group). Collectively, the studies will provide fundamental insights into molecular properties, interactions, and processes relevant to the design of molecular architectures for solar-energy conversion. The accomplishment of these goals is only possible through a highly synergistic program that encompasses molecular design, synthesis, and in-depth characterization.

FY 2014 HIGHLIGHTS

The collaborative research during the reporting period has led to the following advances: (1) Synthesis, photophysical and electronic-structural characterization of hydroporphyrins that absorb across the red and near-infrared spectral regions. (2) Photophysical and molecular-orbital characterization of panchromatic absorbers that consist of a porphyrin and one to four tightly coupled perylenes. (3) Studies of electronic and vibrational properties of hydroporphyrins on surfaces. (4) Synthesis and initial characterization of single-unit and multi-component building blocks of an integrated molecular architecture for light-harvesting, energy transfer, and charge separation. Collectively these studies advance our understanding of the design, synthesis and characterization of tetrapyrrole chromophores and arrays for use in molecular architectures for solar energy conversion.

Electron/Hole Selectivity in Organic Semiconductors for Solar Energy Conversion

Institution: Oregon, University of
Point of Contact: Mark Lonergan
Email: lonergan@uoregon.edu

Principal Investigator: Mark Lonergan
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$332,000 (2014-2015)

PROGRAM SCOPE

The selective collection of charge carriers (electrons or holes) is a critical step in the direct conversion of light into electricity. Organic semiconductors (OSCs) are being widely explored as selective contacts to both organic and inorganic absorber materials in the development of high-efficiency photovoltaics, but the fundamental mechanisms underlying selectivity are not fully understood. The goal of the proposed program is to quantify the electron/hole selectivity of OSC contacts and understand the fundamental origin of this selectivity in terms of relevant microscopic rate processes. The approach involves the study of a range of organic semiconductors using (1) a model system specially designed to probe electron/hole selectivity, (2) comparison of the results from this platform to the energy conversion properties of photovoltaics based on common absorbers where OSCs are finding application, and (3) the introduction of junction transient photocapacitance and photocurrent measurements to directly measure the relative efficiency of electron versus hole collection of complete photovoltaic systems.

FY 2014 HIGHLIGHTS

During the first 90 days of the project, we successfully developed and demonstrated the utility of the proposed platform for studying selectivity and developed the necessary numerical modeling tools for interpreting the results.

EARLY CAREER: Bio-Inspired Electro-Photonic Structure for Dye-Sensitized Solar Cells

Institution: North Carolina, University of
Point of Contact: Rene Lopez
Email: rln@physics.unc.edu
Principal Investigator: Rene Lopez
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Efficient absorption of photons and effective carrier extraction are usually antithetical goals in traditional photovoltaic device configurations. Typical solar cell designs try to maximize photon capture by increasing the thickness of the absorbing layer. But this is detrimental to charge harvesting since increased transport path lengths lead to increased carrier recombination. The objective of our program is to comprehensively redesign the full opto-electronic properties of dye sensitized solar cells to develop the ultimate cell structure, at all length scales, which will enable DSSCs with perfect light capturing and electron harvesting. Our program is based on two developments advanced by our laboratory that decouple carrier transport from optical absorption: 1) A novel high surface area oxide fabrication technique "corn-field" that significantly improves anode properties over conventional nanoparticle sintering. This is especially relevant since this unique photo-anode nanostructure allow us to use thinner films to achieve full dye loading and at the same time provide more direct paths for charge transport, reducing travel lengths and recombination opportunities. 2) The optical control allowed by non-invasive

photonic structuring in solar cells. In contrast to conventional planar cell designs or bulky inverse opal photonic crystal approaches that degrade the electronic performance, a photonic crystal design can provide optical enhancement to the wavelengths where it can be most beneficial (the red side of the absorption spectrum where material's absorption is the weakest) and also reduce electrical transport lengths requirements simultaneously. Together this two independent technologies will allows us great latitude to understand and ultimately control in the optoelectronic properties of the dye sensitized photoanodes.

FY 2014 HIGHLIGHTS

Porous $\text{In}_2\text{O}_3:\text{Sn}$ (ITO) films resembling from brush carpets to open moss-like discrete nanostructures were grown by pulsed laser deposition under low to high background gas pressures, respectively. The charge transport properties of these nanoporous substrates were probed by pulsed laser photo-current and voltage transient measurements in N719 dye sensitized devices. Although cyclic voltammetry and dye adsorption measurements suggest a lower proportion of electro-active dye molecules for films deposited at the high-end background gas pressures, the transient measurements indicate similar electron transport rates within the films. Solar cell operation was achieved by the deposition of a conformal TiO_2 shell layer by atomic layer deposition (ALD). Much of the device improvement is shown to be due to the TiO_2 shell blocking recombination of photoelectrons with the electrolyte as recombination lifetimes increased drastically from few seconds in uncoated ITO to over 50 minutes in the ITO with TiO_2 shell layer. Additionally, an order of magnitude increase in the electron transport rate in ITO/ TiO_2 (core/shell) films was observed, giving the core-shell structure a superior ratio of recombination/transport times. We have also started to probe the potential use of our nanostructure photoanodes for other types of devices beyond the DSSC. In particular, we have analyzed with full computational optoelectronic design their applicability with Quantum dot solar cells. With simple photonic nano-structuring, we can show potential improvements from 8 to 16% efficiency improvements that we will try to realize in the coming year.

Light-Stimulated Hole Injection at Dye-Sensitized Phosphide Photocathodes

Institution: Michigan, University of
Point of Contact: Stephen Maldonado
Email: smald@umich.edu
Principal Investigator: Stephen Maldonado
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$133,000 (2014)

PROGRAM SCOPE

The primary research objective of this proposal is to measure hole injection from a photoexcited, adsorbed sensitizer into an inorganic semiconductor photoelectrode, with the impetuses to develop a more detailed, quantitative understanding of dye-sensitized systems and to construct efficient dye-sensitized photo-electrodes for solar energy storage and conversion using phosphide semiconductors. Light-stimulated hole injection is of immense importance for solar energy applications for two reasons. First, sensitized hole injection is the inverse of the sensitized electron injection process used successfully in 'Grätzel' cells. Second, dye-sensitized hole injection is naturally compatible with using optical energy to drive reductions that result in energy-rich chemical fuels. The regenerative redox couple can be reduced by the dye and can either be directly coupled to pertinent electrochemical transformations, e.g.

reduction of H^+ or CO_2 , or be the desired redox reactions themselves. Despite early experimental evidence showing that both light-stimulated electron and hole injection in dye-sensitized systems are possible, the primary focus of most research groups has been on photoexcited electron transfer processes. As a result, while the capacity for solar energy conversion of electron-injection-based dye-sensitized n-type semiconductor electrodes has advanced significantly over the past four decades from the level of lab curiosity to commercially viable photovoltaic architectures, the development of dye-sensitized p-type photoelectrodes is still in its infancy.

FY 2014 HIGHLIGHTS
