In the third full year of funding, we made progress on several important aspects of the project. First, we showed a viable surface functionalization route for p-GaP photoelectrodes through the reaction between surficial P-O-H groups and alkyl/ benzyl bromides via a Williamson ether-type synthesis. Surface analyses (i.e. FTIR and XP spectroscopies) indicated the introduction of a disordered monolayer of alkyl chains through an ether-like P-O-C linkage. Surface reaction yields were tightly regulated through the action of a nucleophilic base promoter, highlighting a level of control atypical of analogous reaction chemistries on pure metal oxide surfaces. The collected evidence supported the premise that the resultant surface state density is low enough to support sensitization with high internal quantum yield if the extent of depletion/ inversion in the p-GaP photoelectrode is sufficient. Second, we demonstrated that GaP surfaces reacted with CH_3MgCl showed markedly enhanced chemical stability with respect to cathodic degradation. Although cathodic operation is generally perceived to be less corrosive towards semiconductor photoelectrodes in water, reductive degradation of binary p-type semiconductors through the formation of metallic clusters/particles is possible. Specifically, since native GaP surfaces are not electrocatalytic towards H^+ reduction in water, photogenerated electrons in p-GaP that reach the electrode/electrolyte interface may participate in the reduction of atop Ga atoms which form metallic Ga clusters/particles. Depending on the Pourbaix diagram of the electrolyte, the newly formed elemental Ga either can leach into solution (e.g. in $NaOH$, H_2SO_4) or accumulate on the surface (H_3PO_4). Either scenario results in a catastrophic attenuation/elimination of photocurrent. Following 15 hours of illumination and net cathodic current passage, the CH_3 -terminated GaP(111)A electrodes retained 66% of the photocurrent passed at $t = 0$.

Nanostructured Photocatalytic Water Splitting Systems

Institution: Pennsylvania State University
Point of Contact: Thomas Mallouk
Email: tem5@psu.edu
Principal Investigator: Thomas Mallouk
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$190,000 (2014)

PROGRAM SCOPE

This project investigates fundamental problems associated with visible light-driven water splitting in molecular photoelectrochemical systems. In natural photosynthesis, light-absorbing molecules are coupled to chains of electron donors and acceptors that drive electrochemical oxidation and reduction reactions using enzymatic catalysts. The example of natural photosynthesis suggests that it should be possible to design efficient functional mimics by combining photoredox molecules, electron relays, and nanoparticle catalysts. This goal has been elusive so far because of the problem of controlling back

electron transfer reactions, which are often much faster than the catalytic reactions that make hydrogen and oxygen. In this project, the oxidative half-cycle of water splitting is carried out using dye molecules coupled to water oxidation catalysts on porous semiconductor electrodes. The reduction of water is driven by light at a photocathode consisting of dye molecules, semiconducting oxide sheets, electron relays, and nanoparticle catalysts. Both arrangements provide control over the distances between components at the nanometer length scale. Transient spectroscopy and electrochemical methods are used to measure the rates of forward and back electron transfer. Molecular design and spectroscopic methods are used to control and understand electron transfer at the molecule-nanoparticle catalyst interface. The problem of proton management in water splitting photosystems is also being studied by electrochemical methods.

FY 2014 HIGHLIGHTS

This project had earlier demonstrated overall water splitting in a molecule-based system, using ruthenium tris(bipyridyl) dyes coupled to iridium oxide nanoparticles on high surface area TiO₂ electrodes. Several groups have since made similar photoanodes using different molecular catalysts and have achieved photocurrents in the mA range, comparable to some of the best oxide photoelectrode materials for water splitting. A problem with the molecular system, not understood before this year, is the rapid polarization of the photoanode. We have now developed a full kinetic model of the photoanode that explains the polarization, and have used dynamic measurements (photovoltage decay, electrochemical impedance spectroscopy) to measure the relevant kinetic parameters. These measurements suggest that more efficient systems will be possible using core-shell electrode structures and molecular catalysts. They also elucidate the important role of surface protonation in back electron transfer. For photoelectrolysis cells that operate near neutral pH, proton management across the membrane that separates the anode and cathode is a significant problem. Our earlier work showed that pH gradients develop in such cells because the transference number of protons is less than unity. We have recently investigated bipolar membranes for use in these cells and showed that they enable water splitting with low losses when the anode and cathode operate at high and low pH, respectively. This finding is promising for developing water and CO₂ electrolysis systems that operate at low overpotentials using earth-abundant photoelectrode and catalyst materials.

First-Row Transition Metal-Based Chromophores for Dye-Sensitized Solar Cells: Fundamental Issues and Applications

Institution: Michigan State University
Point of Contact: James McCusker
Email: jkm@chemistry.msu.edu
Principal Investigator: James McCusker
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$181,000 (2014)

PROGRAM SCOPE

The overall focus of this research program is to explore the fundamental science underpinning the notion of using first-row transition metal complexes as chromophores in solar energy conversion strategies. These compounds hold the promise of having a transformative impact on solar energy science due to their earth-abundant nature, but do not perform well relative to their 2nd- and 3rd-row counterparts in strategies that require photo-induced charge separation. Our hypothesis for why this is

the case is that the nature of the electronic structure of 1st-row metal complexes (e.g., compounds of Fe(II)) results in ultrafast deactivation to lower-lying electronic states such that they are not kinetically competitive with processes such as interfacial electron transfer (as required in a dye-sensitized solar cell) or bimolecular electron transfer (as might occur when coupling light absorption to a catalyst). This hypothesis is supported by a string of significant observations stemming from research directly funded by DOE's Solar Photochemistry program and is now a generally accepted paradigm in the photo physics and solar energy community. The specific goal of the research program is to (1) identify the key factors that are responsible for driving these ultrafast excited-state processes, i.e., the conversion of charge-transfer excited states to lower-energy ligand-field excited states, and (2) to use this knowledge to inform synthetic design for the realization of chromophores that can be incorporated into solar energy conversion schemes that currently require rare, more expensive components such as ruthenium.

FY 2014 HIGHLIGHTS

Research during FY2014 has been focused on two specific themes within the broader goals outlined in the previous section. First, we have developed chemistry allowing for the synthetic elaboration of the dcpp ligand. The Fe(II)-bis adduct of this compound, published in 2014, was a breakthrough discovery for us insofar as it offered the possibility of altering the electronic structure of an Fe(II) complex such that it would resemble its 2nd- and 3rd-row congeners in terms of the relative energetic ordering of its charge-transfer and ligand-field excited states. Specifically, we believe that we have identified the key aspect of this compound's composition that is responsible for its unique optoelectronic properties; this discovery is going to fuel a significant portion of our research in this area and will be described in a renewal proposal that will be submitted next month. We have also developed the necessary chemistry to functionalize this ligand system for attachment to semiconductor nano particles for testing in dye-sensitized solar cells. The second theme has involved a more detailed examination of structural features that appear to be driving ultrafast surface crossings in this class of compounds. Ultrafast time-resolved absorption measurements have revealed a clear sensitivity to geometric distortions about the primary coordination sphere of the metal center. We have therefore designed new ligand frameworks around this idea in an effort to modulate the dynamics sufficient for electron transfer processes out of the charge-transfer states to become kinetically competitive. This is going to be coupled to a new effort in the group - variable-temperature ultrafast time-resolved absorption spectroscopy - that will be pursued in the next phase of the research program so that we can obtain more quantitative information about the nature of the barriers associated with the ultrafast dynamics that undermine the utility of this class of chromophores.

Metal-to-Ligand Charge Transfer Excited States at Interfaces and in Rigid Media

Principal Investigator: Thomas Meyer
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$181,000 (2014)

PROGRAM SCOPE

Photo-Induced, Interfacial Electron Transfer at the Transparent Oxide-Solution Interface and Long Range Electron and Energy Transfer in Polymer Films are being investigated for possible applications in energy conversion processes.

FY 2014 HIGHLIGHTS

Photo-induced interfacial electron transfer to and from nanoparticle, mesoscopic thin films of conducting transparent conducting oxides (TCO) is under investigation for possible applications in energy conversion. Excitation, injection and back electron transfer by Ru(II) polypyridyl complexes, surface-bound to Sn-doped In_2O_3 (nanoITO) in acetonitrile solutions have been investigated by transient absorption measurements. Excitation of the metal-to-ligand charge transfer (MLCT) excited states of these complexes is followed by efficient excited state electron injection with injection efficiencies of $\sim 100\%$. Injection occurs on the picosecond time scale and back electron transfer (BET) on the nanosecond time scale. By varying the external bias, the influence of driving force on electron transfer was investigated over a range of 1.8 eV. Kinetics data for electron injection and BET were analyzed by application of Marcus-Gerischer theory to obtain key fundamental electron transfer parameters - reorganization energy and electronic coupling matrix element - for both injection and BET. These results demonstrated the versatility of nanoTCOs as a tool for studying photo-induced electron transfer reactions relevant to solar energy conversion in dye-sensitized devices. The photophysical and photochemical properties of a series of Ru(II) and Os(II) polypyridyl MLCT excited-states were investigated at the fluid-to-film transition in a poly(ethyleneglycol) (PEG). In PEG films with added anthracene derivatives, long-range energy transfer and energy transfer followed by electron transfer have been observed by transient absorption measurements. MLCT emission energies in the PEG fluid increase following thermal polymerization to give semi-rigid films which enhances emission and lifetimes consistent with the energy gap law for non-radiative excited-state decay.

Singlet Fission

Institution: Colorado, University of
Point of Contact: Josef Michl
Email: michl@eefus.colorado.edu
Principal Investigator: Josef Michl
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

It was proposed to combine experimental and theoretical tools to improve the presently unsatisfactory understanding of the singlet fission process to a level that will allow efficient design of (i) new singlet fission chromophores with optimal excitation energies, about 2.2 eV for S_1 , and about 1.1 eV for T_1 ; (ii) optimal modes of inter-chromophore coupling. The goal is the development of a predictive competence for the design of useful materials for 200% triplet yield from singlet fission in a dimer, oligomer, aggregate, polymer, or solid. Our laboratory is set up to perform organic synthesis, spectroscopic and photophysical measurements, and quantum chemical calculations, and we have prior experience in all of these.

FY 2014 HIGHLIGHTS

We are seeking access to efficient singlet fission (SF) materials using theory, synthesis, and photophysics, collaborating with a group at NREL and with a Czech theoretician. We have used the diabatic approximation and a model that considers the HOMO and the LUMO of each chromophore in a dimer. For approximately isoergic SF, we have a formula for the Fermi Golden Rule matrix element TRP, with a term for a direct interaction of the initial and final states and a term for interaction mediated by virtual charge transfer states. The formula for TRP was evaluated (i) exactly, (ii) with neglect of intermolecular overlap, and (iii) with neglect of zero differential overlap. The mediated term dominates. Case (iii) only requires knowledge of Hückel MOs and overlaps between AOs on the chromophores. We proposed that biradicaloids are a likely source of new SF chromophores and identified several promising ones. We examined SF in 1,3-diphenylisobenzofuran (1), many of its covalent dimers, and a polymer. One of the two crystalline modifications is about 20 times more efficient than the other, although their crystal structures are very similar. A carboxylic acid derivative was adsorbed on TiO₂ nanoparticles coated with a thin layer of ZrO₂ and an optimal ZrO₂ thickness allowed injection from T₁ produced by SF to dominate over injection from S₁. In polar solvents, excitation of weakly coupled dimers produced a directly observable CT intermediate (two-step SF). Among directly coupled dimers, the p,p isomer is interesting since we observe a planar and a twisted conformers of both S₀ and T₁, with excitation delocalized in the former and localized on one half of the dimer in the latter. A polystyrene carrying 1 on each repeat unit showed no SF in solution. We have examined two polymorphs of the biradicaloid dye cibalackrot. In each, the Davydov splitting is 0.2 eV, making SF endoergic.

Electrochemical and Spectroscopic Investigations of H₂O Oxidation by Porous Coordination Network Catalysts

Institution: Virginia Polytechnic Inst. and State U.
Point of Contact: Amanda Morris
Email: ajmorris@vt.edu
Principal Investigator: Amanda Morris
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014-2017)

PROGRAM SCOPE

Metal organic frameworks (MOFs), 3D crystalline porous coordination networks of metal ions connected in close proximity by multi-dentate organic linkers, have tremendous potential for use in catalysis. Molecular secondary building units assemble to produce largely porous materials with the highest surface areas reported. This surface area can be exploited to produce higher catalytic reaction rates than those observed with traditional heterogeneous or homogeneous approaches. Capitalizing on this advantage, the proposed research aims to explore MOF materials for photoelectrochemical water oxidation. Specifically, the project will (1) identify MOF materials capable of electrochemical water oxidation, and (2) integrate these MOFs as thin films on semiconductor surfaces for photoelectrochemical activation. The proposal focus will be on in-depth electrochemical and spectroscopic studies of reactivity and mechanism to elucidate the design constraints of such catalysts. MOF catalyst candidates have been identified based on the following criteria: (1) the MOF must be stable in aqueous solution, preferably over a wide range of pH; (2) include a redox active metal sites; and (3) exhibit high internal surface area. Exploration of MOF water oxidation catalysts and photoelectrochemical MOF behavior is in its infancy and our studies represent the first to combine the

two concepts. Therefore, accomplishing the aforementioned goals will provide new discoveries about the structure–function relationship of MOFs and allow the rational design of next generation MOF-H₂O oxidation catalysts. Once developed, a complete H₂O oxidation system will improve the nation’s energy profile by providing a means to store solar energy. Thus, this proposal describes a series of unique materials and fundamental studies that hold the potential for unparalleled environmental and economic impacts.

FY 2014 HIGHLIGHTS

Funding for this project began June 1, 2014. In the initial 3 months, we have collected preliminary data on two MOF constructs that are viable for water oxidation catalysis. The first construct utilizes the nodal clusters of cobalt and palladium-based MOFs to facilitate water oxidation. These redox active centers are connected by an organic linker capable of intraMOF proton transfer to facilitate proton-coupled electron transport. A complete electrochemical analysis has been conducted on the two materials and catalysis occurs at moderate overpotential with impressive catalytic rates. We expect to publish these results within the next funding period. The second construct incorporates known small molecular water oxidation catalysts (ruthenium and copper-based) into water-stable MOF backbones with zirconium and lead-based nodal clusters. The small molecule catalysts have been studied in homogeneous solution in this initial funding period and both efficiently oxidize water electrochemically. We will expand this work to MOFs within the next funding period.

Hangman Catalysts for Photo- and Photoelectrochemical Activation of Small Molecules

Institution:	Harvard University
Point of Contact:	Daniel Nocera
Email:	dnocera@fas.harvard.edu
Principal Investigator:	Daniel Nocera
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding:	\$228,000 (2014)

PROGRAM SCOPE

Solar-to-fuels generation requires the rearrangement of stable chemical bonds with light as the impetus for the fuel-forming reaction. All such reactions, regardless of the specific fuel, require the transfer of multiple electrons and protons. Energy barriers to such bond rearrangements are minimized only if electrons are efficiently coupled to protons. A catalyst can mediate this coupling, and as well as it does so, will determine the solar-to-fuels efficiency. The scope of this project includes several aspects of this energy conversion process as it applies to hydrogen and oxygen production from water, carbon dioxide reduction for the purposes of yielding a liquid fuel (in place of hydrogen) and the complementary fuel cell reaction, oxygen reduction by hydrogen (fuel cell reaction). In this program, a new class of catalysts—called Hangman catalysts—is under study with an eye towards water splitting. In Hangman constructs, an acid-base functionality is poised over a redox active metal platform. On a mechanistic front, the Hangman systems orthogonalize Proton Coupled Electron Transfer (PCET) and in doing so they permit control of proton transfer over short distances and electron transfer over long distances. Hangman catalysts comprising porphyrin, corrole and chlorin macrocycles have been explored for promoting reactions of oxygen reduction (fuel cell catalysts), O₂ and H₂ production from water (solar energy catalysts) and CO₂ reduction (liquid fuels). The physical and chemical properties of the Hangman catalysts are varied in order to define the optimal conditions in which the aforementioned energy

conversion reactions may be best carried out. Using picoseconds and nanosecond laser methods, we have begun setting the groundwork to observe bond forming steps in real time.

FY 2014 HIGHLIGHTS

Work during the past funding cycle has focused on: (1) adapting and elaborating synthetic methods to enable the delivery of hangman macrocycles in sufficiently high yields and quantities to enable PCET studies to be undertaken with facility; (2) designing hangman macrocyclic platforms that promote the HER reaction with an emphasis on elucidating key intermediates via the construction of mechanistic models. During 2014, we have shown that Co hangman porphyrins catalyze HER from weak (benzoic) and strong (tosic) acids in acetonitrile solutions. Electrokinetic mechanistic studies of HER were consistent with formation of the Co(II) hydride by stepwise electron-transfer followed by proton transfer (ET-PT). Catalytic enhancement by the hangman moiety arose from a rapid intramolecular rate-limiting PT (ca. $8.5 \times 10^6 \text{ s}^{-1}$). This is the first direct measure of a proton transfer rate in a HER conversion and our results indicate that the presence of the pendant proton relay proximate to the metal center gives rise to a rate enhancement that is equivalent to an effective benzoic acid concentration $>3000 \text{ M}$. This is the first quantitative measurement of the benefits of a pendant proton transfer in the secondary coordination sphere of a HER catalyst. Studies were expanded to iron hangman porphyrins with a larger cleft to allow for the accommodation of a diverse set of hanging groups possessing different steric and acid/base properties. The key step in obtaining this library relied on the synthesis of a precursor that contained an aldehyde functionality and a protected carboxylic acid (methyl ester). The chemistry was carried out in four steps on a decagram scale in 37% overall isolated yield. We employed the foot-of-the-wave analysis (FOWA) to analyze the electrocatalytic reduction of protons to hydrogen and CO_2 to CO and H_2O .

Studies of Photoinduced Electron Transfer from Dyes, Polymers and Quantum Confined Systems into Semiconducting Single Crystals

Institution: Wyoming, University of
Point of Contact: Bruce Parkinson
Email: bparkin1@uwyo.edu
Principal Investigator: Bruce Parkinson
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The project has studied the sensitization of many single crystal oxide semiconductors as well as gallium phosphide with both sensitizing dyes and quantum dots. Some light absorbing polymers were also studied.

FY 2014 HIGHLIGHTS

Mott-Schottky analysis is used to determine the band-edge positions for ZnO single crystals in acetonitrile electrolytes. The band alignment between ZnO and PbS QDs suggests that electron injection can occur for PbS quantum dots (QDs) over a wide range of sizes. Sensitization of ZnO single crystal electrodes with PbS QDs is then demonstrated using ferrocene/ferrocenium as the regenerator (hole acceptor). The largest 5.5 nm QDs are sensitizing the ZnO out to 1580 nm or 0.84 eV, to our knowledge

the longest wavelength sensitization measured for any oxide semiconductor. The driving force for the hole transfer from the 5.5 nm PbS QDs with a band gap of 0.84 eV using ferrocene/ferrocenium regenerator in acetonitrile was found to be close to zero which may result in a high open circuit voltages for QDs sensitized solar cells (QDSSCs) with a spectral response extending well into the infrared. Homoepitaxial growth of highly ordered and pure layers of rutile on rutile crystal substrates and anatase on anatase crystal substrates using atomic layer deposition (ALD) was accomplished. The epilayers grow in a layer-by-layer fashion at low deposition temperatures but are still not well ordered on rutile. Subsequent annealing at higher temperatures produces highly ordered, terraced rutile surfaces that in many cases have fewer electrically active defects than the substrate crystal. The anatase epitaxial layers, grown at 250°C, have much fewer electrically active defects than the rather impure bulk crystals. Annealing the epilayers at higher temperatures increased band gap photocurrents in both anatase and rutile.

Transition Metal Polypyridine Complexes: Studies of Mediation in Dye-Sensitized Solar Cells and Charge Separation

Institution: Colorado State University
Point of Contact: Amy Prieto
Email: alprieto@lamar.colostate.edu
Principal Investigator: Amy Prieto
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014-2015)

PROGRAM SCOPE

The research comprises two problems in solar photoconversion. The first considers photoinduced charge separation within the context of discrete molecular assemblies composed of a chromophore simultaneously linked to an electron donor(s) and an electron acceptor(s).

The second considers photoinduced charge separation in dye-sensitized solar cells. In each of these platforms, absorbed light initiates a cascade of electron transfer events, the relative rates of which determine the final outcome. The interplay between many factors (thermodynamic driving force, reorganization energy, donor-acceptor electronic coupling, mass transport and spin dynamics) control those rates and thus define the processes efficiency. Through appropriate structural and energetic manipulation of the molecular charge-separation and –transport machinery it is possible to gain fundamental mechanistic insight about the relevant electron transfer processes involved.

FY 2014 HIGHLIGHTS

Catalysis and Light Harvesting at Interfaces-Focus on Solar Fuels

Institution: Purdue University
Point of Contact: Yulia Pushkar
Email: ypushkar@purdue.edu
Principal Investigator: Yulia Pushkar
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$360,000 (2014-2015)

PROGRAM SCOPE

In artificial photosynthesis, an effective way to store solar energy is to convert it into chemical energy via the rearrangement of chemical bonds. The water oxidation reaction plays a crucial role in this process. The main challenge towards the future use of artificial photosynthesis is the development of economically feasible catalysts for water splitting. This catalyst will work as a part of an integrated assembly for light driven water splitting. The goal of this proposal is to determine the structure and electronic configurations of the critical intermediates of water oxidation as well as their dynamics under catalytic conditions. Time resolved techniques will be used to monitor the evolution of electronic states during the water oxidation and light harvesting. The relationship between molecular structure and catalytic activity will be uncovered and reaction barriers will be modeled based on experimental information. The informative techniques to study *in situ* catalytic water oxidation and dynamic of light harvesting are synchrotron-based X-ray spectroscopy, including X-ray absorption near edge structure (XANES), extended X-ray absorption fine structure (EXAFS) and X-ray emission spectroscopy (XES), electron paramagnetic resonance (EPR) and multiwavelength kinetic resonance Raman spectroscopy. These experimental techniques will deliver information on the structure of the intermediates and their electronic configuration and evolution of samples during the catalytic processes *in situ*. Ultimately, the results of the proposed research will constitute a major step towards development of future light-to-fuel energy solutions, thus contributing to the US security through energy independence and will help to reduce greenhouse gas emissions.

FY 2014 HIGHLIGHTS

As a research highlight we would like to list our publication "Spectroscopic analysis of catalytic water oxidation by $\text{Ru}^{\text{II}}(\text{bpy})(\text{tpy})\text{H}_2\text{O}]^{2+}$ suggests that $\text{Ru}^{\text{V}}=\text{O}$ is not a rate-limiting intermediate" by Yulia Pushkar, Dooshaye Moonshiram, Vatsal Purohit, Lifan Yan, Igor Alperovich, Journal of the American Chemical Society, 2014, 136 (34), pp 11938–11945. Modern chemistry's grand challenge is to significantly improve catalysts for water splitting. Further progress requires detailed spectroscopic and computational characterization of catalytic mechanisms. We analyzed one of the most studied homogeneous single-site Ru catalysts, $[\text{Ru}^{\text{II}}(\text{bpy})(\text{tpy})\text{H}_2\text{O}]^{2+}$ (where bpy = 2,2'-bipyridine, tpy=2,2';6',2''-terpyridine). Our results reveal that the $[\text{Ru}^{\text{V}}(\text{bpy})(\text{tpy})=\text{O}]^{3+}$ intermediate, reportedly detected in catalytic mixtures as a rate limiting intermediate in water activation is not present as such. Using a combination of EPR and X-ray absorption spectroscopy, we demonstrate that 95% of the Ru complex in the catalytic steady state is of the form $[\text{Ru}^{\text{IV}}(\text{bpy})(\text{tpy})=\text{O}]^{2+}$. $[\text{Ru}^{\text{V}}(\text{bpy})(\text{tpy})=\text{O}]^{3+}$ was not observed and according to DFT analysis might be thermodynamically inaccessible at our experimental conditions. A reaction product with unique EPR spectrum was detected in reaction mixtures at about 5% and assigned to Ru^{III} -peroxo species with (-OOH or -OO- ligands). $[\text{Ru}^{\text{II}}(\text{bpy})(\text{tpy})\text{H}_2\text{O}]^{2+}$ is the simplest representative of a larger class of water oxidation catalysts with neutral, nitrogen containing heterocycles. We expect this class of catalyst to work mechanistically in a similar fashion via $[\text{Ru}^{\text{IV}}(\text{bpy})(\text{tpy})=\text{O}]^{2+}$ intermediate unless more electronegative (oxygen containing) ligands are introduced in the Ru coordination sphere, allowing the formation of more oxidized Ru^{V} intermediate.

Energy, Electron Transfer and Photocatalytic Reactions of Visible Light Absorbing Transition Metal Complexes

Institution: Tulane University
Point of Contact: Russell Schmehl
Email: russ@tulane.edu

Principal Investigator: Russell Schmehl
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$80,000 (2014)

PROGRAM SCOPE

Effective systems for photochemical reduction of water to hydrogen must involve efficient approaches for using sunlight to generate chemical reductants to provide electrons necessary for catalysts to combine with protons from water to yield hydrogen. A parallel avenue of research is development of the catalysts. In the end systems containing a light-absorbing unit, an electron relay and a catalyst must be combined and evaluated under laboratory and solar irradiation conditions. Our group has worked on making highly reliable photochemical systems in an effort to clearly evaluate the efficiency of various catalysts under solar photochemical conditions. This is a necessary step for comparison of catalytic systems being developed (there are many). Our work here includes testing water reduction catalysts made in other labs and we have a variety of collaborations with chemists developing new, more effective catalysts. Another objective that is a continuation of earlier work is the investigation of the photochemistry and light induced electron transfer reactions of square planar Pt(II) imine complexes, principally terpyridyl complexes. Through a thorough examination of light induced one electron reduction and oxidation reactions of the Pt(II) complexes and the subsequent thermal reactions of the unstable intermediate species (Pt(III) or Pt(I)), the factors influencing net two-electron reaction of the complexes can be understood. Of particular interest are processes that result in one electron oxidation of the Pt(II) complex, because the Pt(III) intermediates generated are highly reactive and could yield photoproducts that ultimately react further to regenerate the Pt(II) complex and also yield an oxidized substrate; for example, it may be possible to oxidize water to hydrogen peroxide via a photocatalytic cycle.

FY 2014 HIGHLIGHTS

Highlights for the group in FY 2014 include development of new photochemical systems for generation of very strong reducing agents in aqueous and nonaqueous solutions. The systems are air stable until photolyzed and are capable of serving as reductants for a wide range of water reduction catalysts aimed at generation of hydrogen (see *J. Phys. Chem.* v. 118, p.10400). A key to making the systems was employing coupled near self-exchange electron transfer reactions between reversible electron donors and sacrificial electron donors. A second highlight involves development of new visible light absorbing sensitizers for photoinduced electron transfer reactions that consist of earth abundant metal complexes (Sn(IV)) that can serve as substitutes for the more commonly used noble metal complexes (see: *Dalton Transactions*, v. 43, p. 17754). These chromophores form triplet excited states in high yield, but have been heretofore ignored because they do not exhibit phosphorescence. A third highlight illustrates the use of ultrafast time resolved infrared spectroscopy to follow the flow of electron density upon creation of an excited state (in Re(I) carbonyl complexes) and subsequent intramolecular electron transfer events that result in what can best be described as partial charge transfer (see: *J. Phys. Chem. B*, v. 117, p. 15903). The system involves a delocalized hole between the metal center and a dimethylamino moiety on one of the coordinated ligands. The work, in collaboration with Igor Rubtsov (Tulane), has been expanded to other systems wherein full charge separation occurs; changes in infrared stretching frequencies of the carbonyl ligands provide clear and dramatic evidence for the shifts in electron density following visible light excitation.

Organic, Nanoscale, and Self-Assembled Structures Relevant to Solar Energy Conversion

Institution: Duke University
Point of Contact: Michael Therien
Email: michael.therien@duke.edu
Principal Investigator: Michael Therien
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$171,000 (2014)

PROGRAM SCOPE

This program seeks to understand the molecular-level principles by which complex chemical systems carry out photochemical charge separation, transport, and storage, and utilize these principals to impact the design of practical solar energy conversion and storage devices. Towards this goal, this program focuses on: (i) delineating new compositions of matter relevant to solar energy conversion, (ii) understanding the basic photophysical properties of next-generation conjugated materials for excitonic solar cells, (iii) elucidating rules and principles relevant to controlling charge transfer, charge migration, photoconductivity, and exciton diffusion dynamics in structures and assemblies pertinent to light-driven energy transduction, (iv) probing the extent of electronic coupling between conjugated organic materials and nanoscale structures in both ground and excited states, and (v) engineering high quantum yield electron-hole pair production from initially prepared excitonic states in organic materials and organic compositions that feature nanoscale, electrooptically active components.

FY 2014 HIGHLIGHTS

Single-Handed Helical Wrapping of Single-Walled Carbon Nanotubes by Chiral, Ionic, Semiconducting Polymers. We have established the requisite design for aryleneethynylene polymers that give rise to single-handed helical wrapping of single-walled carbon nanotubes (SWNTs). Aryleneethynylene polymers were synthesized that feature a 2,2'-(1,3-benzyloxy)-bridged (b)-1,1'-bi-2-naphthol unit: this 1,1'-bi-2-naphthol derivative is characterized by a bridging 2,2'-1,3 benzyloxy tether that restricts the torsional angle between the two naphthalene subunits along its C1-C1' chirality axis to larger, oblique angles that facilitate more extensive van der Waals contact of the naphthyl units with the nanotube. Related semiconducting polymer-SWNT superstructures have been realized that demonstrate that the combination of single-handed helical wrapping and electronic structural modification of conjugated polymer motif opens up new opportunities for engineering the electro-optic functionality of nanoscale objects. Ionic Self-Assembly Provides Dense Arrays of Individualized, Aligned Single-Walled Carbon Nanotubes. Developing the means to control single-walled carbon nanotube (SWNT) organization in multi-component ensembles has been a long-standing goal. We demonstrated for the first time that SWNTs, helically wrapped by a single chain of an anionic [arylene]ethynylene polymer, can be structured into organized microscale objects through ionic self-assembly (ISA). These microstructures are composed of rigorously aligned nanotubes at high areal density (2.5×10^{10} SWNTs cm^{-2}), and maintain the optical properties characteristic of individualized SWNTs. We posit that the combination of chiral polyanionic polymers, SWNTs having electronic structural homogeneity, the ability to modulate polymer electronic structure by design, and the facility of ISA to provide hierarchical organization, offers exceptional promise for the development of new types of electro-optic materials.

Further Studies on Photocatalytic Water Decomposition

Institution: Houston, University of

PROGRAM SCOPE

This project involves the design, synthesis, and study of chromophore-catalyst assemblies that will use energy inherent in the photoexcited state of the chromophore to activate a catalyst that in turn will carry out the bond breaking and bond making steps required for the conversion of water into its elements. Such assemblies can be envisioned to accomplish both the reduction of protons to make hydrogen and the oxidation of hydroxide to make oxygen. As long as these two processes are separate, however, a sacrificial electron donor or acceptor will be necessary to complete the catalytic cycle. An important objective is to integrate these processes and thereby avoid sacrificial reagents. We have discovered a family of mono- and dinuclear Ru(II) complexes that are efficient catalysts for water oxidation. These catalysts possess polypyridine ligands and are classified as Type I, II, and III catalysts. Current studies concentrate on the Type III catalyst having a tetradentate dipyriddyphenanthroline (dpp) equatorial ligand. The isolation of a dpp di-N-oxide Ru complex during the generation of O₂ has evoked the interesting question as to whether this species might be an intermediate in the oxidation process. Parallel studies are aimed at the development of water reduction catalysts based on Co(II) and Ni(II). A Co(II) polypyridine catalyst has been discovered that affords light-driven H₂ production (TON > 300 h⁻¹) in pure water. By ligand modification we will optimize and modify this system to improve performance and to allow incorporation into a dyad assembly. Bridging ligands will be explored with respect to the ability to gate and direct electron flow.

FY 2014 HIGHLIGHTS

We have prepared the ligand 8-(1',10'-phenanthroline-2'-yl)-2-(pyridin-2'-yl)quinoline (ppq) that contains an additional sp² carbon (C₈ of quinoline). This ligand readily accommodates Co(II) to form [Co(ppq)Cl₂]. The critical precursor to ppq can be accessed by either the Friedländer condensation of 3-bromo-2-aminobenzaldehyde with 2-acetylpyridine or the selective Stille coupling of 2-pyridyl-tri-n-butylstannane with 2,8-dibromoquinoline. In a similar fashion a variety of ppq derivatives have been prepared. To measure evolved hydrogen by these complexes, we developed a reactor in which the internal pressure is monitored by a transducer in real time. Properly used, this method is useful for measuring either hydrogen or oxygen. We have prepared a series of dyad assemblies C-L-P where C = water oxidation catalyst derived from [Ru(tpy)(bpy)(I)]⁺, P = a photosensitizer derived from [Ru(bpy)₂(phen)]²⁺, and L is a linker that consists of a combination of ethynylene or phenylene moieties. These systems are being evaluated for light-driven water oxidation. Together with our collaborators at Brookhaven National Lab, we have been examining a series Ru(II) water oxidation catalysts that involve a meridional quaterpyridine-type ligand. During water oxidation by the complex [Ru(dpp)(pic)₂]²⁺ (dpp = 2,9-di-(pyridin-2'-yl)-1,10-phenanthroline, pic = 4-picoline) we isolate a Ru(II)-complexed di-N-oxide intermediate and are in the process of determining the origin of this species and its importance in the water oxidation process. A 6-5 chelator is a tridentate ligand that binds a metal forming both a five and six-membered chelate ring. It appears that this less strained situation allows for water attack on the oxidized metal

center to form a seven-coordinate pentagonal bipyramid intermediate that is not accessible from a 5-5 chelator. Unlike $[\text{Ru}(\text{tpy})_2]^{2+}$, these complexes are active as water oxidation catalysts.

Photocatalysts for H_2 Evolution: Combination of the Light Absorbing Unit and Catalytic Center in a Single Molecule

Institution: Ohio State University
Point of Contact: Claudia Turro
Email: turro@chemistry.ohio-state.edu
Principal Investigator: Claudia Turro
Sr. Investigator(s): Kim Dunbar; Texas A&M University
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$158,000 (2014)

PROGRAM SCOPE

The search for renewable, clean sources of energy is critical for the future of the planet. The use of abundant sunlight to generate electricity or to efficiently and catalytically transform inexpensive simple molecules into clean fuels, such as the splitting of water into H_2 and O_2 , remains a challenge. This research project aims to design and develop single-component photocatalysts for the reduction of protons to hydrogen, whereby the light absorbing (LA) unit and hydrogen-evolving center (HEC) are combined within a single molecule. Combining function-specific molecular components decreases the number of required bimolecular charge transfer processes, often a cause of limited efficiency in photocatalytic systems. The use of a redox-active $\text{Rh}_2(\text{II},\text{II})$ dimeric core whose light absorbing, electrochemical, and excited state properties are modulated by electron-donating formamidinate and electron-accepting polypyridyl ligands provides insight into the interplay between each component and how this impacts overall catalysis. This strategy employs bimetallic complexes with highly reducing excited states and open coordination sites to function as both the LA and HEC.

FY 2014 HIGHLIGHTS

Collaborative efforts between the Turro (The Ohio State Univ.) and Dunbar (Texas A&M University) research labs have led to the synthesis of multiple formamidinate-bridged $\text{Rh}_2(\text{II},\text{II})$ dimers. Varying the electron-accepting ability of the neutral, bidentate polypyridyl ligand tunes the LUMO within the molecule, impacting the reductive capabilities and pathways within catalysis. Conversely, modifying the electron-donating ability of the anodic formamidinate bridging ligands modulates the electron density at the $\text{Rh}_2(\text{II},\text{II})$ core and therefore the HOMO. Electrochemical studies and DFT calculations confirm the impact that formamidinate and polypyridyl ligands have on the energies of the molecule's HOMO and LUMO, respectively. In depth electrocatalytic studies revealed some of the thermodynamic and kinetic aspects of catalytic proton reduction to hydrogen using this $\text{Rh}_2(\text{II},\text{II})$ architecture. Addition of a weak acid (CH_3COOH , $\text{pK}_a = 13.5$ in DMF) in organic solutions displays the rapid turnover frequency, TOF, of 10^4 s^{-1} , of this system functioning at a mild overpotential ($\text{OP} = 0.45 \text{ V}$). These studies also provide insight into the mechanism of hydrogen evolution, with the current description suggesting formation of a $\text{Rh}_2(\text{II},\text{I})$ core, followed by protonation to give a $\text{Rh}_2(\text{II},\text{III})$ -hydride species before further protonation and reduction to evolve hydrogen and regenerate the catalyst. Currently, a manuscript for submission in a peer-reviewed journal detailing the electrocatalysis findings is underway. Future work within the FY 2015 includes continued synthesis of strong visible light absorbing $\text{Rh}_2(\text{II},\text{II})$ dimers, increasing the excited state lifetime within these dimers, and inclusion of anchoring substituents for coordination to semiconductor electrodes and nanoparticles.

A Concerted Synthetic, Spectroscopic, and Computational Approach Towards Water Splitting by Heterometallic Complexes in Solution and on Surface

Institution: Wayne State University
Point of Contact: Claudio Verani
Email: cnverani@chem.wayne.edu
Principal Investigator: Claudio Verani
Sr. Investigator(s): John Endicott; Wayne State University
H. Bernhard Schlegel; Wayne State University
Students: 1 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$418,000 (2014)

PROGRAM SCOPE

The basic premise of this collaborative project is the investigation of monometallic modules and multimetallic modular complexes in solution and on surfaces. We aim to understand the requirements necessary to effective electron transfer in antenna/catalyst/acceptor modules of a single molecule, as well as the mechanisms of photo and electrocatalytic proton and water reduction and water oxidation. The modular antenna is aimed to function as a sensitizer absorbing solar radiation and generating an excited state able to transfer an electron. For proton and water reduction this electron is supposed to be transferred directly to the catalyst module, whereas water oxidation requires that ET involves an acceptor module in order to provide a hole to the catalyst module, thus implying that the metal center will be able to reach a highvalent oxidation state. Aiming to use Earth-abundant metals, we have focused our efforts on cobalt-containing modules for reduction and manganese-containing modules for oxidation. Study of new modular catalysts starts with the evaluation of their electrocatalytic properties, and we aim to attach the most promising catalysts to ruthenium-based antenna modules. Therefore, emphasis has been given to monometallic modules containing cobalt and ruthenium ions. The Verani group is responsible for syntheses, electrochemical, and catalytic studies, while the Endicott group focuses on the photochemistry and photophysical aspects and the Schlegel group provides DFT and TD-DFT calculations. For the long run, the relevance of this work relates to a new class of integrated [acceptor/antenna/active site] photocatalysts that allow for generation of dihydrogen and dioxygen from water.

FY 2014 HIGHLIGHTS

In a close and interactive collaboration, the Verani and Schlegel groups have studied the behavior of two series of electrocatalysts capable of proton and water reduction. We investigated the redox, spectroscopy, and catalytic reactivity of new cobalt(III) complexes $[\text{Co}^{\text{III}}(\text{LPhOX})\text{MeOH}]$, based on phenolate-rich $[\text{N}_2\text{O}_3]$ ligands, where X indicates the presence of chloro, bromo, iodo, or tert-butyl substituents in the 3rd and 5th positions of each phenolate ring. The Cl^- species reduces effectively protons in weakly acidic media with a TON of 11 after 3 h of bulk electrolysis at $-2.20 \text{ V}_{\text{Fc}/\text{Fc}^+}$. We also studied a series of cobalt complexes $[\text{Co}^{\text{III}}(\text{LP}_y)\text{Cl}]$ with pentadentate pyridine-rich ligands. An initial Co(II) amine complex is prone to aerial oxidation yielding a Co(III) imine complex that is further converted into an amide complex in presence of adventitious water. Introduction of an N-methyl protecting group to the ligand inhibits this oxidation and gives rise to a Co(II) species. Both the amide and Co(III) and methylated Co(II) show electrocatalytic H_2 generation in weakly acidic media with TONs of ca. 15 after 3h at -1.9 V vs. Fc^+/Fc . Remarkably these complexes are soluble in water and yielded TON of 7,000 after 18 h. Mechanisms of catalysis seem to involve the protonation of a $\text{Co}^{\text{II}}\text{-H}$ species generated *in situ*, and no indication of proton-coupled electron transfer was observed. The Endicott and Schlegel groups have

found that most of the observed variations in $^3\text{MLCT}$ excited state distortions, emission intensities and to some degree lifetimes of Ru-(aromatic ligand) complexes arise from configurational mixing with higher energy ligand centered excited states. A major factor determining $^3\text{MLCT}$ excited state lifetimes, especially under ambient conditions, is the relative energies of the lowest energy $^3\text{MLCT}$ and triplet metal centered excited states (^3MC).

Approaches to Integrated Photochemical Systems for Solar Energy Conversion

Institution: Northwestern University
Point of Contact: Michael Wasielewski

Principal Investigator: Michael Wasielewski
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$304,000 (2014)

PROGRAM SCOPE

Natural photosynthesis is carried out by organized assemblies of photo-functional chromophores and catalysts within proteins, which provide specifically tailored environments to optimize solar energy conversion. Artificial photosynthetic systems for practical solar fuels and electricity production must collect light energy, separate charge, and transport charge to catalytic sites where multi-electron redox processes for fuel formation will occur or to electrodes where charge is collected for electricity production. The primary goal of our research is to understand the fundamental principles needed to develop integrated artificial photosynthetic systems. These principles include how to promote and control within complex molecular systems: 1) energy capture, charge separation, and long-range directional energy and charge transport, 2) coupling of separated charges to multi-electron catalysts for fuel formation, and 3) supramolecular self-assembly for scalable, low-cost processing from the nanoscale to the macroscale. Identifying and determining the dynamics of both short- and long-lived intermediates produced by photo-initiated charge separation and transport in complex molecular systems is critical to understanding how to design functional artificial photosynthetic systems. We employ synchrotron-based X-ray diffraction and scattering techniques to characterize molecular structures and assemblies. We also use femtosecond transient absorption, fluorescence, stimulated Raman, and IR spectroscopy to study ultrafast energy and charge transfer dynamics in these systems, while we use time-resolved pulsed-EPR spectroscopy to probe the nanosecond and longer timescale dynamics of the paramagnetic intermediates. These techniques provide the detailed structural data essential to understanding how to design integrated molecular systems for photochemical solar energy conversion.

FY 2014 HIGHLIGHTS

We have shown that singlet exciton fission (SF) occurs in high yield (170%) in robust perylene diimide (PDI) polycrystalline solid films aided by crystal engineering of a slip-stacked structure. We have also shown that crystal engineered terrylenes (the longer homolog of perylene) have SF performance approaching the theoretical maximum of 200%. Moreover, comparing our PDI and terrylene data shows that if SF is exoergic, then the structural requirements for high efficiency SF are somewhat relaxed, while if SF is endoergic these structural requirements are much more restrictive. This discovery is important for designing solar cells based on SF. We have developed columnar, ordered zinc tetrabenzoporphyrin-PDI assemblies that undergo single-step charge separation to yield a long-lived ion pair. Time-resolved

EPR spectroscopy shows that the positive and negative ions move independently within the ordered charge conduit structure. We have shown that solid films of a PDI-DPP-PDI molecule, where DPP is a pyrrole dye, upon solvent-vapor-induced self-ordering show an increase in charge separation lifetime from 340 picosec to 4 microsec, providing important insights into how photo-generated charges escape the Coulomb well in which they are generated within molecular solids. Understanding this phenomenon is critical to developing high performance molecular solar cells. We have demonstrated that bio-inspired hydrogen-bonded guanine-quadruplexes provide an important new platform on which to self-assemble photo-driven charge separation systems, and that cyclic naphthalene diimide (NDI) structures serve as excellent charge accumulators to store multiple electrons to drive reduction catalysts. We have shown that visible-light-absorbing perylene-based electron donors have sufficiently good excited state potentials to provide electrons to Pd-phosphine CO₂ reduction catalysts, thus paving the way for generating photodriven multi-electron sources for driving CO₂ reduction catalysts.

EARLY CAREER: Chemical Control of Charge Trapping and Charge Transfer Processes at the Organic-Inorganic Interface within Quantum Dot-Organic Complexes

Institution: Northwestern University
Point of Contact: Emily Weiss
Email: e-weiss@northwestern.edu
Principal Investigator: Emily Weiss
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2010-2014)

PROGRAM SCOPE

The research program funded through the Early Career Research Award aims to design complexes of colloidal semiconductor nanocrystals, also called quantum dots (QDs), and organic molecules in which the interfacial chemistry controls the electronic structure and dynamics of the excitonic state (photoexcited electron-hole pair) of the QD. The program includes two main projects: (1) investigation of the mechanisms by which organic surfactants control the quantum confinement of excitonic charge carriers, and (2) development of models for electron transfer between QDs and adsorbed molecules as a function of interfacial chemistry. Project (1) explores how organic molecules – in particular phenyldithiocarbamates (PTC) – change the confinement potential for excitonic carriers within QDs, and thereby change the steady state and transient properties of the exciton. The objective of Project (2) is to determine the chemical factors that influence the rates of charge separation and charge recombination across the interfaces between semiconductor nanocrystals and adsorbed (or transiently adsorbed) molecules.

FY 2014 HIGHLIGHTS

Project 1: We showed previously that coordination of PTC ligands to colloidal CdSe, CdS, and PbS QDs decreases the optical bandgaps, E_g , of the QDs by up to 970 meV. These values of ΔE_g are—by more than an order of magnitude in energy—the largest bathochromic shifts achieved for QDs in either the solution or solid phases. Within FY 2014, we have determined the dependence of the degree of delocalization by PTC (and similar molecules, thiophenolates) on their surface coverage on the QD by developing an NMR-based method to count PTC and thiophenolate molecules on the surface of the QD. This measurement is challenging because rigid molecules that adsorb strongly to nanoparticles have no NMR signal. We instead count native ligands that are displaced by adsorption of PTC to infer the number of bound PTC.

We have modeled the dependence of exciton delocalization on surface coverage in order to further clarify the interfacial electronic structure of QD-organic complexes. We have also proven that adsorption of PTC and other exciton-delocalizing molecules increase the probability of absorptive and emissive optical transitions, and thereby increases the photoluminescence quantum yield of the QD.

Project 2: We focused this year on a particular system comprising a di-triphenyldiamine (TPD) molecular donor and a CdS QD acceptor. Selective excitation of TPD, which is linked to the QD through a thiolate group, results in the ultrafast transfer of an electron into the conduction band of the QD. The interesting aspect of this system is that it forms a spin-correlated radical ion pair. The lifetime of the charge separated state in this system depends on the strength of an applied magnetic field. The magnetic field dependence, along with EPR spectra, tell us that the electron on the QD is localized in a surface state and avoids recombination with the hole on TPD by hopping across the surface of the QD.

EARLY CAREER: Design of Efficient Molecular Electrocatalysts for Water and Carbon Dioxide Reduction Using Predictive Models of Thermodynamic Properties

Institution: California-Irvine, University of
Point of Contact: Jenny Yang

Principal Investigator: Jenny Yang
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 2 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

Hydrogen and reduced carbon compounds have been proposed as ideal candidates for chemical fuels from intermittent renewable energy sources, such as solar. However generation of chemical fuels from electricity requires competent electrocatalysts. The proposed research focuses on developing electrocatalysts for the reduction of water to hydrogen, and carbon dioxide to formate. In heterogeneous catalysis, the Sabatier principle is used to generate volcano curves that describe optimal thermochemical properties for key intermediates that result in peak catalytic activity. In most cases, such as hydrogen production and oxidation, the most favorable metals (Pt, Re, Rh, and Ir) are rare and expensive. Molecular inorganic complexes provide an opportunity to use electronic and steric ligand effects to tune the critical thermodynamic parameters of abundant metals to values comparable to key surface intermediates on precious metals. This principle will be applied to the design of aqueous homogeneous catalysts for the reduction of H₂O and CO₂ optimized to function at specific pH ranges. The critical intermediate in both of these reactions is a metal hydride. The strength of this bond, or hydricity (ΔG^{\ddagger}) dictates the overall thermodynamics of the reduction of H⁺ to H₂ and the sequential reduction of C₁ substrates, such as CO₂, CO, and H₂CO (the latter to CH₃OH). ΔG^{\ddagger} will be systematically measured for a series of first row metal complexes to form predictive models for metal and ligand electronic effects.

FY 2014 HIGHLIGHTS

This project was funded in July 2014. During fiscal year 2014 the initial target complex, a water soluble nickel bis(diphosphine), was synthesized and fully characterized. The hydricity of this complex was measured in water, dimethyl sulfoxide, and acetonitrile. We also determined that this complex is stable in water from pH 1 through 7, and our preliminary electrochemical experiments indicate catalytic proton reduction under these conditions.

Students: 2 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$900,000 (2014)

PROGRAM SCOPE

This program aims at understanding and investigating roles of coherent electronic and nuclear movements in the photochemistry of transition metal complexes (TMC) which is crucial in solar energy conversion and utilization. The program has three specific objectives. The first objective is to identify, characterize and compute functionally important coherent electronic and nuclear motions in the excited state properties of TMCs with one or multiple metal centers. This part of the program focuses on understanding and characterizing fundamental processes involving the fs dynamics of TMCs including (a) interaction mechanisms for ultrashort laser pulses to produce a coherent superposition of excited states whose properties can be controlled by pulse sequence and shaping, (b) subsequent evolution of the excited states of the TMC's, including electronic state relaxation by nonadiabatic effects and subsequent thermal flow to phonons and solvent, and (c) electronic structure studies and modeling of the measureable properties of the TMC's during and after this time evolution. The second objective is to understand and engineer ultrafast two-electron transfer reactions in chromophore-catalyst-chromophore supramolecular TMC assemblies via control of electronic coupling between the chromophores in the assemblies through the linker bridges or via the photoexcitation pulse sequence. The third objective is to investigate the effect of ultrafast "breathing modes" in nanoparticles on the interfacial electron and energy transfer processes of TMC-nanoparticle hybrid structures. Our focus will be on the properties of the TMCs that are influenced by these phonon modes in nanoparticles. For metal nanoparticles, we expect that plasmon excitation will play an important role, leading both to enhanced absorption and scattering of light, and to a number of secondary processes as time evolves, including hot electron excitation and acoustic phonon excitation.

FY 2014 HIGHLIGHTS

The program started in August, 2014. The research highlight is pending until sufficient results are obtained. By the end of FY2014, the most of key players are all in place. The coming ultrafast X-ray absorption spectroscopy experiments at the Linac Coherent Light Source (LCLS) has been planned in

early 2015, and a series of computations have started on excited state optical and X-ray spectroscopic features. The syntheses of several TMCs have been started.

PECASE: Engineering Principles for the Efficient and Effective Manipulation of Energy and Information at the Nanometer Scale

Institution: Lawrence Berkeley National Laboratory

Principal Investigator: Gavin Crooks
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$50,000 (2014)

PROGRAM SCOPE

In our proposed research we will develop the theory and simulation tools necessary to understand thermodynamics of molecular machines on the nanoscale, where large fluctuations and deviations from equilibrium make traditional approaches problematic. We seek the design principles that will allow us to engineer and customize our own efficient and effective molecular gadgetry. We wish to understand the thermodynamic efficiency of molecular motors, the tradeoff of efficiency with power output, how to determine the optimal thermodynamic processes, and how to engineer machines that can approach these optimal performances. We will do so by building on the recent breakthroughs in non-equilibrium small system thermodynamics discussed in the introduction. We will also draw on a wide range of disciplines, including thermodynamics, statistical mechanics, information theory, quantum optics, computer simulation and statistics, with the aim of uncovering additional theoretical and practical insights into nanothermodynamics.

We specifically wish to understand how to engineer our own effective nanoscale mechanism for highly efficient energy transformation, how to master energy and information on the nanoscale, how to mimic capabilities of biological systems, and how to control and characterize molecules machines far from equilibrium. We currently lack the necessary theoretical guidance on the practical limitations to efficient energy conversion on the molecular scale, and away from thermal equilibrium, and practical guidance as how to design and optimize molecular scale machinery to meet our energy efficiency and engineering goals.

Primary Processes in Photosynthesis

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Ali Belkacem
Email: abelkacem@lbl.gov

Principal Investigator: Graham Fleming
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$557,000 (2014)

PROGRAM SCOPE

The aim of this work is to determine the design principles used by natural photosynthetic systems to harvest solar energy and perform charge separation. The photosynthetic unit is one of the supreme and most elegant examples of nanoscale engineering found in nature. Application of these design principles to the conception of new synthetic solar energy devices holds great promise. Both energy and electron transfer are ultrafast processes and thus require the use of femtosecond spectroscopy for their elucidation. This project focuses on the fundamental processes of energy and electron transfer in natural photosynthesis. New ultrafast nonlinear optical spectroscopies have been developed and combined with new quantum-dynamical theoretical methods to provide new insights into the primary steps of photosynthesis.

FY 2014 HIGHLIGHTS

We revisited a previous study of bacteriopheophytin (H) to bacteriochlorophyll (B) energy transfer in the bacterial photosynthesis reaction center experimentally by refining the two-color peak shift and studying neutral, oxidized reaction centers and a mutant lacking the special pair. We found long-lived (up to 2 ps) oscillatory signals that at long time clearly originate from vibrational wavepackets in the B ground state. We note that the electronic structure and function of the bacterial RC is distinct from typical light harvesting complexes, and estimated coupling constant are significantly larger than in FMO and LHCII complexes. To date, the advantages of multidimensional infrared and electronic spectroscopies have never been combined to directly correlate the electronic and vibrational degrees of freedom simultaneously. We have developed two-dimensional electronic-vibrational spectroscopy and implemented the technique in a partially collinear geometry. This has been a very technically challenging project because of the very small signals arising from electronic and vibrational interactions with samples. We constructed the first structure-based model of energy transfer in photosystem II (PSII). In order to model the large number of pigment molecules present in a supercomplex (as many as 324), a coarse grain model was implemented to cluster chlorophylls into domains, that increases the separation of timescales between inter and intra-domain transfer. Using the complete energy and electron transfer model for $C_2S_2M_2$, we showed that light harvesting in PSII cannot be simplified to a single rate-limiting step. Rather, substantial contributions arise from both excitation diffusion through the antenna pigments and transfer from the antenna to the RC. We have shown that the average timescale of excitation energy capture is linearly dependent on the distance of the excitation from the nearest reaction center.

Chemistry with Near Infrared Photons

Principal Investigator: Heinz Frei
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$477,000 (2014)

PROGRAM SCOPE

The scope of this project consists of the development of efficient, robust photocatalytic subsystems and complete systems for the synthesis of renewable fuels and chemicals using carbon dioxide and water as starting materials, and sunlight as energy source. All-inorganic oxo-bridged heterobinuclear light absorbers coupled to metal oxide nanoclusters are being developed for accomplishing visible light induced multi-electron catalysis for carbon dioxide reduction and water oxidation, using photodeposition methods for the proper coupling of chromophore and nanocluster catalyst. Structures, charge transfer processes and catalytic mechanisms are elucidated by X-ray spectroscopy, transient optical and time-resolved FT-infrared spectroscopy and atomic resolution imaging. The mechanistic understanding gained from the infrared studies combined with electron transfer investigations of the heterobinuclear charge transfer units by time-resolved optical spectroscopy guide the design of units for improved photocatalytic efficiency under visible and near infrared light. Metal oxide core-shell constructs are being developed for separating the water oxidation catalysis from light absorption and reduction chemistry by a nanoscale silica-based membrane. Synthetic methods have been developed for embedding electron or hole conducting molecular wires into the insulating silica membrane, and proton transmission properties of the silica have been quantified. Emphasis is on tightly controlled electron transport from light absorber to catalyst through the molecular wires, on atomically defined contacts between the components, and on the elucidation of charge transport kinetics and efficiency across the assembly. The long term goal is to close the photocatalytic cycle of carbon dioxide reduction and water oxidation on the nanoscale while achieving product separation on the macroscale.

FY 2014 HIGHLIGHTS

Closing of the photosynthetic cycle of carbon dioxide reduction using water as electron source has been demonstrated with a heterobinuclear ZrOCo light absorber coupled to an Ir oxide nanocluster catalyst anchored on mesoporous silica surfaces. Upon charge transfer excitation of the ZrOCo unit, gaseous carbon dioxide is split to carbon monoxide while the charge transferred to the Ir oxide nanocluster oxidizes water to oxygen. Efficient coupling of the light absorber with the Ir oxide catalyst was accomplished by the development of a photodeposition method for the proper positioning of the nanocluster. A similar photodeposition method was developed for the coupling a cuprous oxide nanocluster catalyst for carbon dioxide reduction to the Zr (or Ti) acceptor center, and efficient multi-electron transfer to the nanocluster and subsequent carbon dioxide reduction was observed. Using our recently developed Co oxide-silica core-shell nanotubes as building blocks of arrays for the photoreduction of carbon dioxide by water under product separation, proton transmission through the silica layer under complete blocking of molecular oxygen was demonstrated. The proton transmission property as function of layer thickness was quantified by electrochemical methods. With embedded electron conducting molecular wires, these silica layers constitute robust artificial photosynthetic membranes for product separation. In order to understand the detailed water oxidation mechanism on the Co oxide (spinel) nanoparticle surface, time-resolved FT-infrared spectroscopy was conducted and two transient surface intermediates observed under reaction conditions. One is a Co(IV) oxo species, the other a superoxide surface intermediate. The temporal behavior of the intermediates revealed the presence of a fast and a slow catalytic site on the Co oxide surface.

Artificial Photosynthesis for Fuel Generation in Solution and at Interfaces

Institution: Brookhaven National Laboratory

Students: 7 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$2,355,000 (2014)

PROGRAM SCOPE

The goal of our research is to gain a fundamental understanding of processes involved in the chemical conversion of solar energy. The long-term storage of solar energy as fuels requires efficient coupling of light absorption, photo-induced electron-transfer processes, and chemical transformations, together with managing proton movement and charge leveling in catalysts.

The effort in subtask 1 entitled "Reductive Half-reactions for Photogeneration of Fuels" consists of: (1) searching for visible-light absorbers (e.g., metal complexes and semiconductors) and coupling them with catalytic processes; (2) avoiding high-energy intermediates through multi-electron/multi-proton processes; (3) using inexpensive metals, or metal complexes that have bio-inspired or non-innocent ligands to achieve low-energy pathways via 2nd-coordination sphere interaction; (4) immobilizing catalysts on electrode or semiconductor surfaces for the highest possible reaction rates and slowest unwanted side reactions; and (5) adopting water as the source of protons and electrons. The utilization of water as a source of protons and electrons for solar-derived fuels requires the concurrent oxidation of water to oxygen.

In subtask 2 entitled "Photo- and Electrochemical Water Oxidation", mechanisms and new catalysts for photo- and electrochemical water oxidation are investigated in addition to efforts (1-4) mentioned above.

FY 2014 HIGHLIGHTS

- Reversible H₂ storage via interconversion of CO₂ and formic acid near room temperature with pH as the 'switch' for controlling the direction of the reaction has been investigated using as catalysts Iridium species with a series of bioinspired ligands. The pH-dependent mechanisms of formic acid dehydrogenation have been elucidated by kinetic isotope effects. Related new cobalt(III) complexes have been prepared and tested for CO₂ hydrogenation.
- A new strategy for the electrocatalytic reduction of CO₂ to CO, using a room-temperature ionic liquid as both the solvent and electrolyte, has resulted in enhanced catalytic activity at lower overpotential than in acetonitrile. When a Re-based catalyst is used, the CO₂ reduction rate constant in the ionic liquid exceeded that in acetonitrile by over an order of magnitude.
- A mononuclear ruthenium(II) complex that contains no water molecule in its primary coordination shell was evaluated as a catalyst for water oxidation. Using a detailed theoretical characterization of the energetics, thermochemistry, and spectroscopic properties of intermediates together with electrochemical and spectroscopic experimental data, a new mechanism for the water oxidation process that involves an unprecedented sequence of seven-coordinate ruthenium complexes as intermediates was elucidated.
- Kinetic isotope effects of novel carbon-to-metal hydrogen atom transfer reactions, in which homolytic cleavage of a C–H bond is accomplished by a photogenerated metal-centered radical, were investigated for the first time. The large primary kinetic isotope effect of 16.8 ± 1.4 observed for hydrogen atom abstraction from xanthenes to an Os radical at 25°C together with the observed

activation energy difference and the preexponential factor ratio suggest a quantum mechanical tunneling mechanism.

- Alternative materials to platinum-based catalysts are required to sustainably produce hydrogen from water at low overpotentials.

Fundamental Investigations of Water Splitting of Model TiO₂ Photocatalysts Doped for Visible Light Absorption

Institution: Pacific Northwest National Laboratory
Point of Contact: Bruce Garrett
Email: bruce.garrett@pnl.gov

Peter Sushko; Pacific Northwest National Laboratory
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$699,000 (2014)

PROGRAM SCOPE

The goal of this project is to provide new fundamental knowledge regarding complex oxides employed in solar photocatalysis through deeper understanding of interfacial phenomena that impact photocatalytic performance and long-term stability. The need for alternative energy sources has motivated intense searches for new materials capable of efficiently converting sunlight into electrical or chemical energy. To date, a major focus of heterogeneous solar photocatalysis research has been on discovery and optimization of new solar photocatalytic materials guided primarily by bulk material properties (e.g. composition, structure, optical properties and photoconductivity). Unfortunately, the inclusion of interfacial properties is frequently neglected despite the fact that interfaces are the gateways through which solar absorptivity is translated into chemical conversions. Key knowledge gaps exist in the optimization of bulk and interfacial oxide properties that control interfacial electron transfer performance. We employ advanced epitaxy oxide film growth methods, high-level theoretical approaches and modern surface science techniques to provide a combined bulk and interfacial understanding to the field of solar photocatalysis. Focusing on ternary model Fe oxides capable of solar photocatalysis (because of their low cost and high visible light absorptivity), this project is dedicated to preparing well-characterized oxide films and understanding their photochemical properties under similar well-controlled conditions. We also strive to understand how energy is dissipated from interfacial electron transfer events and how such effects contribute to photocorrosion of iron-based oxides. These proposed activities directly address the DOE's mission to promote fundamental understanding of photochemical conversions.

FY 2014 HIGHLIGHTS

The focus of this project in FY14 has been on the growth, characterization and photochemical study of mixed corundum oxides of Fe. Below are highlights from those efforts:

- Growth and characterization of α -(Fe_{1-x}Cr_x)₂O₃ films: We prepare single-crystal corundum films of α -(Fe_{1-x}Cr_x)₂O₃ (0 ≤ x ≤ 1) on α -Al₂O₃(0001) in which the Fe and Cr were homogeneously distributed. High 'x' films were partially strained and O deficient; low 'x' films contained excess O. XPS verified that both cations were 3+. The VB shifted toward the Fermi level for x up to ~0.5 resulting in a decrease in the bandgap observed by optical absorption spectroscopy and

photoconductivity. Alloying Fe_2O_3 with Cr_2O_3 also raised the conducting band minimum, which may reduce the over-potential required for photoelectrochemical water splitting.

- Optical transitions in $\alpha\text{-(Fe}_{1-x}\text{Cr}_x)_2\text{O}_3$ and $\alpha\text{-(Fe}_{1-x}\text{V}_x)_2\text{O}_3$: We calculated the optical properties of $(\text{Fe}_{1-x}\text{Cr}_x)_2\text{O}_3$ using an embedded cluster approach and the time-dependent DFT (TDDFT) method. At $x=0.5$, the bandgap was calculated to be ~ 0.7 eV less than that of pure $\alpha\text{-Fe}_2\text{O}_3$, consistent with experiment. This resulted from two effects: (i) a raised valence band maximum, and (ii) the appearance of $\text{Cr} \Rightarrow \text{Fe } d-d$ transitions (≈ 1.9 eV) in the solid solutions. Spin disorder promoted rehybridization of the O $2p$ and Fe/Cr $3d$ states.
- Photochemistry of a mixed Fe+Cr oxide surface: Underscoring the importance of interfacial properties, we found that the interface of a bulk $\alpha\text{-(Fe}_{.75}\text{Cr}_{.25})_2\text{O}_3(0001)$ film reconstructed in vacuum to a $(\text{Fe}_{.6}\text{Cr}_{.4})_3\text{O}_4(111)$ surface structure. Using NO as a probe, we observed distinct binding behaviors in TPD associated with surface Fe^{3+} , Cr^{3+} , and Fe^{2+} sites. Photoactivity, as gauged by NO photodesorption, revealed rates sensitive to the NO binding site, following the trend: $\text{Fe}^{3+} > \text{Fe}^{2+} > \text{Cr}^{3+}$. The rates were independent of the wavelength in the visible (460 to 630 nm) and showed activity below the absorption threshold of pure $\alpha\text{-Fe}_2\text{O}_3$, as predicted above.

Charge Separation and Escape in Low Dielectric Media

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: John Miller
Sr. Investigator(s): Andrew R Cook; Brookhaven National Laboratory
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$588,000 (2014)

PROGRAM SCOPE

The efficiency of organic photovoltaic devices to convert solar energy into electricity depends critically on escape of photo-generated electron-hole pairs from their mutual Coulomb field. Experiments are testing the hypothesis that delocalized electrons and holes can escape from each other even in low dielectric constant media such as conjugated polymer films. The experiments are examining how the Coulomb binding is reduced for delocalized charges and how the Marcus inverted region is enhanced for delocalized species. Experiments to measure these proposed effects of delocalization will determine lifetimes and escape yields for delocalized exciplexes and for electron-hole pairs on conjugated polymer chains. We will also study possibly greater charge delocalization in single-walled carbon nanotubes and in films of conjugated polymers. A central experimental tool is pulse radiolysis, which can rapidly inject electrons or holes into delocalized structures. Pulse radiolysis with absorption spectroscopy on sub-microsecond to picosecond timescales utilizes the facilities of the BNL Accelerator Center for Energy Research (ACER). In addition, advances in applying three other diagnostic techniques along with pulse radiolysis are supporting the scientific objectives: 1) transient microwave conductivity, 2) infrared transient absorption to detect delocalized charges, and 3) pulse radiolysis of thick ($\sim 100 \mu\text{m}$) conjugated polymer films.

FY 2014 HIGHLIGHTS

Electrons and holes on pairs of three unit fluorene oligomers, ($\text{F}^{3+}, \text{F}^{3-}$), show lifetimes of ~ 50 ns when created by pulse radiolysis, suggesting that ions in close contact can live unexpectedly long times before

recombination. The slow recombination may be due to delocalization of the charges. Push-pull or DA polymers, like F8BT, having alternating donor and acceptor groups are known to achieve low band gaps and high efficiencies. We have found the expected result that chemical reduction of F8BT produces electrons localized on the BT acceptor groups. But unexpectedly chemical oxidation produces holes delocalized over at least two donor (F8) groups and F8BT shows a substantial mobility in pulse radiolysis transient microwave conductivity (PR TRMC). The PR-TRMC is a new instrument created in collaboration with Rumbles and Reid of the National Renewable Energy Laboratory. Synthesis of three-unit fluorene oligomers having ortho methyl groups showed that large dihedral angles between the fluorenes raise the energies of electrons, holes and triplets moderately, but have a much greater impact on the energies of singlet excited states. This suggests that short diffusion lengths of single excitons in conjugated polymers may be due to the unusual sensitivity of singlets to dihedral angles.

Electron and Photo-Induced Processes for Molecular Energy Conversion

Institution: Brookhaven National Laboratory
Point of Contact: Alex Harris
Email: alexh@bnl.gov
Principal Investigator: John Miller
Sr. Investigator(s): Diane Cabelli; Brookhaven National Laboratory
Andrew R Cook; Brookhaven National Laboratory
David Grills; Brookhaven National Laboratory
Sergei Lyamar; Brookhaven National Laboratory
James Wishart; Brookhaven National Laboratory
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$2,431,000 (2014)

PROGRAM SCOPE

Using complementary techniques of excitation by fast electrons or photons, we investigate ionizing radiation chemistry and fundamental solar energy conversion chemistry, focusing on short-lived species including excited states, radical ions, and free radicals in condensed media from aqueous and organic solvents to ionic liquids. Work on ionic liquids examines fundamental radiation chemistry, properties and reactivity patterns relevant to energy-related applications. The program develops and operates instruments to study short-lived species, at the Accelerator Center for Energy Research (ACER). These include the picosecond Laser Electron Accelerator Facility (LEAF) with advanced nanosecond mid-IR detection based on quantum cascade lasers and optical fiber single-shot detection with time resolution to 15 ps, a 2 MeV electron Van de Graaff and a ^{60}Co source. The resources provide powerful and rare capabilities to several BNL programs and to external collaborators and users in energy research, as well as unique research on biological processes involving free radicals.

FY 2014 HIGHLIGHTS

Extensive efforts yielded dramatic improvements in LEAF's new transient infrared (TRIR) detection system. The new system allowed, for the first time, direct observation of all the intermediates involved in the formation of a Mn-based CO_2 reduction electrocatalyst. It also provided a new view into formation of ion pairs with organic radical ions and a new method to measure association constants. IR-based dosimetry methods have been developed. We also demonstrated that the LEAF TRIR system could follow the radiation-induced polymerization of a vinylimidazolium ionic liquid on timescales from tens of nanoseconds up to minutes by following the bleaching of the vinyl monomer C=C stretch. This result

indicates that the IR detection systems for radiolysis will be extremely useful for studying polymer synthesis and grafting in many different systems. Pulse radiolysis at LEAF has given new insight into the nature of redox potentials and their relation to ion pairing, and the possibility to measure thermodynamic redox potentials in the absence of electrolyte. Ultrafast capture of pre-solvated holes, a previously unknown process in radiation chemistry, discovered recently using LEAF's OFSS detection system, has been found to play an important role in the production of delayed fluorescence, important to basic understanding of radiation chemistry as well as scintillators.

Jointly funded by the Chemical Sciences, Geosciences, & Biosciences Division and Materials Sciences and Engineering Division

PROGRAM SCOPE

This research consortium, co-led by the Indian Institute of Science-Bangalore and the National Renewable Energy Laboratory, sets out to create an environment for cooperation and innovation "without borders" to develop and ready emerging and revolutionary solar-electricity technologies toward the long-term success of India's Jawaharlal Nehru National Solar Energy Mission and the U.S. DOE SunShot Initiative. SERIUS carries out fundamental and applied research, analysis and assessment, outreach, and workforce development through specific bi-national projects in three research thrusts: (1) Sustainable Photovoltaics (PV) to develop next-generation materials, devices, and advanced manufacturing processes tailored to the needs, environment, and resource availability of India and the US; (2) Multiscale Concentrated Solar Power (CSP) to overcome critical science and engineering challenges for reliable multiscale (including small 25–500 kW) CSP systems; and (3) Solar Energy Integration (SEI) to identify and assess key technical, economic, environmental, and policy barriers, enabling a research agenda for technical readiness in India and of benefit to the U.S. SERIUS has created a bi-national network for fostering new ideas and collaborations to expedite a sustainable industry. SERIUS is developing disruptive technologies through foundational research in PV and CSP to address the critical barriers for solar energy development in India that intersect the grand challenges for solar

energy in the U.S. SERIUS is jointly funded under the Joint Clean Energy Research and Development Center (JCERDC) through the U.S. DOE and the Government of India over a 5-year period (starting October 1, 2012). The Consortium is also supported by cost share from its members. The Consortium comprises 32 partners from India and the U.S.; further information on these organizations and specific SERIUS activities is available on its website: www.SERIUS.org.

FY 2014 HIGHLIGHTS

Photovoltaic Thrust: • Development of new polymers for dye-sensitized solar cells (DSSC) and organic photovoltaics (OPV) based on starting molecule computational analysis, and initial device development and subsequent testing across the team. • Initial CZTS electrodeposition showed correct phase formation without hydrazine on Willow Glass; nanoparticle-based CIGS resulted in meaningful efficiencies. • The electroluminescence technique was developed as a tool to evaluate heterojunction with intrinsic thin layer (HIT) solar cells. Tests on initial 1-cm² and subsequent 25-cm² samples were accomplished. Initial results demonstrate that this can be an important basic diagnostic for HIT and other solar cells. • Developing a comprehensive database for insolation and reliability vs. climate across India to provide a basic understanding of resource availability and failure modes in order to produce mitigation strategies for this significant Indian problem. • Developing an understanding of the dust and soiling problems in India and the development of coatings-based mitigation strategies. • New nano-hybrid encapsulation technology gives very low water vapor transmission rate (WVTR).

Multiscale Concentrated Solar Power Thrust: • Optimization and engineering models for new scalable systems using CO₂-based Brayton (high temperature) and organic-based Rankine cycles (low temperature) have produced new technology-specific designs that are now under construction. • A new turboexpander is being fabricated and will be evaluated in a new test bed for high-temperature Brayton cycle. • A tubular serpentine receiver was designed; CFD model predicts an efficiency > 74%. • New Earth-abundant high-performance reflector and absorber coatings developed. • New low-cost heliostats have been developed at very low capex and are begin tested.

Solar Energy Integration Thrust: • Analysis of policies and techno-economics of grid-connected PV in India Roadmap • Draft Roadmap for Energy Storage for India was developed. • Technology improvement opportunities for PV and CSP thrusts are being defined.

Solar Photoconversion in Molecular, Nanoscale and Semiconductor Systems - Excitons in Molecular and Nanoscale Organic Systems

Institution: National Renewable Energy Laboratory
Point of Contact: Bill Tumas
Email: bill.tumas@nrel.gov
Principal Investigator: Garry Rumbles
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$984,000 (2014)

PROGRAM SCOPE

This project focuses on novel concepts for harvesting solar energy in molecular, nanoscale and semiconductor systems, with the goal of understanding how to convert efficiently the energy of absorbed photons into electricity, chemicals or fuels. The subtask addresses fundamental studies of light absorption, carrier generation, transport and transfer, and focuses on (1) converting photogenerated excitons to charges in molecular and organic nanoscale systems; (2) studying the photophysics and

photochemistry of excitons in conjugated molecules, polymers, and single-walled carbon nanotubes; and (3) uncovering, through chemical doping and photoexcitation, the mechanisms that govern and control the generation of charges, their transport, and recombination kinetics.

FY 2014 HIGHLIGHTS

- In collaboration with Argonne National laboratory, NREL and Argonne researchers demonstrated charge injection from a semiconducting polymer (P3HT) into single-walled carbon nanotubes (SWCNTs) and observed the spin signature of electrons in SWCNTs. This was the first measurement of a true EPR spin signature of SWCNT electrons. In collaboration with Brookhaven National laboratory, researchers investigated the high-frequency mobility of positive charges (holes) moving along the backbones of an extensive series of fluorene-based oligomers and polymers in benzene using pulse-radiolysis, time-resolved microwave conductivity (PR-TRMC). A one-dimensional diffusion model was used to describe the data that took into account the curvature of the polymer backbone, the length distributions of the polymers, and the possibility of defects along the chain.
- NREL researchers utilized a distinct spectroscopic signature of charges within single-walled carbon nanotubes (SWCNTs), the absorbance of a trion quasiparticle, to measure both the ultrafast photoinduced electron transfer time (τ_{pet}) and yield (ϕ_{pet}) in photoexcited SWCNT-C₆₀ bilayer films. This was the first use of the trion spectroscopic signature to measure ultrafast photoinduced electron transfer in any system, and the first measurement of τ_{pet} at the SWCNT-C₆₀ interface.
- NREL researchers used ultrafast transient absorption (TA) spectroscopy to explore the origin of the high singlet fission (SF) yield in crystalline thin films of 1,3-diphenylisobenzofuran. Spectral fitting of absorption lineshapes indicates that thin films of this model SF compound are composed of two polymorphs, the least stable of which displays very high SF yields. The thermodynamically stable form has very low SF yields, attributed to fast excimer or trap formation that competes with SF. The less stable polymorph undergoes SF with a 10-30 ps time constant and much slower trapping.

Solar Photoconversion in Molecular, Nanoscale and Semiconductor Systems - Interfacial Photochemistry and Catalysis

Institution: National Renewable Energy Laboratory
Point of Contact: Bill Tumas
Email: bill.tumas@nrel.gov
Principal Investigator: Garry Rumbles
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$1,217,000 (2014)

PROGRAM SCOPE

This thrust combines an integrated approach to understanding and controlling the many, coupled processes involved in converting sunlight into fuel. Efforts focus on understanding interfacial photochemistry and photophysics relevant to both small molecule activation (in particular to solar water splitting) and photoinduced electrical energy generation. Model sub-systems are chosen for their ability to provide insight into the most important aspects of photoconversion. In some cases they may be candidates for complete fuel-forming systems, in other cases, they are designed specifically to answer fundamental questions. Specific areas in the FY14 scope included: (1) General methods for producing and measuring the electronic properties of strained catalytic species in nonequilibrium geometries; (2) Studies of the interfacial photochemistry of thin film III-V semiconductor surfaces to understand the

fundamental processes controlling the mechanisms of surface recombination, photocorrosion and fuel production; (3) Exploring the effects of surface defects, interfacial layers, catalysts, etc. on the interfacial photochemistry that controls charge transport and interfacial charge transfer in nanostructured semiconductors such as Si and metal oxides; (4) Addressing fundamental charge generation, separation, and transport events in lead-halide and related perovskite semiconductors.

FY 2014 HIGHLIGHTS

- The first quantitative measurements of the effect of Mo doping on the electron transport rate in nanoporous Mo:BiVO₄ films were performed. It was determined that these films had an electron diffusion length of 300 nm and a charge separation efficiency of 90% and an 80% absorbed photon-to-current efficiency (at 1.23 V vs. RHE).
- NREL researchers described work exploring the hypothesis that each material possesses a continuum of electrochemical and electrocatalytic properties that can be reversibly tuned by mechanical stress over its elastic range. Stretching Ni oxy-hydroxide-coated stainless steel springs was found to provide only a small elastic strain (~0.1% lattice deformation) but, confirming the hypothesis, had significant and reversible increases in the rates of HER electrocatalysis.
- A novel secondary Pt-assisted etch process was found to bury Pt nanoparticle catalysts deep within the nanoporous surface of “black Si” electrodes. This second etch shifted the onset voltage positively, from +0.25 V to +0.4 V vs. RHE, and reduced the charge-transfer resistance with no performance decrease seen for at least two months. Electrochemical impedance studies revealed that the second etch leads to a considerably smaller interfacial charge-transfer resistance than samples without the additional etch, suggesting that burying the Pt NPs improves the interfacial contact to black Si surface.
- Dye sensitized solar cells were fabricated with the singlet fission molecule 1,3-diphenylisobenzofuran as the sensitizer. The short-circuit photocurrent was shown to vary non-monotonically as a function of the thickness of an intervening zirconia layer. The reduced injection rate from the photoexcited singlet state of DPIBF enabled the relatively slow SF process to occur prior to electron injection. Subsequently, the two triplets born from SF could inject into the TiO₂ support and enhance the photocurrent yield.

Solar Photoconversion in Molecular, Nanoscale and Semiconductor Systems - Quantum Confined Nanocrystals and Nanostructures

Institution: National Renewable Energy Laboratory
Point of Contact: Bill Tumas
Email: bill.tumas@nrel.gov
Principal Investigator: Garry Rumbles
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$1,178,000 (2014)

PROGRAM SCOPE

This project focuses on novel concepts for harvesting solar energy in molecular, nanoscale and semiconductor systems, with the goal of understanding how to convert efficiently the energy of absorbed photons into electricity, chemicals, or fuels. The subtask addresses fundamental studies of light absorption, carrier generation, transport and transfer, and focuses on developing and learning how to incorporate quantized nanostructures into high-efficiency solar harvesting systems elucidating the

factors that control energy flow via excitons and carriers through modifying surface chemistry, inter-nanoparticle coupling, composition, and plasmonic interactions.

FY 2014 HIGHLIGHTS

- NREL researchers used QDs as reactants to produce fused PbSe QD dimers by oriented attachment with up to 50% reaction yield. The spectroscopy of the dimers revealed a size-dependent splitting of the 1st exciton band, and a mechanism of the splitting was proposed. Polarization anisotropy and transient grating measurements indicate that the lowest exciton wavefunction in dimers that is neither fully localized nor delocalized. We also have demonstrated the fusing of two different size QDs into a heterostructure, as well as two different materials (i.e., PbSe/CdSe) via the cation-exchange method. These heterostructures serve as models for QD arrays and may facilitate fast charge separation and reduced Auger recombination.
- A study of Si nanocrystals (NCs) revealed that Si trihydride surface groups are the most kinetically reactive species under both thermal- and radical-initiated hydrosilylation conditions. Importantly, PLQY values were found to be comparable for both the radical-mediated and thermal-initiated routes, demonstrating that the surface is equally well passivated by both techniques. Raman spectroscopy of the Si NCs revealed an asymmetric broadening of the Raman peaks, shown to be a unique signature of resonance between LO phonons and carriers undergoing intraband transitions. The results reveal differences in the density of states between bulk, 1D, and 0D Si that may control carrier relaxation channels. Finally, it was discovered that the absorption cross-section of Si NCs when plotted on a per-Si atom basis is up to 5 times greater than that found for bulk Si. Calculations showed that interface-induced scattering enhances quasi-direct, zero-phonon optical transitions and cause the increase in oscillator strength.
- NREL and CU-Boulder researchers have developed a method to probe spatially varying chemical composition of soft matter systems by use of optically controlled and elastically self-assembled plasmonic nanoantennae.

Hierarchical Photosynthetic Systems

Funding: \$1,824,000 (2014)

PROGRAM SCOPE

This program investigates fundamental mechanisms for solar energy conversion in natural and artificial photosynthesis. The comparison between natural and artificial photosynthesis is used to resolve fundamental cross-cutting mechanisms for solar energy conversion, and to develop strategies for the design of sustainable photosynthetic systems for solar energy conversion. The program investigates mechanisms for coupling transient excited-states produced by photon absorption in light-absorbing molecules to multiple-electron, proton-coupled fuels catalysis in bio-inspired synthetic assemblies and in

chemically-inspired biohybrid assembly. Modular, bio-inspired light-harvesting-linked-catalyst artificial photosynthetic architectures are developed to investigate design principles found in Nature, while chemically-inspired photosynthetic bio-hybrids are developed as an approach for achieving improved solar photons-to-fuels efficiency in photosynthesis by augmenting photosynthetic architectures with abiotic cofactors that introduce novel photocatalytic function. The two opportunities are linked by shared cross-cutting mechanisms for solar energy conversion. A distinguishing feature of this program is the development and combined use of time-resolved synchrotron x-ray spectroscopy and scattering techniques, ultrafast transient optical techniques, and time-resolved, multi-frequency electron paramagnetic resonance (EPR) analyses for determining ground and excited state structures and function of biomimetic hybrid architectures for solar chemical energy conversion.

FY 2014 HIGHLIGHTS

The development of pump-probe X-ray transient absorption spectroscopy capabilities at beamline 11-IDB of the Advanced Photon Source with sensitivities that allow excited-state solar energy conversion processes to be resolved across a wide range of biological and artificial photosynthetic systems. These included resolution of electronic and geometry changes in excited states formed in both copper diimine complexes photosensitizers in artificial photosynthesis (*Dalton Trans.* 2014 2014,43: 17615) and protein environments using the photo-deligation reactions in myoglobin (*Chem. Sci.*, 2014,5, 4136). These results are significant by establishing advanced techniques for achieving high-resolution transient X-ray absorption fine structure (XAFS) and near-edge (XANES) spectroscopy on photo-active protein and photosynthetic samples with 80 ps time-resolution. New ligand chemistries were developed for assembly of mixed-metal, supramolecular architectures comprised of a light-harvesting ruthenium polypyridyl module linked to a hydrogen-evolving cobalt catalyst. These supramolecular assemblies demonstrated complete metal-to-metal charge transfer in the earliest excited state, duplicating the ultrafast long-range separation found in the earliest excited states in photosynthesis, but implemented in a supramolecular design that directly couples light-absorption with the first reduction step needed for hydrogen-evolving solar catalysis (*PCCP* 2013, 15: 21070). Further, a new mechanism for self-assembly of a photosynthetic-catalyst biohybrid was developed, one that utilized protein-directed delivery of a molecular hydrogen-evolving catalyst to the reducing side of photosystem I for light-driven catalysis, and created a photosynthetic hybrid that generated hydrogen in aqueous media near neutral pH at rates greater than two orders of magnitude faster than comparable artificial systems (*JACS* 2013, 135:13246).

Sr. Investigator(s): Juan de Pablo; Chicago, University of
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2017)

PROGRAM SCOPE

Biology uses elastic stresses, defects, chirality and hierarchical design strategies to assemble or create a wide range of functional materials, perhaps best exemplified by the complex functions carried out by meso-structured liquid crystalline cell membranes. This hierarchical organization serves as an amplifier that allows highly localized, nanoscale molecular events to propagate into the meso-scale, resulting in dynamic functional properties of biological systems that have not yet been fully realized in synthetic material designs. We are pursuing a program of research in which we seek to recreate such principles using synthetic liquid crystals (LC) as a versatile platform. We are elucidating new hierarchical design strategies that heavily leverage chirality and topological defects to realize equilibrium and non-equilibrium, dynamic meso-scale phenomena in the context of nano- and micrometer-sized LC droplets containing nanoparticles. Specifically, we are unmasking how equilibrium and dynamical phenomena emerge from hierarchical organizations in responsive, chiral liquid crystalline assemblies. Overall, this research will advance new hierarchical designs of meso-scale materials in which biomimetic principles, including the propagation of events or information over multiple temporal and spatial scales, are enacted in a facile manner. The proposed program of research does not seek to design materials for a particular application, but rather elucidate broad design principles that will be employed in future studies targeted at solving energy-related issues.

FY 2014 HIGHLIGHTS

During fiscal year 2014, we have prepared aqueous dispersions of nano- and micrometer-sized droplets of liquid crystals (LCs), and used them as a platform for the development of bioinspired principles leading to hierarchical meso-scale soft materials. Topological defects were formed within the equilibrium morphology of the LC droplets, thereby enabling systematic, fundamental studies of defects and their use in driving functional assemblies with hierarchical structures at the meso-scale. In the context of this latter goal, progress was achieved on two fronts. First, we demonstrated new hierarchical designs of soft matter by focusing on the role of chirality in LC droplets using cholesteric and blue phase droplets. A wide range of previously predicted (but not experimentally observed) morphologies were characterized in experiments, and unanticipated chiral LC droplet structures were also documented. In

addition, we elucidated the effects of adsorbates on the internal organization of chiral LC droplets. These studies, when combined, have substantially advanced our understanding of the ways in which the elasticity of LCs, topological defects and surface anchoring combine with chirality to give rise to mesoscale organizations within the confines of LC droplets. Both equilibrium and dynamical aspects were explored, with a particular focus on the principles by which molecular phenomena, including chirality, were amplified across space and time to the mesoscale. The second area of progress incorporated an additional level of hierarchical organization and complexity by introducing achiral nanoparticles into the chiral LC systems. We elucidated the interplay of LC and nano/microparticle organizations that occur in the resulting assemblies. The large parameter space and multitude of possible outcomes demanded a concerted computational and experimental program, with computational approaches identifying unanticipated meta-stable organization of nanoparticles.

Harnessing Chemo-mechanical Energy Transduction to Create Systems that Selectively Catch and Release Biomolecules

Institution: Harvard University
Point of Contact: Joanna Aizenberg
Email: jaiz@seas.harvard.edu
Principal Investigator: Joanna Aizenberg
Sr. Investigator(s): Anna Balazs; Pittsburgh, University of
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$435,000 (2014)

PROGRAM SCOPE

Living organisms exhibit a remarkable ability to selectively catch, transport, and release biomolecules. For example, motor proteins bound to microtubules can select, bind and carry specific biomolecules as cargo along the microtubule network. The goal of this program is to develop energy-efficient bioinspired materials that harness conversion of chemical and mechanical energy to perform programmable, selective catch, transport and release of specific biomolecules, with further expansion to catching bacterial and mammalian cells. To emulate the cooperative processes of biomolecular signaling and transport, we devise a new class of integrated materials that combine following synthetic and biological chemo-mechanical “smart” components: 1) stimuli-responsive hydrogels, which undergo a volume change in response to external cue, acting as “muscle” and 2) biologically-specific binding species (such as aptamers) that can reversibly change molecular configuration to bind and release targets upon changes in temperature or pH. In such a system, hydrogel can convert chemical energy into mechanical one by actuating embedded microposts, carrying binding species. When submerged in a bilayer fluid containing a biological mixture, the moving posts bind targets and subsequently transport and release them into a different collecting fluid. This platform provides efficient routes to a nondestructive, sequential ‘detection-and-separation’ of targets from complex biofluids, without the need for expensive tools or high-energy inputs. The studies will lay foundation for designing systems that translate a molecular input into a large-scale motion, enabling programmable ‘catch-release’ of specific biomolecules and cells. The research effort involves a computer modeling component, as well, that utilizes a variety of methodologies, including dissipative particle dynamics (DPD) simulation method, to model the catch-release processes, better understand them, and optimize their energy footprint.

FY 2014 HIGHLIGHTS

We have transformed our previously developed adaptively reconfigurable dynamic material system into an efficient sorting device capable of reversible, dynamic capture and release of unmodified target biomolecules from solution. Our broad effort is aimed at exploring the sorting of different types of objects - from proteins to cells. As a first step, we have integrated a pH-responsive hydrogel with embedded microstructures modified with pH-sensitive aptamers, known to strongly bind to the protein thrombin at physiological pH, and subsequently unfold at lower pH to release it. We have measured the device's capture capacity, sorting efficiency, and demonstrated its robustness in repeated catch-release cycles. In parallel, we developed a theoretical model and performed computer simulations allowing us to gain deeper insight in the catch-release process and the effects of key parameters of the system on the separation process and its efficiency. We also demonstrated isolation of thrombin from human serum, confirming the design's performance in complex media. The work is currently under review in a leading chemistry journal. Next, we have started experiments on sorting leukemia T-lymphoblast cells using newly-designed Bioinspired Aptamer-Loaded Dynamic Systems (BALDS), which incorporate cell-binding aptamers in hydrogel rather than on top of microstructures. Preliminary results have shown the capture of the CCL-119 cells, provided first data on the sorting capacity, efficiency and selectivity, and on the cell viability. Simultaneously, we have utilized DPD simulations to model an array of flexible polymer chains attached to a support. The polymer chains display a conformational change from the hairpin to an unfolded structure with an increase in temperature, which modulates their binding ability. Our current model can reproduce this temperature-triggered effect paving the way to modeling the behavior of the polymer chains attached to the thermo-responsive gel network.

Inducing Artificial Morphogenesis in Soft Synthetic Materials

Institution: Pittsburgh, University of
Point of Contact: Anna Balazs
Email: balazs@pitt.edu
Principal Investigator: Anna Balazs
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$142,000 (2014)

PROGRAM SCOPE

In biology, morphogenesis refers to the process that causes an organism to develop its shape. In the proposed studies, we will design synthetic systems that can exhibit a form of "artificial morphogenesis", where three-dimensional microscopic objects actively control their association into macroscopic structures. In effect, we will be devising a Lego set where the individual pieces autonomously come together to form a larger assembly and can dynamically rearrange to perfect their structure. Furthermore, in one of the proposed systems, the individual pieces of our Lego set are soft, deformable objects that can morph into different shapes. Hence, the collective migration and merger of these deformable units can lead to larger-scale objects that exhibit a tremendous variety of morphologies. In effect, we will be developing new methods for engineering the growth, shape and functionality of smart, biomimetic materials. The fundamental issue we are attempting to address through these studies is: to what extent can we drive soft matter to organize or self-organize in a programmable manner? We focus on two distinct systems that offer unique attributes for addressing this question. Namely, the communicating microcapsules that can undergo autonomous motion and thus, could provide ideal candidates for self-organizing, programmable systems. Photo-responsive gels constitute another ideal

system since their shape can be readily manipulated and our preliminary studies have revealed a novel means of using light to organize and combine the individual pieces. By attempting to control the shape and growth of soft materials over a range of length scales, we will be addressing one of the stated grand challenges for DOE-related research. Furthermore, by controlling the structure of these systems, we could achieve unprecedented control over the functionality of the material.

FY 2014 HIGHLIGHTS

A remarkable feature of certain biological species is their ability to dramatically alter their shape in response to environmental cues. We developed a computational model for photo-responsive polymer gels that contain spirobenzopyran (SP) chromophores and showed that these materials can undergo three-dimensional biomimetic shape-changes in non-uniform illumination. The SP moieties are hydrophilic in the dark within acidic aqueous solutions, but become hydrophobic under illumination with blue light. Hence, by incorporating these chromophores into gels, light can be harnessed to control the gel's swelling or shrinking and thereby, dynamically alter the gel's shape. We first validated our model for the SP-functionalized gels by determining the effects of uniform illumination on the temperature-induced volume phase transitions in these materials and showed good agreement between our results and available experimental data. We then demonstrated that these gels can be patterned remotely and reversibly by illuminating the samples through photomasks, and thus, "molded" into a variety of shapes with feature sizes that are on the sub-mm length scale. The same sample can be dynamically remolded into another shape, which could enable a different function. Such processes would have a dramatic effect on manufacturing and sustainability since the same sample could be utilized for multiple applications. Furthermore, we showed that by repeatedly rastering the light source over the sample, the system can be driven to exhibit another biomimetic behavior: sustained, directed motion. The introduction of a temperature gradient provides a means of further controlling this autonomous movement (1). The results point to a robust method for controllably reconfiguring the morphology of soft materials. Beyond a single piece of the gel, our findings also provide guidelines for driving the self-organization of multiple reconfigurable pieces into complex architectures.

Integrating Modeling and Experiments to Design Robust Self-Healing Materials

Institution:	Pittsburgh, University of
Point of Contact:	Anna Balazs
Email:	balazs@pitt.edu
Principal Investigator:	Anna Balazs
Sr. Investigator(s):	Krzysztof Matyjaszewski; Carnegie Mellon University
Students:	1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$320,000 (2014)

PROGRAM SCOPE

Our goal is to create robust self-healing materials by utilizing predictive computational models and precise macromolecular synthesis. In the prior funding period, we successfully fabricated self-healing coatings based on stars and nanogels that contained disulfide links, which could undergo a rapid degenerative exchange, allowing new bonds to be formed as old bonds were broken. Hence, when the network of nanogel particles was mechanically deformed, the particles quickly rearranged and reshuffled so that the structural integrity of the coating was maintained. In effect, this dynamic behavior prevented the coating from undergoing catastrophic failure. The initially prepared materials employed soft polymers, as self-mending occurred only at temperatures above the glass transition temperature.

Also, a degenerative exchange process via radical means required a constant supply of radicals, UV irradiation and the absence of oxygen. We propose to alleviate the limitations of these first generation samples by preparing materials that can self-heal in visible light and in air. We will also address the healing of harder materials by devising a bi-component system, where a soft matrix is reinforced by harder nanodomains. Furthermore, we will introduce a biologically inspired hierarchy of bonding interactions to improve the overall mechanical properties of the hybrid systems. The creation of strong, hard materials that undergo self-repair in air at ambient conditions constitutes a transformative step. This development will pave the way for creating more energy-efficient, reliable systems and extending the lifespan for a broad range of manufactured devices.

FY 2014 HIGHLIGHTS

We collaborated to develop a hybrid computational model for the behavior of networks of cross-linked polymer-grafted nanoparticles (PGNs). The first report on this work was published in *Soft Matter* in 2013 and was featured on the back cover of the issue. We extended the model to investigate the mechanism of strain recovery and self-healing in these dual cross-linked polymer grafted nanoparticle networks. The individual nanoparticles are composed of a rigid spherical core and a corona of grafted polymers that encompass reactive end groups. With the overlap of the coronas on adjacent particles, the reactive end groups form “permanent” or labile bonds, and thus form a “dual cross-linked” network. (Here, “labile” refers to reactive bonds that can readily break and reform, while “permanent” refers to stronger, less reactive bonds that break but do not reform.) We considered the strain recovery of the material after it is allowed to relax from the application of a tensile force. Notably, the existing labile bonds can break and new bonds can form in the course of deformation. Hence, a damaged material could be “rejuvenated” both in terms of the recovery of strain and the number of bonds, if the relaxation occurs over a sufficiently long time. We showed that this rejuvenation depends on the fraction of permanent bonds, strength of labile bonds, and maximal strain. Specifically, we showed that while an increase in the labile bond energy leads to formation of a tough material, it also leads to delayed strain recovery. Further, we showed that an increase in the fraction of permanent bonds not only enables faster recovery, but also yields improved recovery even after multiple stretch-relaxation cycles. Building on this result, we determined the effect of introducing a small fraction of high-strength connections between the dual cross-linked nanoparticles.

EARLY CAREER: Rigid Biopolymer Nanocrystal Systems for Controlling Multicomponent Nanoparticle Assembly and Orientation in Thin Film Solar Cells

Institution: Colorado, University of
Point of Contact: Jennifer Cha
Email: Jennifer.Cha@Colorado.edu
Principal Investigator: Jennifer Cha
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The project seeks to direct the assembly of nanoparticles into two- and three-dimensional crystals of any desired configuration and crystallographic orientation using tunable DNA interactions. Despite the wealth of nanoscale materials that may benefit many current and future solid state technologies, difficulties in controlling and directing their placement and orientation into desired architectures has led

to significant impediments in their applicability. Biological systems can form such structures using their inherent molecular information as guides to assemble organic and inorganic materials into highly organized structures ordered at multiple length scales. Using bio-inspired strategies, the research will control the two- and three-dimensional arrangement of semiconductor nanocrystals into well-defined orientations and demonstrate that this organization can yield optimal performance over traditional approaches. The particular target applications will be photovoltaics and photocatalysis for fuel production.

FY 2014 HIGHLIGHTS

In the past year, we have succeeded in using DNA for producing close packed nanoparticle thin films by using the DNA-QDs and by promoting interparticle DNA hybridization by use of DNA “linkers”. Because we also wanted to explore the effect of DNA on charge transport through the QD films, we focused on using the p-type DNA conjugated CdTe QDs to build p-n heterojunction based solar cells that consist of ITO/ TiO₂/DNA-CdTe/Au. For the photovoltaic studies, DNA-CdTe QD films composed of different sized nanocrystals was prepared and devices were tested first as a function of QD size and later film thickness. All of the devices from the different sized CdTe QDs showed consistent and reasonable current-voltage characteristics where the V_{oc} values were set around 400mV while the short circuit currents (J_{sc}) showed an increase with the larger QDs. In addition to photovoltaics, we have recently shown that using small molecule linkers or DNA to couple two different photocatalysts could yield a significantly higher amount of H₂ produced directly from water and light as opposed to using a single catalyst alone or simply mixing the two photocatalysts in solution.

Self-Assembly and Self-Replication of Novel Materials from Particles with Specific Recognition

Institution: New York University
Point of Contact: Paul Chaikin
Email: chaikin@nyu.edu
Principal Investigator: Paul Chaikin
Sr. Investigator(s): Nadrian Seeman; New York University
David Pine; New York University
Marcus Weck; New York University
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$443,000 (2014)

PROGRAM SCOPE

The goals of our program are to understand, discover, design and control the basic interactions between nanoscopic and microscopic units so that complex self-assembly processes and architectures are enabled. We are particularly interested in specific interactions between particles which potentially allow the design of functional structures involving many different components precisely arranged. To this end we have been using DNA with its specific hybridization only between complementary sequences and particularly DNA origami structures with their breadboard like templates to make both reversible and irreversible bonds. The reversibility results from the strong temperature dependence of the hybridization so that bonds form on cooling through a designed temperature and melt on heating. One of our major accomplishments is to selectively permanently bind some of the hybridized pairs using cinnamate and CNVK incorporated instead of bases on a DNA backbone and UV light. We take as a major challenge for demonstrating complex self-assembly the development of a process whereby a designed information containing structure can be self-replicated and exponentially grow. This would

accomplish something that has previously only been observed in living systems and in a few specific synthetic molecules. It would also have a great impact on nanotechnology since large scale production of nanogenerators, machines, electronics, reactors, sensors etc. could be performed with exponential growth. Further, exponential growth can be used to have different “species” evolve by selection and competition. We have used DNA and origamis to program the design of emulsion droplets and colloids as well as nanoparticles. We can also activate processes using light to heat and melt specific hybridized bonds.

FY 2014 HIGHLIGHTS

Self-Replication and Selective Evolution of DNA Origamis: We have designed a process and a system of DNA origami tiles that exponentially replicate a seed pattern, doubling the copies in each diurnal-like cycle of temperature and UV illumination, producing more than 7 million copies in 24 cycles. We use this system to demonstrate exponential selection: two similarly-growing sub-populations, one with a “red” dye incorporated, the other with a “green” dye, can be controlled by colored light. The light heats one species reducing its replication rate. The progeny of the non-absorbing species replicate preferentially and take over the system. The species selection is enhanced by competition for a resource, critical crosslinking strands required for replication. This addressable selectivity of different constituents in the same solution should be adaptable to the selection and evolution of multi-component nanoscopic-microscopic self-replicating materials.

Reentrant depletion Interactions: The depletion interaction, an attraction between colloidal particles from the entropic pressure of smaller particles, is used extensively in self-assembly. The depletion interaction is temperature independent. A common formulation involves non-adsorbing polymers such as PEO dispersed with micron sized colloidal particles. On the other hand adsorbing polymers universally provide a sticky energetic - enthalpic attraction between particles. Nobelist P. G. de Gennes suggested that the most interesting yet unexplored regime is the crossover from non-adsorbing to adsorbing. He was right! A combination of the two attractive interactions leads to a novel regime in which assembled particles disperse. As temperature is increased there are colloidal crystals which then melt and finally re-aggregate. Our discovery provides a fundamental understanding of the polymer-colloid system and opens new possibilities for colloidal self-assembly, crystal and glass, and controlled viscoelasticity.

Hierarchical Active Matter: From Extensile Bundles to Flowing Gels, Streaming Liquid Crystals and Motile Emulsions

Institution: Brandeis University
Point of Contact: Zvonimir Dogic
Email: zdogic@brandeis.edu
Principal Investigator: Zvonimir Dogic
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$246,000 (2014)

PROGRAM SCOPE

Active matter is an assembly of microscopic objects, each of which consumes energy to generate continuous dynamics. Interactions between such objects lead to collective emergent properties that are strikingly different from those of conventional materials assembled from inanimate objects. An example of active matter is the biological cytoskeleton that is built from ATP consuming actively propelled molecular motors and other filamentous and other building blocks. Being released from the constraints

of the equilibrium the cytoskeleton exhibits remarkable properties such as motility, rapid shape changes and spontaneous internal flows. Our goal is to create biologically inspired far-from-equilibrium polymeric and liquid crystalline materials from purified biological components. We do not want to reverse-engineer any specific biological process, but rather by starting from the bottom up, to systematically explore a nearly limitless space of functionalities that arise once the materials are released from the tight constraints imposed by the laws of equilibrium statistical mechanics. For example, by incorporating molecular motors into microtubule-based liquid crystals we assemble active liquid crystals, a novel non-equilibrium material that exhibits motile defects, spontaneous flow and self-healing. We seek understanding of soft active matter at multiple levels of hierarchy. At the most fundamental level we are developing optical tweezer based technique to characterize the mechanics and dynamics of extensile bundles, which are the fundamental building blocks of microtubule based soft active matter. At the next level of hierarchy we are characterizing how active bundles assemble into bulk isotropic gels and streaming nematic liquid crystals. Finally, we are also examining how confining active matter leads to novel emergent properties such as directional currents capable to material transport.

FY 2014 HIGHLIGHTS

We highlight two important accomplishments during the past year. First, we have developed a technique to measure the depletion interaction between a pair of microtubule filaments using a method that combines single filament imaging with optical trapping. By quantifying the dependence of filament cohesion on both polymer concentration and solution ionic strength, we demonstrated that the minimal model of depletion, based on the Asakura-Oosawa theory, fails to quantitatively describe the experimental data. By measuring the cohesion strength in two- and three- filament bundles we verified pairwise additivity of the depletion interaction. The described experimental technique can be used to measure pairwise interactions between various biological or synthetic filaments, thus complementing information extracted from bulk osmotic stress experiments. In the second important accomplishment we have discover novel far-from-equilibrium dynamical phases in active liquid crystals. It has been well known that in active nematics a uniformly aligned state is inherently unstable and leads to spontaneous generation of topological defect pairs which stream through the system and later annihilate, yielding a complex, seemingly chaotic dynamical steady-state. The common assumption was that such dynamics destroy any long-range order in active nematics. We have identified emergence of order from this chaos in the form of previously unknown broken-symmetry phases in which the topological defects themselves undergo orientational ordering. So far this experimental observation is not described by any existing theoretical model. As such our quantitative experimental finding should spurn the development of more realistic theoretical models active nematics.

Electromagnetic Interactions in Self-Assembled Metallo-Dielectric Biomaterials

Institution: Indiana University
Point of Contact: Bogdan Dragnea
Email: dragnea@indiana.edu
Principal Investigator: Bogdan Dragnea
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$185,000 (2014)

PROGRAM SCOPE

The proposed work seeks to unveil and take advantage of the self-organization principles encountered in viruses and virus systems in order to design, model, and synthesize novel biomaterials with unique functionalities.

FY 2014 HIGHLIGHTS

Fluorescence emission from multi labeled nucleic acid molecules encapsulated in Brome mosaic virus capsids were examined as a function of macromolecular compactness. A kinetic model relating chain compactness to single-molecule fluorescence emission provided a qualitative description of energy transfer and its dependence on shell compactness. We have found that in a dense multichromophore system the rate of energy transfer should scale with distance more gradually than the rate of the Förster energy transfer between two chromophores. As a proof-of-principle experiment, we have compared predictions from a numerical model for confined diffusive motion with the fluorescence emission from virus-encapsulated and free single RNA molecules decorated with multiple cyanine dyes and encapsulated inside microscopic emulsion droplets. Effective quantum yield per labeled particle depended on the expansion state, in agreement with theoretical predictions.

Semiconductor Nanocrystals as Light Harvesters for Biomimetic Solar Fuel Generation

Institution: Colorado, University of
Point of Contact: Gordana Dukovic
Email: Gordana.Dukovic@Colorado.edu
Principal Investigator: Gordana Dukovic
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$221,000 (2014)

PROGRAM SCOPE

This project focuses on use of semiconductor nanocrystals as light absorbing elements of bio-inspired structures for solar fuel generation. II-VI semiconductor nanocrystals are strong absorbers (i.e., have high molar absorptivities when compared to natural light harvesting proteins), and their absorption spectra can be tuned through control of size, shape, and composition. For that reason, they can be synthetically tailored to have optimal properties for particular light-harvesting applications. In this proposal, we focus on photochemical conversion of the absorbed solar photons into chemical bonds to create fuels (i.e., artificial photosynthesis). Fuel-generating reactions are kinetically complex, involving multiple charge transfer steps, and typically require the use of catalysts. In natural photosynthesis, this function is carried out by enzymes. Our aim is understand how the light-harvesting function of nanocrystals can be integrated with catalytic functions of fuel-producing enzymes to create synergistic biohybrid structures that efficiently convert solar photons into fuels. For this 3-year period, we focus on H^+ reduction to H_2 , catalyzed by a hydrogenase enzyme. In collaboration with the Photobiohybrid group at NREL, we have developed nanocrystal-hydrogenase biohybrids that produce H_2 under solar illumination. H_2 generation is governed by charge transfer from photoexcited nanocrystals. We aim to understand the details of kinetics and dynamics of photogenerated charges as they move through the integrated system, and to synthetically tailor nanocrystals to control the efficiencies of the desired charge transfer processes and the overall photochemical efficiency. The expected outcome of this project is a set of design principles for bio-mimetic structures that integrate light harvesting and

catalysis to drive desirable chemical reactions with solar energy. The insights developed in this project are expected to have an impact on solar fuels research.

FY 2014 HIGHLIGHTS

The following was accomplished in FY 2014: (1) We utilized ultrafast transient absorption spectroscopy to measure rates and efficiencies of electron transfer from photoexcited CdS nanorods to hydrogenase (H₂ase). This work was published in the Journal of the American Chemical Society and was highlighted in JACS Spotlights. (2) We started the examination of the effects of nanocrystal surface-capping ligands on nanocrystal-H₂ase electronic coupling and electron transfer dynamics. (3) We started the modeling of electron transfer kinetics to determine intrinsic rate constants for the process. (4) We utilized type-II nanocrystal heterostructures to spatially separate photoexcited electrons and holes and measure the effects of resulting long-lived excited states on H₂ production efficiencies. (5) We synthesized surface-capping ligands that may be resistant to photooxidation from the nanocrystal surface.

Experimental Realization of 'Repair-and-Go' Using Microencapsulation of Nanomaterials

Institution: Massachusetts, University of
Point of Contact: Todd Emrick
Email: tsemrick@mail.pse.umass.edu
Principal Investigator: Todd Emrick
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$128,126 (2014)

PROGRAM SCOPE

This project supports the investigation of biologically-inspired materials science, and specifically nanoparticulate encapsulation methods geared towards promoting the manipulation of nanoparticles on substrates, as well as facile methods of materials repair. In living systems, the rolling adhesion action of leukocytes enables a probing of tissue of various types, with associated sensing of cues (chemical/biological signals) of healthy versus damaged regions. This project develops artificial leukocytes, focusing especially on emulsion droplets that encapsulate nanoparticles, probe damaged substrates, and respond to those damaged regions by depositing nanoparticles into them. Crucial to the success of the project are polymer designs that specifically recognize damaged regions of substrates and are benign to pristine regions. Such specific recognition of damaged vs pristine areas of structures is adapted to this project using purely synthetic systems and replacing biological signals with materials surface energies.

FY 2014 HIGHLIGHTS

Numerous accomplishments were realized in fiscal year 2014, including: (1) The original concept of 'repair-and-go' using polymer capsules as artificial leukocytes was expanded to include different compositions and sizes of encapsulated nanoparticles. This was a critically important development for realizing mechanical repair of damaged substrates, relying on tailoring interfacial properties and wettability of the nanoparticle, polymer, and surface components. Dynamic mechanical analysis serves as a useful reporter of the modulus and stiffness of materials before and after capsule-based repair processes. (2) The project exploited new theoretically-based literature suggesting that liposomes can act

as 'artificial osteoclasts' by probing substrates for debris, and successfully picking up and carrying the debris off of the substrate and into the exterior media. This project showed that properly functionalized polymer droplets, termed 'osteodroplets', perform just this function - in some cases picking up nanoparticles and inserting them onto the capsule interfacial layer, and in other cases engulfing the nanoparticles into the interior solution phase. These findings are particularly new and exciting since the concept is envisaged to have broad applicability in the context of macromolecular materials science and engineering, and new approaches to self-cleaning and self-healing systems.

EARLY CAREER: Directed Assembly of Hybrid Nanostructures Using Optically Resonant Nanotweezers

Institution: Cornell University
Point of Contact: David Erickson
Email: de54@cornell.edu
Principal Investigator: David Erickson
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Recently, we have demonstrated how the electromagnetic fields in nanophotonic devices are sufficiently strong that they can be used to physically manipulate biological (nucleic acids & proteins) and non-biological (nanoparticles) materials as small as a few nanometers in size. As is discussed in the proposal, this represents as much as a 100 fold improvement over the state of the art and, I believe, could open up brand new area of materials science in which complex hybrid nanostructures with arbitrary properties and composition can be created at will. In the context of this research I propose a fundamental analytical and experimental study aimed at elucidating the underlying physics behind our new assembly process. Specifically we propose to first develop a series of experimentally validated trapping stability and kinetic models aimed at: determining the conditions under which stable nanoparticle manipulation can be realized and understanding the dynamics of particle release. We will then extend these initial efforts to more complex material systems including gold nanoparticles, quantum dots and carbon nanotubes. Finally we will examine multi-particle effects and demonstrate the assembly of at least one novel nanostructure which cannot be assembled via any other existing technique.

FY 2014 HIGHLIGHTS

In 2014 this DOE funding contributed to the development of an entirely new method of measuring nanomaterial interaction forces using the nanotweezer technology. Briefly, direct measurements of particle-surface interactions are important for characterizing the stability and behavior of colloidal and nanoparticle suspensions. Current techniques are limited in their ability to measure piconewton scale interaction forces on sub-micrometer particles due to signal detection limits and thermal noise. Here we present a new technique for making measurements in this regime which we refer to as Nanophotonic Force Microscopy. Using the DOE funded nanotweezer technology, we generate a strongly localized region of exponentially decaying, near-field, light that allows us to confine small particles close to a surface. From the statistical distribution of the light intensity scattered by the particle we are able to map out the potential well of the trap and directly quantify the repulsive force between the nanoparticle and the surface. We have shown that our technique is not limited by thermal noise and

therefore we are able to resolve interaction forces smaller than 1 pN on particles as small as 100 nm in diameter.

Controlling Structure Formation Pathways in Functional Bio-Hybrid Nanomaterials

Institution: Cornell University
Point of Contact: Lara Estroff
Email: lae37@cornell.edu
Principal Investigator: Lara Estroff
Sr. Investigator(s): Uli Wiesner; Cornell University
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014)

PROGRAM SCOPE

This project aims to understand the structure formation pathways in organic-inorganic hybrid materials in which information transfer from the organic into the inorganic phase is critical to directing the assembly of the composites. Self-assembly of silica nanomaterials directed by small molar mass surfactants is the simplest system of study, both in terms of the organic, as well as the amorphous, inorganic phase. The second system uses synthetic block copolymers to direct the assembly of amorphous calcium phosphate hybrids. The structural complexity of the organic structure-directing agents, as well as the inorganic phase is enhanced over the first system, resulting in an increase in the complexity of the expected chemical pathways. Finally, we are using synthetic/peptide block copolymers to direct the formation of crystalline calcium phosphate bio-hybrids. In this system, we are looking at the effect of peptide sequence, i.e. a significantly increased information transfer from the organic phase, on the crystallization of the calcium phosphate phase. In all three cases, controlling interactions at the interfaces of organic and inorganic materials and elucidating assembly pathways is a central focus. Efforts include synthesis of all organic/inorganic precursors and their composites, as well as in-depth characterization of local, global, and where possible interface structure, of assembly intermediates and final products to elucidate governing principles for structure/shape control in the materials synthesis. When successful, results will provide general guidelines and methodologies for the controlled synthesis of hybrid nanomaterials with increasing complexity offering enormous scientific and technological promise, in areas ranging from energy conversion and storage to drug delivery and bone repair.

FY 2014 HIGHLIGHTS

(1) In our studies of silica nanomaterials, we have developed an inorganic material that changes shape upon exposure to water vapor. After the wetting treatment, the cross-sectional shape of aminated mesoporous silica nanoparticles with hexagonal pore lattice changed from hexagonal to six-angle-star, accompanied by the loss of periodic mesostructural order. NMR spectroscopy of samples after wetting treatment displayed a higher degree of silica condensation, indicating that the shape change was associated with the formation of more siloxane bonds within the silica matrix. A model based on the hexagonal pore lattice and assuming shrinkage due to capillary pressure of water in micropores within the silica walls can account for the observation of preferential shrinkage along the (11) direction relative to the (10) direction of the hexagonal lattice. This work may open a path towards novel stimuli-responsive materials based on inorganic components. (2) We have begun to study pathway complexity in the formation of methylammonium lead iodide perovskites (MAPbI_3), an emerging organic-inorganic hybrid material for photovoltaic devices. We have focused on quantitative analysis of the kinetics of MAPbI_3 crystallization and the role of the lead anion in modulating the formation pathway. To this end,

we have studied, by means of *in situ* synchrotron x-ray scattering, the transformation of a crystalline precursor to MAPbI₃ as a function of the lead salt reagent used in the synthesis. By using well-established kinetics models we extracted activation energies for 4 systems based on different lead salts. Furthermore, detailed analysis of the scattering data as well as kinetic parameters allowed elucidation of precursor compositions. The results provide insights into fundamental parameters that govern perovskite growth and grain coarsening. Part of this work has been accepted for publication in Nature Communications, with an additional two manuscripts under review.

Materials Lessons of Biology: Structure Function Studies of Protein Sequences Involved in Inorganic Organic Composite Material Formation

Institution: New York University
Point of Contact: John Evans
Email: jse1@nyu.edu
Principal Investigator: John Evans
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$270,000 (2014)

PROGRAM SCOPE

This DOE project focuses on families of proteins that inhabit the nacre layer of the mollusk shell, a high-performance composite structure that exhibits fracture-toughening and a mineral assembly process that spans several length scales. These proteins create and guide mineral nanoparticles into organized assemblies and introduce micro, meso, and macroporosities to mineral crystals

FY 2014 HIGHLIGHTS

We have identified five mollusk proteins (PFMG1, AP7, AP24, Pif97, n16) that form protein phases that control the nucleation and organization of mineral nanoparticles, leading to the formation of mesoscale mineral assemblies in solution. Further, each of these proteins becomes incorporated into the growing crystal and introduces porosities or voids within the crystal.

Programmable Dynamic Self-Assembly of DNA Nanostructures

Institution: California-Riverside, University of
Point of Contact: Elisa Franco
Email: efranco@engr.ucr.edu
Principal Investigator: Elisa Franco
Sr. Investigator(s): Rebecca Schulman; Johns Hopkins University
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$137,000 (2014)

PROGRAM SCOPE

Biological cells achieve dynamic spatial organization by directing the non-equilibrium self-assembly of molecular materials using the outputs of dynamic molecular circuits. These circuits are comprised of receptors (sensors), signaling cascades and gene networks that compute responses to external inputs. Dynamic changes in the outputs of these networks result in changes in the structure of self-assembled materials. The cytoskeleton is an example of molecular dynamic material presenting this organization.

We aim to build materials inspired by this architecture in which rationally designed nucleic acid (NA) structures are controlled by designed NA circuits with dynamic outputs. NAs are highly programmable polymers; a large number of NA structures and circuits have been previously designed. However, the integration of circuits and structures in a complex material is relatively unexplored. We focus on DNA nanotubes, tubular structures that assemble from tiles (monomers), which can be regarded as artificial microtubules, with the goal of controlling how these tubules assemble, disassemble and organize into higher order structures. We aim to 1) Demonstrate that self-assembly of DNA nanotubes can be controlled by the presence in solution of NA species which induce assembly or disassembly pathways; 2) Program assembly and disassembly of nanotubes using NA circuits, including autonomous circuits such as oscillators; 3) Build integrated sensing, processing, and actuation systems for adaptive NA materials. We are designing materials with the ability to reorganize in response to multiple stimuli, to logically integrate multiple stimuli to produce a single, potentially multistep response. Our research will result in modular, scalable NA-based materials presenting programmable geometries at the nanoscale, which can adapt in complex ways to an expandable array of environmental signals.

FY 2014 HIGHLIGHTS

We designed and characterized nanotubes assembling from DAE-E DNA double crossover tiles. We modified tiles to include binding domains for unique DNA or RNA input species. We designed pathways for isothermal assembly (growth) and disassembly (decay) driven by DNA inputs. We optimized tile design (sequence and length of binding domains) to control these reactions in a range of temperatures between 25 and 37° C. Growth and decay can be induced in several cycles, obtaining nanotubes with length distribution whose mean shifts between 6-8 μm and virtually zero. We have also demonstrated assembly and disassembly pathways triggered by the RNA output of synthetic genes. In the next months, we will direct these growth and decay reactions using an *in vitro* synthetic transcriptional oscillator. To design more complex reconfiguration, we have focused on the organization of nanotubes into higher order structures using DNA seeds and capping devices. We developed methods to control where nanotubes grow and in what patterns. By assembling hierarchical seeds we can build flexible nanotube structures (using floppy linkers, publication in preparation) or rigid superstructures with specific geometries (work in progress). The functionality of these seeds can be altered by NA circuit outputs, making it possible to control material structure using signal processing circuits. To redesign the shape of these complex structures in response to a variety of combinations and intensities of environmental stimuli, we have devised new NA signal processing circuits. We are developing general methods to quantitatively control NA circuits using a large variety of non-nucleic acid inputs, including small molecules and proteins. We have also been developing new kinds of NA circuits that dynamically change their outputs in response to changing inputs. A final thrust of our efforts will be to design and construct NA circuits that enable multistage responses.

Long Range van der Waals-London Dispersion Interactions for Biomolecular and Inorganic Nanoscale Assembly

Institution: Case Western Reserve University
Point of Contact: Roger French
Email: rxf131@case.edu
Principal Investigator: Roger French
Sr. Investigator(s): Rudolf Podgornik; Massachusetts, University of
Adrian Parsegian; Massachusetts, University of
Steinmetz Nicole F.; Case Western Reserve University
Wai-Yim Ching; Missouri-Kansas City, University of

Students: 1 Postdoctoral Fellow(s), 7 Graduate(s), 4 Undergraduate(s)
Funding: \$181,396 (2014)

PROGRAM SCOPE

Our new and expanded overarching objective is to understand and control all fundamental aspects of long-range interactions in heterogeneous materials on the level of nano- and mesoscale materials, providing a platform for novel materials design, assembly and function. Apart from van der Waals interaction, macromolecular assembly design depends also on the detailed knowledge of direct electrostatic (mono- and multi-polar) and solvent-mediated interactions, that did not feature in our previous proposal. In addition to continuing to advance the van der Waals interaction phenomenology, we now identify three additional methodological and conceptual frameworks. These include electrostatic interactions acting between net-charged molecules, as well as between molecules with a multipolar charge distribution and detailed molecular description of solution environment including solvent mediated interactions. This augmented framework of our proposed research will allow us to cover the mesoscales that are implicit in the long-range interactions driven mesoscale design, spanning both the regime of molecular details and then all the way to macroscopic response functions and theories. Our augmented collaborative and interdisciplinary team, involving experimentalists and theorists from Case Western Reserve University, University of Massachusetts- Amherst, and University of Missouri-Kansas City, is singularly qualified for this extension of the framework of our proposal into the field of macromolecular electrostatic, solvent-mediated structural and van der Waals interactions, their fundamental underpinnings as well as applications. We are in fact pushing forward to set up an 'overarching DOE program', dedicated in its entirety to the fundamental aspects of long-range interactions, not shunning the various materials applications on which it will be firmly based.

FY 2014 HIGHLIGHTS

We continued to investigate van der Waals interactions and began implementing theoretical and experimental method to study the charge regulation under various solution conditions and its effect on the non-isotropic charge distributions, as well as to incorporate the structural solvent-mediated interactions into our theatre of biomolecular and inorganic mesoscale assembly and function. We investigated the effect of changes in the dielectric response of a material, amorphous SiO₂, on the Hamaker coefficient of van der Waals interactions. We formulated the theory of van der Waals-London dispersion interaction between different SWCNTs. We calculated the *ab initio* optical properties of amorphous SiO₂, berlinite aluminum phosphate and 7-2 heterostructure model of type I Collagen. Based on the *ab initio* method, detailed studies of the electronic structure and partial charge of RGD (1FUV) peptide and B-DNA oligonucleotides with various composition and stacking sequence under different solution conditions were carried out. Experimentally-determined UV optical properties of berlinite aluminum phosphate and DNA oligonucleotides show strong correspondence with the theoretical results. Our open-source Gecko-Hamaker software project calculates Hamaker coefficients, interaction free energies, forces and torques using the full Lifshitz theory. It was improved by incorporating the specific advances in theory and computation of long-range interactions. The software has more than 1000 downloads during this research program. In addition to the various theoretical approaches, we initiated experimental techniques to measure and manipulate long-range interactions directly. We set up the modified SAXS-osmotic stress experiments and applied it for DNA/DNA long-range interactions and used the static light scattering-second virial coefficient method to investigate interactions of Bovine Serum Albumin proteins at various solution conditions.

A Hybrid Biological/Organic Half-Cell for Generating Dihydrogen

Institution: Pennsylvania State University
Point of Contact: John Golbeck
Email: jhg5@psu.edu
Principal Investigator: John Golbeck
Sr. Investigator(s): Donald Bryant; Pennsylvania State University
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Although a number of solar biohydrogen systems have been developed over the last decade, few attain the electron transfer throughput of oxygenic photosynthesis. Any strategy designed to connect the naturally occurring photosynthetic reaction centers with a non-physiological catalyst is limited by the accessibility of its redox chain, which is largely buried within the membrane-spanning region. Two sites in Photosystem I (PSI) show promise for straightforward manipulation: the membrane-extrinsic PsaC subunit, which harbors the terminal redox cofactors, FA and FB, and the phylloquinones in the binding pockets, A1A and A1B. Extraction of the electron from FB would provide an electron with a favorable redox potential for H₂ production ($E^{\circ} = -580$ mV), while a larger driving force for catalysis would be imparted by extraction from A1A and A1B (E° is -800 mV for A1B and E° is -620 mV for A1A). Our DOE-sponsored work has focused on the development of a hybrid biological/organic photo-electrochemical half-cell, which directly connects the FB cluster of PSI to the distal [4Fe-4S] cluster of an [FeFe]-H₂ase with the use of a molecular wire. This allows electrons to be delivered from the acceptor side of PSI to the catalyst rapidly without the involvement of diffusion chemistry. Our results show that when Cyt c₆ is cross-linked to PSI, the PSI-wire-[FeFe]-H₂ase construct evolves H₂ at a rate of 2885 $\mu\text{moles mg Chl}^{-1} \text{h}^{-1}$, which is equivalent to a throughput of 142 $e^- \text{PS I}^{-1} \text{s}^{-1}$. Placing this in perspective, evolve O₂ at a rate of $\sim 400 \mu\text{moles mg Chl}^{-1} \text{h}^{-1}$, which is equivalent to 47 $e^- \text{RCPSI}^{-1} \text{s}^{-1}$, given a PSI to PSII ratio of 1.8. The three-fold greater electron throughput by this hybrid biological/organic nanoconstruct over *in vivo* oxygenic photosynthesis validates the concept of tethering proteins through their redox cofactors to overcome diffusion-based rate limitations on electron transfer.

FY 2014 HIGHLIGHTS

Illumination of the PSI-wire-H₂ase nanoconstruct with visible light between 400 nm and 700 nm resulted in an average quantum yield of 0.10 to 0.15 molecules of H₂ per photon absorbed. The theoretical quantum yield for H₂ generation in the PSI-wire-H₂ase nanoconstruct is 0.50 molecules of H₂ per photon absorbed. The difference is likely the occurrence of non-productive PSIC13G-1,8-octanedithiol-PSIC13G (PSI-PSI) dimers, which would absorb light without generating H₂. Assuming the thiol-Fe coupling is equally efficient at producing PSI-PSI dimers, the theoretical quantum yield would decrease to 0.167 molecules of H₂ per photon absorbed. This value is close to the range of measured values in the current study. We also showed that the electron can be extracted from an acceptor earlier than the FB cluster. A naphthoquinone-containing molecular wire (1-[15-(3-methyl-1,4-naphthoquinone-2-yl)]pentadecyl disulfide) was synthesized and added to the menB variant, where it occupies both the A1A and A1B sites. When a Pt nanoparticle is attached to the free thiol, H₂ is produced at a rate of 67.3 $\mu\text{mol H}_2 \cdot \text{mg Chl}^{-1} \cdot \text{h}^{-1}$. As expected, no H₂ is produced using wild-type PS I, which does not incorporate the quinone, or in the absence of (NQ(CH₂)₁₅S)₂ or the Pt nanoparticle. Surprisingly, the lifetimes of the forward and reverse electron transfer to and from the FA/FB iron sulfur clusters were the same as in native PS I. This means that that the electrons are not transferred from the quinone in the A1A and A1B

sites directly to the Pt nanoparticle. Instead, the rate of H₂ production depends strongly on the concentration of the sacrificial electron donor cytochrome c6. This eliminates the recombination channel between [FA/FB]⁻ to P700⁺ and allows the electrons to be stored in FA and FB. Over time, the electrons bleed up the electron transfer chain from FA/FB to A1A and A1B through molecular wire to the Pt catalyst, where they generate H₂.

Optical and Electro-Optic Modulation of Biomimetically-Functionalized Nanocarbon Materials

Institution: Wisconsin-Madison, University of
Point of Contact: Padma Gopalan
Email: pgopalan@wisc.edu
Principal Investigator: Padma Gopalan
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$285,000 (2014)

PROGRAM SCOPE

Light-driven molecular transformations have been long explored for various applications from photorefractives, electro-optics, and energy storage to photodetectors. Natural photo-transduction processes such as vision rely on the cis to trans isomerization of a small molecule “retinal”, which induces conformational changes in the surrounding protein and triggers a cascade of biochemical events culminating in transmission of an electrical impulse through the optic nerve to the brain. Many of these light absorbing molecules found in natural systems are not stable outside their biological environment as they photo-bleach quite easily. However, there are a number of synthetic analogues that can potentially mimic the natural photoconduction process. Among many classes of light switchable molecules, azobenzene molecule, which can reversibly isomerize between trans and cis form by illumination with UV light (trans to cis) and visible light (cis to trans), has been of great interests as the dipole moment can be tuned with chemistry, and are remarkably photochemically stable. In the synthetic world coupling these molecules to known semiconductors can result in an ultrasmall light-driven switching device in solid state which mimics natural phototransduction processes. Our research led to the very first demonstration of an optically active nanotube hybrid material by noncovalent functionalization of SWNT field-effect transistors with an azo-based chromophore. Upon UV illumination, the chromophore underwent a trans-cis isomerization leading to charge redistribution near the nanotube. The resulting change in the local electrostatic environment led to a shift in the threshold voltage and increased the conductivity of the nanotube. Our research is focused on understanding the chromophore/ nanotube interactions and gaining mechanistic insight into the effect photo-switching in the molecule on the nanocarbon electronic properties.

FY 2014 HIGHLIGHTS

Summary of accomplishments: (1) Measured Orientation of a Monolayer of Dipolar Molecules on Graphene from X-ray Absorption Spectroscopy: While second harmonic generation can give the macroscopic polarization of the molecules on the substrate, XAS can provide complementary information by directly probing the orientation of specific molecular orbitals. The element- and bond-specific nature of XAS allows us to look specifically at the most relevant part of the chromophores for determining their orientation. (2) Developed a Mechanistic Understanding for Raman Enhancement of Dipolar Molecules on Graphene: A detailed comparison of wavelength dependent Raman signals and spatial mapping of Raman signal from the chromophore on graphene and on bare SiO₂/Si substrates was

undertaken to elucidate the underlying mechanism for a large enhancement in the Raman signal from the molecule on graphene. TD-DFT studies showed that the electronic structure of DR1P/SLG is significantly modified, resulting in a lower band gap. These suggest that the strong Raman signal is due to the strong interaction of large molecular dipole with graphene. (3) Tested the Dipole Hypothesis by Reversal of Internal Dipole: The ability to shift threshold voltages to either more negative or more positive directions would provide significant design flexibility, offering the potential to engineer electro-optic detectors with zero current flow (and thus reduced power consumption) in both the “off” and the “on” states, in analogy with CMOS electronics. *Ab initio* calculations were used to obtain the structure and dipole moments of these molecules. Publications: “Functionalization of Single-Wall Carbon Nanotubes with Chromophores of Opposite Internal Dipole Orientation.” ACS Appl. Mater. Interfaces 2013, 5, 9355; “Raman Enhancement of a Dipolar Molecule on Graphene.” J. Phys. Chem. C 2014, 118(4), 2077; “Orientation of a Monolayer of Dipolar Molecules on Graphene from X-ray Absorption Spectroscopy.” Langmuir 2014, 30(9).

Phospholipid Vesicles in Materials Science

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Steve Granick
Email: sgranick@uiuc.edu
Principal Investigator: Steve Granick
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$235,000 (2014)

PROGRAM SCOPE

This proposal has the objective to develop the science basis needed to deploy phospholipid bilayers as functional materials in energy contexts, specifically to: (1) Develop an integrated molecular-level understanding of what determines their dynamical shape, phase behavior and spatial organization, mainly using a combination of fluorescence microscopy and direct optical measurements of long-range fluctuations that characterize membrane bending stiffness and tension when nanoparticles and other adsorbates to bind; and (2) Develop understanding of their diffusion in crowded environments, which our preliminary measurements suggest to be fundamentally more rapid than traditional solid particles of the same size. While fundamental understanding is the main goal, the knowledge gained from this work can be expected to be employed for rational design of biologically-inspired materials function, as the proposed experiments are generic in scope. The context is that materials science of phospholipid vesicles is largely unexplored, having been dominated by biological and biosensor perspectives, yet is critically needed to fuel energy-related science needs. Some involve laying the science basis for eventual artificial photosynthetic membranes for the protein-based conversion of light into chemical energy. A parallel context is that the prominent role of sieving through the environment, when a vesicle diffuses through a network of neighboring molecules that crowd it, has commonality with solute migration through the flexible meshes of membranes.

FY 2014 HIGHLIGHTS

Our methods of single-molecule visualization with large statistical confidence to quantify the full distribution of behavior have resulted in breakthroughs regarding the phenomenon of polymer entanglement, which is one of the most spectacular, and most energy-focused, aspect of polymer science. These studies focus on single actin filaments (on the one hand) and on single chains of DNA (on

the other hand), the advantage of both these molecules being that their internal conformations can be imaged, molecule by molecule. Regarding actin, a combination of sparse and full fluorescence labeling of entangled actin solutions (filaments 17 μ m long at 1mg/ml concentration) allowed us to probe both filament-scale and local polymer dynamics. Despite the fact that on the coarse filament scale the reptation tube idea of classical polymer physics works well, on local scales comparable to mesh size, local tube width fluctuation becomes important, and the correlation between local transverse constraint (width fluctuations) and accompanying longitudinal dynamics was quantified. Regarding vesicles of lipids and polymers, this has been accompanied by focus on precise control the local environment of vesicles, as well as on the dynamics of vesicle shape transformation, with special attention to the mechanical and chemical responses of lipid vesicles and polymersomes on a level of single-vesicle resolution, enabled by a custom-designed, hydrogel based microfluidic device. Other accomplishments concern extending particle tracking capability in the direction of deep quantitative imaging.

Bioinspired Hydrogen Bonding-Mediated Assembly of Nano-Objects toward Adaptive and Dynamic Materials

Institution: California-Irvine, University of
Point of Contact: Zhibin Guan
Email: zguan@uci.edu
Principal Investigator: Zhibin Guan
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$480,000 (2014-2017)

PROGRAM SCOPE

The objective of this project is to investigate new strategies for designing strong, autonomous self-healing materials for potential energy relevant applications. The design of polymeric materials that spontaneously repair mechanical damages would dramatically improve the safety, lifetime, and energy efficiency of many systems. During the previous grant period, our lab has successfully developed a few new strategies for designing autonomously self-healing polymers using both supramolecular and dynamic covalent interactions. A key concept we have proposed is the multiphase self-healing material design that can combine high modulus, toughness, and autonomous self-healing capability. We have shown that this concept is generally applicable to a range of multiphase material systems. Furthermore, we have demonstrated for the first time that olefin metathesis is an extremely efficient dynamic covalent interaction for self-healing purpose. Built upon these successes, we propose the following new studies toward the design of strong, autonomous self-healing polymeric materials: 1) dynamic metal-ligand interactions for multiphase self-healing polymers; 2) combining supermolecular and dynamic covalent interactions for self-healing; and 3) self-healing inorganic-organic nanocomposites.

FY 2014 HIGHLIGHTS

In this year, we have achieved a number of major breakthroughs in designing dynamic/self-healing polymeric materials including: (1) We succeeded in a new design of using dynamic metal-ligand interactions for strong polymeric material able to spontaneously repair itself, without any external help from light, heat, healing agents, or plastizers/solvents (J. Am. Chem. Soc. 2014, 136, 16128–16131). (2) In a fundamental study, we demonstrated for the first time a direct correlation of single molecule properties with bulk mechanical performance for biomimetic design of polymers. The work was published in the Nature Materials (Nat. Mater. 2014, 13, 1055–1062).

Multicomponent Protein Cage Architecture for Photocatalysis

Institution: Alabama-Tuscaloosa, University of
Point of Contact: Arunava Gupta
Email: agupta@mint.ua.edu
Principal Investigator: Arunava Gupta
Sr. Investigator(s): Peter Prevelige; Alabama-Birmingham, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The primary goal of the project is to develop protein-templated approaches for the synthesis and directed assembly of semiconductor nanomaterials that are efficient for visible light absorption and hydrogen production. In general, visible-light-driven photocatalysis reactions exhibit low quantum efficiency for solar energy conversion primarily because of materials-related issues and limitations, such as the control of the band gap, band structure, photochemical stability, and available reactive surface area of the photocatalyst. Synthesis of multicomponent hierarchical nano-architectures, consisting of semiconductor nanoparticles (NPs) with desired optical properties fabricated to maximize spatial proximity for optimum electron and energy transfer represents an attractive route for addressing the problem. Virus capsids are highly symmetrical, self-assembling protein cage nanoparticles that exist in a range of sizes and symmetries. Selective deposition of inorganic, by design, at specific locations on virus capsids affords precise control over the size, spacing, and assembly of nanomaterials, resulting in uniform and reproducible nano-architectures. We utilize the self-assembling capabilities of the 420 subunit, 60 nm icosahedral, P22 virus capsid to direct the nucleation, growth, and proximity of a range of component materials. Controlled fabrication on the exterior of the temperature stable shell is achieved by genetically encoding specific binding peptides into an externally exposed loop which is displayed on each of the 420 coat protein subunits. Localization of complimentary materials to the interior of the particle is achieved through the use of scaffolding-fusion proteins. The scaffolding domain drives coat protein polymerization resulting in a coat protein shell surrounding a core of approximately 300 scaffolding/fusion molecules. The fusion domain comprises a peptide which specifically binds the semiconductor material of interest.

FY 2014 HIGHLIGHTS

Plasmonic nanostructures are highly attractive in absorbing visible light and preventing recombination of electron-holes for efficient photocatalysis. A novel synthesis strategy was designed to form core-shell like structure with CdS NPs and Au NPs using genetically engineered P22 templates. In this approach, CdS NPs were confined within the virus-like particle (VLP) via selective peptide sequences on scaffold proteins, prior to nucleation and growth of plasmonic NPs (Au) on the outside coat proteins. The biotemplated Au/CdS nanostructures exhibited significantly enhanced activity for photodegradation of methylene blue as compared to VLPs with only CdS or Au NPs. In another accomplishment, short peptides reported to nucleate the crystallization of TiO₂ in both anatase and rutile forms were genetically fused to the C-terminal 162 residues (141-303) of P22 scaffolding protein. Analytical ultracentrifugation was employed to demonstrate that the fusion proteins re-entered the protein cage. Incubation of these particles with titanium (IV)-bis-ammonium-lactato-dihydroxide (TiBALDH) precursor resulted in the formation of multiple electron-dense NPs contained entirely within the shells. Dissociation of the shells at various times during mineralization allowed us to determine the kinetics of crystal growth and the average size of the NP (2.5 nm). HRTEM demonstrated that the TiO₂ was

crystalline and that the phase (anatase or rutile) corresponded to that expected based on the fused peptide. Under illumination, the particles were capable of generating reducing equivalents as measured by breakdown of methylene blue.

Designing Smart, Responsive Communicating Microcapsules from Polymersomes

Institution: Pennsylvania, University of
Point of Contact: Daniel Hammer
Email: hammer@seas.upenn.edu
Principal Investigator: Daniel Hammer
Sr. Investigator(s): Daeyeon Lee; Pennsylvania, University of
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The continuing goal of this project will be to design motile systems using responsive and adhesive microcapsules that can respond to changes in environmental stimuli and induce collective, smart behavior on length-scales well beyond that of the capsule itself. The general principle that will be employed is particle taxis – or directed motion – in response to nanoparticles or enzymes or analytes that are released from a source capsule in response to light, change in pH, or enzymatic activity. Central to our design are vesicles of various designer chemistries. One such type of vesicle is the polymersome – vesicles whose outer membrane is assembled from block-co-polymers. We have shown that we can make large, uniform populations of polymersomes and have designed these capsules to encapsulate and release active agents such as nanoparticles or molecules in response to stimulation such as light. We also propose to use protein vesicles in which protease cleavable domains have been inserted, and use proteases to release contents on cue, as well as polymer capsules incorporating gold nanorods that release nanoparticles in response to light. In these proposed experiments, we will release encapsulated nanoparticles from source particles, and induce the motion of target particles through haptokinesis (by making a gradient of particles on a surface) or chemokinesis (making a gradient of particles in solution). We have already developed methods for making spatial, ordered arrays of microcapsules using micro-contact printing. Within these ordered arrays, using nanoparticles and surfaces with tailored adhesiveness, and using microfabricated chambers that minimize convection and set the length scale of particle coupling, we will make a direct test of the principles of collective smart particle motion. Furthermore, we include principles of self-propulsion from either thermal or biochemical interactions to make capsules that are motile on designer surfaces.

FY 2014 HIGHLIGHTS

We developed a method for patterning biotinylated polymer vesicles on arrays stamped with avidin, an essential technology for making a communicating array. The patterns allow us to position vesicles with separation distances ranging from 10 to 50 microns (or larger). (Kamat, N.P. *et al.* (2013). *Small*, 9; 2272). Then we showed that these vesicles could be displaced by both soluble biotin as well as particles of different sizes bearing biotin, ranging from 8.6 microns to 33 nanometers. This is an essential step for displacing microcapsules and developing coordinated motion using release from neighboring capsules. These results refute criticisms that avidin-biotin interactions are too strong to permit displacement (Park, S. *et al.*, manuscript in preparation). We measured the materials properties of vesicles made by microfluidics that include a variety of different co-surfactants, including bovine serum albumin and polyvinyl alcohol. These formulations and measurements allow us to determine the best conditions for

making floppy vesicles and hence autonomously motile systems. (Jane, W.-S. in press, Macromolecular Research Communications). We developed a system where by the addition of glucose could lead to the release of contents from vesicles. We encapsulated the enzyme catalase within a vesicle; this enzyme catalyzes the conversion of hydrogen peroxide to water and oxygen radical. We then added glucose and glucose oxidase outside the vesicle. This reaction leads the formation of hydrogen peroxide, which readily permeates the cell membrane. Once it does, it is converted by catalase to oxygen radical, leading to bursting the vesicle and the release of its contents. So, we can coordinate the release of material from vesicles (such as nanoparticles that displace neighboring particles) by the addition of a sugar, ultimately driving the autonomous coordinated motion of capsules through the addition of a sugar. (Jang, W.S. *et al.*, manuscript in preparation).

Surface Mechanical Properties of Bio-Inspired Architectures

Institution: Lehigh University
Point of Contact: Anand Jagota
Email: anj6@lehigh.edu
Principal Investigator: Anand Jagota
Sr. Investigator(s): Chung-Yuen Hui; Cornell University
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$280,000 (2014)

PROGRAM SCOPE

Materials in nature have evolved to form remarkable surfaces with unique surface mechanical properties. These are interesting to the materials scientist because (a) properties are often obtained by manipulation of near-surface architecture, (b) these rely primarily on non-covalent interactions, and (c) combinations difficult to obtain in synthetic materials, such as actively switchable properties and high selectivity, are routinely achieved in nature. The overall goal of our work is to design bioinspired architectures with controllable surface mechanical properties and to understand the surface mechanical properties of compliant materials. In our current work, we have a focus on two problems: (1) The role of surface-tension, solid capillarity, in soft biomaterials Many biomaterials and synthetic biomimetic materials are very compliant compared to conventional engineering materials (e.g., metals and ceramics). Although the role of surface energy is well-known in determining surface mechanical properties such as adhesion and friction, the effect of the equally fundamental surface mechanical property, solid surface tension, has generally been ignored. However, it has become apparent from recent findings that surface tension plays a significant and unexplored role in soft materials. We are studying experimentally and theoretically several phenomena where solid capillarity can play an important and sometimes dominant role, e.g., shape change due to surface tension, resistance to wetting forces, fracture, and adhesive contact. (2) Biomimetic surfaces with highly selective adhesion using shape complementarity There are many examples in nature, ranging from the molecular recognition to millimeter-scale attachment devices, of architectures that obtain highly selective and enhanced adhesion using shape-complementarity. We are studying how some simple designs of shape-complementary surfaces can strongly enhance or reduce adhesion, making it highly selective.

FY 2014 HIGHLIGHTS

(1) Ridge-channel, shape-complementary, surface structuring results in strongly enhanced and highly selective adhesion. We showed that biomimetic ridge-channel surfaces have highly enhanced adhesion (up to a factor of 30) against shape-complementary surfaces and highly attenuated adhesion against

others. We showed that mismatch is accommodated by defects that are effectively screw dislocations. (2) Measuring solid surface tension by placing a liquid drop under a solid thin film. The wetting of solid surfaces by liquid drops is a fundamental phenomenon that, for stiff materials, is governed by the well-known Young's equation for balance of surface energies at the contact line. For compliant materials, the deformation of the material in response to the forces applied by the liquid drop can be quite significant and the resistance to deformation is strongly influenced by solid surface tension. Our work revealed directly the role played by surface tension on a material (PDMS) that is used very widely in research on biomimetic materials. The specific geometry we employed allows one to extract solid surface tensions for materials with stiffness several orders of magnitude greater than done previously. (3) Surface tension of a soft solid flattens surface undulations. Nearly all works on creating biomimetic structures for enhanced and controlled surface mechanical properties rely on creating structured surfaces. In many cases, this is accomplished by some form of molding technique. We have shown how, by exerting forces that flatten and round-off surfaces, surface tension limits our ability to replicate master shapes by molding. To analyze such deformations, we have developed both analytical models as well as computational techniques.

Enzyme-Controlled Mineralization in Biomimetic Microenvironments Formed by Aqueous Phase Separation and Giant Vesicles

Institution: Pennsylvania State University
Point of Contact: Christine Keating
Email: keating@chem.psu.edu
Principal Investigator: Christine Keating
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$207,000 (2014)

PROGRAM SCOPE

The goal of this project will be to develop and understand materials synthesis in biomimetic microcompartments based on lipid vesicles and aqueous phase separation. Phase separation is common in polymer solutions and provides a means of compartmentalizing reagents and reactions in a biocompatible solvent system that models the macromolecular crowding observed *in vivo*. In such systems local concentrations and diffusion-limited reaction fronts can be controlled and symmetry-breaking can be achieved. We will take advantage of molecular partitioning of solutes between the two phases of an aqueous two-phase system (ATPS) to control local concentrations of enzyme catalysis, metal cations, and other molecules that participate in the reactions. The ATPS will be encapsulated within semipermeable microscale reaction vessels to produce artificial mineralizing vesicles that perform materials synthesis. We anticipate that the approach will be generally applicable to many materials systems including but not limited to those traditionally formed by living organisms. Our initial focus will be on the well-characterized biogenic mineral calcium carbonate, to facilitate interpretation of changes in the process and final products of mineralization related to our approach. The long-term impact of this work will be to enable the design of new materials with desired properties based on understanding and controlling spatial and temporal reactant availability by biomimetic compartmentalization.

FY 2014 HIGHLIGHTS

Semipermeable, size-controlled bioreactors with aqueous macromolecule-rich interiors were assembled by liposome stabilization of an all-aqueous emulsion. This new way to form water-in-water emulsions

enables simultaneous formation of many nearly identical bioreactors capable of maintaining favorable interior composition while allowing substrate entry and product egress. The polymer-rich aqueous interior serves as a model for biological fluids such as cytoplasm where polymers and biomolecules such as nucleic acids are concentrated by equilibrium partitioning and consequently will never “leak” out. A submonolayer of ~100 nm lipid vesicles stabilizes the aqueous/aqueous interface while allowing transport in/out of droplets. Individual vesicles are jammed at the interface and immobile, which makes it possible to form Janus droplets. This work was published in Nature Communications. We are now developing these structures as artificial mineralizing vesicles for enzyme-catalyzed formation of calcium carbonate minerals.

DNA-Grafted Building Blocks Designed to Self-Assemble into Desired Nanostructures

Institution: Columbia University
Point of Contact: Sanat Kumar
Email: sk2794@columbia.edu
Principal Investigator: Sanat Kumar
Sr. Investigator(s): Venkat Venkatasubramanian; Columbia University
Oleg Gang; Brookhaven National Laboratory
Michael Collins; Columbia University
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 3 Undergraduate(s)
Funding: \$479,311 (2014)

PROGRAM SCOPE

We develop transformative, computer-based tools to design DNA-grafted colloids (DBB) that will spontaneously assemble into desired crystal structures. Our proposed “Product Design” mode of research runs counter to the Edisonian approach where building blocks are first synthesized, and then examined as to the structures they assemble into. A primary feature of our approach is that we develop hybrid genetic algorithm based methods to replace this trial-and-error methodology with one that can design DBB that will assemble into desired structures. While our model predictions are critically validated against experiments, the more important point is that this new methodology can revolutionize materials design.

FY 2014 HIGHLIGHTS

Our first paper, published in PNAS, focused on the development of the design methodology that is the central focus of the proposal. To date, experimentally it has been found that DNA grafted colloids formed four different structures – CsCl, AlB₂, Cr₃Si and Cs₆C₆₀. This must be viewed in light of the crystal database which suggests that several hundred known crystal structures exist. Our paper has focused on finding regions of parameter space where these other structures may be found, and made several predictions for new structures – for example we suggested that structures such as Cu₅Zn₈ and Pd₅Th₃, among others, could be formed. Experimental verification of these results raised the important question of what the stoichiometry needs to be to observe these structures. That is, do we need to mix colloids in the ratio 5:8 to observe the Cu₅Zn₈ structure, or is the result robust to the chosen stoichiometry. While there are important exceptions, a generally accepted view is that the right stoichiometry of the two building block colloids needs to be mixed to form the desired crystal structure. In a paper under review in PNAS, we combine experiments and theory on a series of DNA-grafted nanoparticles at varying stoichiometries, including non-integer values, to probe this open question. Both experimental results and theoretical calculations reveal stoichiometry as a new parameter that can couple with the

geometries of the building blocks to tune the equilibrium lattice. Theory also shows that phase coexistence between crystal polymorphs can sometimes occur in regions of non-integer stoichiometry. Thus, while stoichiometry can be a powerful handle for direct control of lattice formation, care must be taken in its design and selection to avoid polymorph coexistence. Another variable we have studied in a paper under review in Nature is to use osmotic pressure, specifically through the addition of PEO to the solution, to facilitate crystal morphology transitions.

Biological and Biomimetic Low-Temperature Routes to Materials for Energy Applications

Institution: California-Santa Barbara, University of
Point of Contact: Daniel Morse

Funding: \$350,000 (2014)

PROGRAM SCOPE

New materials are needed to significantly improve the efficiencies of energy harnessing, transduction and storage, yet the synthesis of advanced composites and multi-metallic semiconductors with nanostructures optimized for these functions remains poorly understood and even less well controlled. To address this need, we proposed three goals: (1) To further investigate the hierarchical structure of the biologically synthesized silica comprising the skeletal spicules of sponges that we discovered, to better resolve the role and mechanism of templating by the hierarchically assembled Silicatein protein filament in directing the emergent mineral structure simultaneously with its catalytic synthesis. (2) To extend our successful molecular and genetic analyses and engineering of Silicatein, the self-assembling, structure-directing, silica-synthesizing enzyme we discovered and characterized, to better understand and manipulate in this model system the genetically encoded structural determinants of hierarchical self-assembly and the resultant emergent properties of catalysis and templating of semiconductor synthesis, and (3) to use our biologically inspired, low-temperature, kinetically controlled catalytic synthesis method (based on the kinetically controlled synthesis mechanism we discovered in Silicatein) to investigate the relationship between catalysis and templating of inorganic nanocrystal nucleation and growth in model systems optimized for energy applications. The biologically inspired materials synthesis methods we are developing are low-cost, low temperature, and operate without the use of polluting chemicals. In addition to direct applications for improvement of batteries and fuel cells, the broader impact of this research includes a deeper fundamental understanding of the factors governing kinetically controlled synthesis and its control of the emergent nanostructure and performance of a wide range of nanomaterials for energy applications.

FY 2014 HIGHLIGHTS

Based on our genetic engineering enabling further elucidation of the atomic-level mechanisms of catalysis and nanostructural control by the silica-synthesizing enzyme we discovered, we further developed our biologically inspired, low-cost, kinetically controlled method for catalytic nanofabrication of high-power anodes and cathodes for lithium ion batteries and fuel cells. Nanocomposite electrodes made by our bio-inspired, low-temperature catalytic method consist of tin, silicon or platinum nanocrystals uniformly dispersed by catalytic synthesis *in situ* in the pores of highly conductive microparticulate graphite, carbon nanotubes or exceptionally high surface area graphene; these

nanocomposites exhibited electrochemical capacities, power densities and stabilities significantly greater than commercial materials available at that time. Catalytically produced nanocomposite spinel-CNT cathodes for lithium ion batteries produced by this method exhibit high voltage, high capacity and superior cyclability. Thin films of doped barium strontium titanate made by this method offer the prospect of safer batteries via an internal protectant against thermal runaway. Our kinetically controlled catalytic synthesis of nanocomposite electrodes for fuel cells provided access to new combinations of porosity, conductivity and electrochemical hydrogen oxidation facilitating analysis of the relationships between the porous morphologies of the carbon matrices, the sizes of the platinum nanocrystals and their resulting electrochemical activities. Commercially affordable scalability of these materials was developed with continuous production of the nanocrystalline doped barium strontium titanate. In addition, a new approach to the synthesis of complex ternary nanocomposites of silicon, silica and hydrogen silsesquioxane was developed, enabled by the unique advantages offered by our biologically inspired, kinetically controlled, low-temperature catalytic synthesis method.

Electrostatic Driven Self Assembly Design of Functional Nanostructures

Institution: Northwestern University
Point of Contact: Monica Olvera de la Cruz
Email: m-olvera@northwestern.edu
Principal Investigator: Monica Olvera de la Cruz
Sr. Investigator(s): Michael Bedzyk; Northwestern University
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$650,000 (2014-2017)

PROGRAM SCOPE

Molecular assemblies with externally controlled mesoscale morphologies offer the opportunity for developing biomimetic systems with tunable functionalities. Of particular interest are assemblies generated via electrostatic interactions, which play a ubiquitous and central role in governing the structure and functionality of bio-mimetic constructs. The focus of this program is to understand and control the coupling of elasticity and electrostatic interactions in multicomponent membranes formed by the co-assembly of cationic and anionic amphiphilic molecules in aqueous solutions and at planar fluid interfaces. This research will delineate the basic principles and experimental strategies for achieving nanoscale control of the intramembrane arrangements of the poly-ionic components, which produce 1D, 2D and 3D mesoscale morphologies, such as ribbons, sheets and vesicles. Environmental inputs, such as solution pH, salt concentration, and salt composition, will be used to tune the inter-molecular electrostatic interactions. Similarly, the inter-molecular van der Waals' interactions will be adjusted by varying the length of the hydrophobic tails. To explore the possibility of generating 2D nanoscale charge patterned surfaces, differences in the shapes and the lengths of the cationic and the anionic amphiphiles will be introduced. Apart from elucidating the coupling between molecular geometries and the subsequent surface heterogeneities, appropriately constructed 2D nanopatterned surfaces may find applications as designer templates for generating ordered nanoparticle arrays for optical and sensing applications.

FY 2014 HIGHLIGHTS

The shape of nanoscale objects influences interaction and determines its functional capabilities. In particular, the unique functions of charged filaments such as filamentous viruses and the cellular cytoskeleton have inspired the design of self-assembled nanofibers for applications in regenerative

medicine, drug delivery, and catalysis. Using SAXS, we studied the assembly of nanofilaments of +1 azobenzene-based amphiphiles. SAXS showed these highly charged nanofilaments of 5.6 nm diameter order into 2D arrays with large inter-fiber spacing of up to 130 nm. Solution concentration and temperature can be adjusted to control the interfiber spacing. The addition of salt destroys crystal packing. We described the crystallization of bundles of filament networks interacting via long-range repulsions in confinement by a phenomenological model and by computer simulations. Two distinct crystallization mechanisms in the short and large screening length regimes were obtained, as well as the phase diagram. Understanding how to generate and control shape by modifying the environmental conditions is of primary importance in designing systems that respond to external clues. We showed that electrostatic interactions can be used to change the equilibrium shape of shells. Uniformly charged shells were found to undergo shape changes, transforming into ellipsoids, discs, and bowls, as the electrolyte concentration is decreased. This electrostatics-based shape design mechanism, regulated by varying properties external to the shell, can be used to build efficient nanocontainers. We further described the buckling of ionic, crystalline vesicles formed by co-assembling amphiphiles with 3+ head groups and -1 head groups by computer simulations at different concentration of cationic and anionic amphiphiles. We found that as the size of the vesicle decreases the shape of the crystalline vesicles changes from higher to lower symmetry (from icosahedron to tetrahedron).

Dynamical Self-Assembly: Constrained Phase Separation and Mesoscale Dynamics in Lipid Membranes

Institution: California-Davis, University of
Point of Contact: Atul Parikh
Email: anparikh@ucdavis.edu
Principal Investigator: Atul Parikh
Sr. Investigator(s): Sunil Sinha; California-San Diego, University of
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$419,000 (2014)

PROGRAM SCOPE

We have two over-arching objectives for this project. First, we seek to abstract a physical science based understanding of fundamental rules that determine constrained phase separation processes in lipid membranes. Second, our longer-term objective is to translate these physical principles into quantitative design rules for the development of new classes of membrane-based complex materials that exhibit complex, co-operative, and adaptive behavior at the mesoscale. Our approach is primarily experimental; we employ well-defined model membranes including lipid multilamellae, single supported lipid bilayers, and giant unilamellar vesicles) and examine their spontaneous mesoscale organization and dynamic remodeling in response to intrinsic material constraints and selected environmental perturbations. Specifically, we focus on the roles of (1) interfacial (including interbilayer) interactions and hydration repulsion; (2) imposed shapes and curvatures; and (3) mechano-chemical perturbations including adhesion, tension and lipid-specific chemistries. Interrogating these mesoscale dynamic reorganizations in membrane milieu, which arise from molecular considerations, using spatially- and temporally resolved microscopy and spectroscopy methods (fluorescence, ellipsometric, infrared vibrational, x-ray reflectivity, and neutron reflectivity) yield design rules, which we seek to reconstitute in synthetic material systems. Building on our success during the earlier performance periods, we have organized our work into three specific aims: (1) Characterize the mechanism of inter-layer coupling of laterally phase-separated domains in stacked lipid bilayers; (2) Characterize curvature-dependent dynamic reorganization in membrane milieu; and (3) Characterize real-time effects of mechanochemical

perturbations on lateral phase separation in membrane bilayers. The work is performed in partnership with Prof. Sinha (UC San Diego).

FY 2014 HIGHLIGHTS

Toward each of the aims, we have made significant progress during the FY 2014 academic year, which is elaborated in our technical dissemination through nine journal articles and six presentations by the investigators. The most exciting finding of this period is a study published in a recent issue of eLife: "Oscillatory phase separation in giant lipid vesicles induced by transmembrane osmotic differentials," Kamila Oglęcka, Padmini Rangamani, Bo Liedberg, Rachel S Kraut, Atul N Parikh* eLife 3, Art. No. e03695, 2014 (* Corresponding Author). Here we study dynamic self-assembly at mesoscale in closed lipid vesicles. Giant lipid vesicles are closed compartments consisting of semi-permeable shells, which isolate femto- to pico-liter quantities of aqueous core from the bulk. Although water permeates readily across vesicular walls, passive permeation of solutes is hindered. In this study, we show that, when subject to a hypotonic bath, giant vesicles consisting of phase separating lipid mixtures undergo osmotic relaxation exhibiting damped oscillations in phase behavior, which is synchronized with the swell–burst lytic cycles: in the swelled state, osmotic pressure and elevated membrane tension due to the influx of water promote domain formation. During bursting, solute leakage through transient pores relaxes the pressure and tension, replacing the domain texture by a uniform one. This isothermal phase transition—resulting from a well-coordinated sequence of mechanochemical events—suggests a complex emergent behavior allowing synthetic vesicles produced from simple components, namely, water, osmolytes, and lipids to sense and regulate their micro-environment.

Integrating Rhodopsins in H⁺-FETs for Bioinspired Energy Conversion

Institution: Washington, University of
Point of Contact: Marco Rolandi
Email: rolandi@uw.edu
Principal Investigator: Marco Rolandi
Sr. Investigator(s): Francois Baneyx; Washington, University of
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$285,000 (2014)

PROGRAM SCOPE

Energy transduction at the nanoscale is key for developing ever smaller self-powered biotic- abiotic circuitry. In biological systems, chemical, mechanical, and electromagnetic energy is converted from one form to another using ubiquitous proton gradients. These proton gradients result in proton electrochemical potential differences, referred to as proton motive force (PMF). The proton pump Bacteriorhodopsin is an example. In *Halobacterium Salinarum*, the light energy absorbed from Bacteriorhodopsin is used to pump protons outwards to form a PMF across the membrane. H⁺-ATPase uses this PMF to synthesize ATP. Here, Prof. Rolandi and Prof. Baneyx propose to develop materials and proton (H⁺)- based devices to modulate proton gradients for understanding and exploiting bioinspired energy conversion. This research is enabled by our ability to control proton currents in H⁺-FETs (Rolandi) and express membrane proteins in large quantities in optimized *E. coli* strains (Baneyx). The project objectives are as follows: (1) Express proton-pumping rhodopsins and proteorhodopsins in large quantities in optimized *E. coli* strains and engineer these proteins to selectively bind to proton contacts. (2) Integrate these proteins in solid-state proton conducting transistors with lipid bilayer contacts. (3) Perform proton transport measurements in the resulting devices to evaluate proton-pumping

characteristics (e.g., voltage, current, ΔpH) as a function of light intensity, wavelength, solution pH, and contact protochemical potential. This research will provide a fundamental understanding of H^+ transport in these hybrid devices. This understanding can then be used to develop rhodopsin-powered circuitry and exploit other aspects of proton based bioinspired energy conversion including chemical energy (ATPase) and mechanical energy (bacteria flagella).

FY 2014 HIGHLIGHTS

During the first year of this grant we focused on the components that will be used in year 2 to assemble HdtR onto the protonic devices to perform measurements. (1) Measurement and Simulation of H^+ injection and depletion from PdH_x contact. To characterize the charge injection characteristics of PdH_x contacts, we integrate PdH_x with the well-known proton conductor (Nafion) and measure transient behavior. (2) Measurement of PdH_x Nernst potential as a function of x and pH. The study of the PdH potential was carried out in an open-circuit measurement. (3) Formation of Lipid Bilayers liposomes for integration onto Pd. The formation of Dioleoylphosphatidyl-Choline (DOPC) liposomes has been confirmed through Dynamic Light Scattering (DLS) measurements. (4) Construction of a Pd-binding derivative of HtdR. (5) Pd_4 -HtdR is expressed in a functional form in the *E. coli* membrane.

Miniaturized Hybrid Materials Inspired by Nature

Institution: California-Santa Barbara, University of
Point of Contact: Cyrus Safinya

Youli Li; California-Santa Barbara, University of
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$315,000 (2014)

PROGRAM SCOPE

The objectives of our research program is to develop a scientific understanding of higher-order-assembly in charged biomolecular materials, which may be near equilibrium, in kinetically trapped states (e.g. in environmentally responsive biomolecular assemblies), or out-of-equilibrium. Current focus includes polyampholyte directed assembly of filamentous proteins and polyelectrolyte directed assembly of oppositely charged membranes. Our program also involves developing an understanding of the influence of shape, in environmentally-responsive tunable bio-macromolecular materials systems, on dynamical assembly. Both the building blocks and their directed assembly may contribute important functional properties to the resulting biomimetic materials on different length scales. A strategy that we use to achieve our aims is to design biomimetic materials inspired by complex cellular assemblies, which operate under dissipative conditions. Bio-macromolecules studied in this program include dynamical filamentous proteins, including neurofilaments (NFs) and microtubules, which assemble as a result of electrostatic interactions mediated by unstructured bio-polyampholytes (e.g. the polyampholytic sidearms of NFs and the unstructured microtubule-associated-proteins). The results should aid in the development of nanoscale and micron scale biomimetic materials with potential applications including as templates for nanostructures and chemical encapsulation systems. The projects utilize the broad spectrum of expertise of the PI and the two co-PIs in biomolecular self-assembling methods, synchrotron x-ray scattering, electron and optical microscopy characterization techniques, the

application of the small-angle x-ray scattering (SAXS)-osmotic pressure technique for direct force measurements, and custom organic/polymer synthesis and purification of biological molecules.

FY 2014 HIGHLIGHTS

“Protein Tubule Inversion Triggered by a Molecular Switch: A New Paradigm for Nanoscale Assembly”, our recent study, which appeared as an article in Nature Materials, describes the discovery of a highly charged molecular switch triggering the disassembly of a bundle of microtubules followed by re-assembly into inverted tubulin tubules, which expose the inner surface of the original microtubules [1]. Synchrotron small-angle-x-ray-scattering and electron microscopy uncovered the pathway of the tubule inversion process revealing a straight-to-curved shape transition of protofilaments comprising the precursor microtubule wall. The scientific discovery opens the path for a new paradigm for nanoscale assembly, which incorporates building blocks with a pre-programmed and triggerable shape evolving property (in principal applicable to a range of enzymes with inherent coded properties). The use of encoded building blocks enables trigger-ready assemblies, which disassemble on demand and reassemble shape-remodeled building blocks into a new form of matter with different function resulting from the evolved structure. The study was further highlighted in a Perspectives article in Science [2]. 1. Ojeda-Lopez, M. A.; Needleman, D. J.; Song, C.; Ginsburg, A.; Kohl, P.; Li, Y.; Miller, H. P.; Wilson, L.; Raviv, U.; Choi, M. C.; Safinya, C. R.: Transformation of taxol-stabilized microtubules into inverted tubulin tubules triggered by a tubulin conformation switch. EARLY CAREER: Assembling Microorganisms into Energy Converting Materials

Institution: Columbia University
Point of Contact: Ozgur Sahin
Email: os2246@columbia.edu
Principal Investigator: Ozgur Sahin
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project integrates microorganisms capable of reversible energy transduction in response to changing relative humidity with non-biological materials to create hybrid energy conversion systems. While plants and many other biological organisms have developed structures that are extraordinarily effective in converting changes in relative humidity into mechanical energy, engineered energy transduction systems rarely take advantage of this powerful phenomenon. Owing to their micrometer-scale dimensions, bacterial spores are amenable to integration into macroscopic structures with desired micro-architectures through directed or self-assembly. So, the objective is to create robust and scalable energy conversion materials using bacterial spores as the key biomolecular material responsible for energy conversion. A suite of experimental platforms including atomic force microscopy and micro-electromechanical systems is being used to investigate how to assemble hybrid spore-rubber latex structures that efficiently generate electricity by converting energy from evaporation of water and, how the interaction between water and spore nanostructure imposes limits on energy conversion. Progress can provide opportunities to tap into new forms of renewable energy and environmentally friendly energy storage.

FY 2014 HIGHLIGHTS

We have developed an experimental setup to measure maximum strains and energy densities of individual bacterial spores in response to changes in relative humidity. We also developed a model to better estimate energy density using contact mechanics principles. We studied two different spore species. Our study showed that the energy density of *Bacillus subtilis* is more than 10 MJ m^{-3} , which is two orders of magnitude higher than that of synthetic water-responsive materials. In addition, certain genetic alterations can approximately double the energy density over the wild type. We found that the energy densities of spores also exceed typical values reported for materials frequently used or studied in the context of actuators and stimuli-responsive materials. To demonstrate a potential application of spore-based stimuli-responsive materials, we created a centimeter scale actuator, which can grab and release objects on demand.

Biopolymers Containing Unnatural Building Blocks

Institution: Scripps Research Institute
Point of Contact: Peter Schultz
Email: schultz@scripps.edu
Principal Investigator: Peter Schultz
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$365,000 (2014)

PROGRAM SCOPE

Chemists have exquisite control over the structures of small molecules. However, our ability to control the structures of biological polymers such as proteins and nucleic acids is far more limited. Although it is possible to manipulate protein structures by selective chemical modification and by site directed mutagenesis, we are in general limited by the chemical functionality contained within the canonical twenty amino acid building blocks. For many applications of proteins to problems in energy, the environment or materials science, additional building blocks would be desirable and in many cases essential. To overcome this biological limitation we have developed a method that allows unnatural amino acids, beyond the common twenty, to be genetically encoded in bacteria, yeast and mammalian cells with high fidelity and good yields. Previously, amino acids with novel chemical and photochemical properties, metal ion binding amino acids, and a variety of biophysical probes were genetically encoded. Here we propose to begin to develop approaches to use these new chemistries to selectively modify the structures of protein to generate new functions, and to begin to create new classes of template unnatural biopolymers of defined length and sequence. This work should provide the scientific community powerful new tools to manipulate the properties of proteins in ways currently not possible for energy and materials related applications.

FY 2014 HIGHLIGHTS

We have made significant progress toward this goal of using the templated ribosomal biosynthetic machinery of nature to make unnatural biopolymers. A family of orthogonal nonsense and frameshift suppressor tRNA/aminoacyl-tRNA synthetase (tRNA/aaRS) pairs has been evolved that efficiently incorporate multiple noncanonical amino acid building blocks into proteins. These orthogonal tRNA/aaRS pairs also allow us to simultaneously insert two distinct noncanonical amino acids efficiently into a single polypeptide chain. In addition we have demonstrated that in a TAG codon genomically

deleted strain of *Escherichia coli* which is devoid of the amber stop codon, one can use unique four base suppressor tRNAs to insert amino acids with novel chemical and physical properties into proteins. Furthermore to further expand the range of unnatural building blocks that one can insert into biopolymers using this technology we have evolved a tryptophanyl-tRNA synthetase that genetically encodes a number of novel aromatic amino acids. Finally we have demonstrated that the ability to generate polypeptides with an expanded set of building blocks allows one to evolve novel metal ion binding sites in proteins. This work may afford a strategy for the generation of metal ion binding motifs with novel catalytic or regulatory properties.

Fabrication and Assembly of Robust, Water-Soluble Molecular Interconnects via Encoded Hybridization

Institution: Michigan, University of
Point of Contact: Timothy Scott
Email: tfscott@umich.edu
Principal Investigator: Timothy Scott
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$445,000 (2014-2017)

PROGRAM SCOPE

Nucleic acids present the most versatile class of materials for producing nanostructures to date and, through careful consideration of their residue sequence, can be designed to self-assemble via the hybridization of complementary strands into arbitrary structures with nanometer precision. Additionally, the biological origin of nucleic acids enables oligomeric sequences to be readily enzymatically replicated. Unfortunately, the versatility of nucleic acids as construction materials is tempered by the thermal and mechanical instability of the assembled nanostructures, attributable to the weakness of the hydrogen bonds holding the strands together. The substitution of the canonical nucleic acid base pairs with covalent-based pairs would preclude this instability and yield a unique and powerful nanofabrication strategy wherein the complex, sequence-directed assembly of nucleic acids is combined with the strength of covalent bonds. Moreover, the exact monomer positioning resulting from strong, reversible, covalent interactions between sequence-specific oligomeric templates and complementary monomers enables multi-generational, high fidelity replication and amplification of oligomeric sequences. As the utilization of covalent-based pairs necessarily prevents the prospect of enzymatic amplification of the synthesized oligomers, the nucleic acid backbone can also be replaced without considering its enzyme compatibility. Although nucleic acids exhibit poor long-range electrical conductivity, oligomers incorporating an electron-delocalized backbone would afford excellent electron transport. This research involves the utilization of dynamic covalent bonds to mediate the assembly of complementary oligomers, and the semi-conservative replication of these oligomeric sequences, enabling the deterministic assembly of branched nanostructures constructed from robust, electron-conducting interconnections that can be exponentially amplified via repeated duplication.

FY 2014 HIGHLIGHTS

Upon synthesis, purification, and deprotection, we examined the dynamic covalent hybridization of short, aldehyde- and amine-bearing peptoid oligomers in the first period of this research. Reactions of trialdehyde/triamine and tetraaldehyde/tetraamine exclusively afforded the corresponding tri- and tetramer hybrids, respectively. Approaches to achieve hybridization registry between larger complementary oligomers and polymers have long been challenging owing to kinetic trapping, even for

those employing non-covalent interactions. However, cross-reactions of tetraaldehyde/triamine and trialdehyde/tetraamine both yielded least-common-multiple (i.e., 3×4) vernier dodecamer hybrids, providing a facile path for achieving otherwise unattainable hybridization lengths. Additionally, we are currently examining approaches to incorporate both aldehyde- and amine-based dynamic covalent pendant groups on oligomers whilst avoiding premature deprotection which would lead to uncontrolled inter-oligomer cross-linking and impede oligomer purification efforts. To this end, we have developed pendant groups that can be deprotected *in situ* upon ultraviolet irradiation.

Self Assembly & Self-Repair of Novel Photosynthetic Reaction Center/Single Walled Carbon Nanotube Complexes for Solar Energy Conversion

Institution: Massachusetts Institute of Technology
Point of Contact: Michael Strano
Email: strano@mit.edu
Principal Investigator: Michael Strano
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Nature continually develops and maintains an infrastructure for light harvesting and energy storage using the self-assembly of photosynthetic protein complexes coupled with mechanisms of repair and replacement of active components. The goal of this project is to continue to study and develop synthetic analogs to natural self assembly and self repair processes in working photoelectrochemical and photovoltaic cells. Previously, we extended these concepts to develop the first synthetic photoelectrochemical complex capable of mimicking key elements of this self-repair cycle (Nature Chemistry, 2010). We found that phospholipids, an amphipathic apolipoprotein (membrane scaffold protein; MSP), single-walled carbon nanotubes (SWNT), a photosynthetic reaction center (RC) isolated from the purple bacterium, *Rhodobacter sphaeroides* all spontaneously assemble into a specific configuration, enabling a photoelectrochemical cell capable of self repair. In this current work, the project will explore two additional topics: energy transfer to biological chromophores and the study of exciton antenna structures. Biological chromophores have an advantage in that they can be directly produced by known biological infrastructure, forming an important basis for self repair. Carbon based antenna structures are a new invention of the Strano laboratory at MIT (solar funnels, Nature Materials, 2010) that allow us to tune and direct excitation to specific reaction centers, giving us the ability to control wavelength and the spatial concentration of excitations. The project will invent several example systems capable of self repair, particularly using nano- and bio-technology interfaces. We also intend to extend our modeling of exciton diffusion and reaction in such systems using Kinetic Monte Carlo methods.

FY 2014 HIGHLIGHTS

From 2014, we published our first work on Plant Nanobionics in Nature Materials, starting a new field of nanoparticle modification of living plants. A press release is below: <http://newsoffice.mit.edu/2014/bionic-plants>

Nanoengineering of Complex Materials

Institution: Northwestern University
Point of Contact: Samuel Stupp
Email: s-stupp@northwestern.edu
Principal Investigator: Samuel Stupp
Sr. Investigator(s):
Students: 6 Postdoctoral Fellow(s), 8 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014)

PROGRAM SCOPE

Our research program is based on complex materials derived from functional nanostructures that emerge as a result of self-assembly of organic molecules. The self-assembly processes can be directed by external forces or can be encoded in the molecules themselves by exploiting chemical reactions involving organic or inorganic substances. The first fundamental objective is to further develop the supramolecular science necessary to design molecules for nanostructure synthesis and function. A second objective is to integrate the synchronized templating of organic and inorganic phases to understand phenomena such as epitaxy on nanostructures and nanoscale confinement of chemical reactions. Self-assembly and templation are two fundamental phenomena used intensely in biological systems for the control of function over many length scales. It is our opinion that both need to be understood deeply to advance materials chemistry over the next few decades. From a functional standpoint, we are interested in new structural concepts in nanoengineered materials for capturing, transducing, and storing energy. We are also interested in enzyme mimics for catalysis and in the design of biomolecular structures to control cell behavior for biosynthesis. Fundamentally, we hope to use the self-assembly strategies that we develop to control and exploit the properties of the resulting bulk materials. Our longer-term goals include development of applications of these nanostructured materials to solar energy conversion, electronic and ionic conductivity, and energy storage.

FY 2014 HIGHLIGHTS

In our project on supramolecular interactions for photovoltaic function, the objective is to use hydrogen bonding to direct the assembly of molecules on an active layer. We designed a family of asymmetric donors containing diketopyrrolopyrrole groups. Since the synthesis of asymmetric molecules is complicated, we switched to a symmetric design. Initial testing of the new symmetric design revealed an improvement on open circuit voltage, but solubility remains a challenge. Going forward, we will keep the symmetric design, but try to design molecules with additional solubilizing groups that do not compromise the electronic properties. Our research into dye sensitized solar cells with a lamellar hybrid organic-inorganic system showed that our initially synthesized dyes did not provide efficient devices. We are now developing new hybrid systems based on electrodeposited molybdenum sulfide-chromophore hybrids for photocatalytic hydrogen production and new, lead-free perovskite systems for solar cells. In our work on supercapacitor and battery electrodes, we have successfully optimized conditions for homogeneous electrodeposition of lamellar surfactant-Co(OH)₂ supercapacitor electrodes and characterized the nanostructure with grazing incidence x-ray scattering (GIXS) and traditional XRD. The electrochemical performance was measured using galvanostatic charge-discharge cycling and cyclic voltammetry. Current efforts include incorporating crosslinking surfactants for improved structural stability during cycling. We have designed and characterized a charge transfer complex that forms nanostructures with alternating electron donor/acceptor functionality. In our newest syntheses, we

have altered the molecular design to improve solubility in organic solvents. We also designed two molecules that incorporate either short peptide or sugar moieties.

Chemically Directed Self-Assembly of Protein Superstructures and Construction of Tunable Redox Functionalities in their Interfaces

Institution: California-San Diego, University of
Point of Contact: Faik Akif Tezcan
Email: tezcan@ucsd.edu
Principal Investigator: Faik Akif Tezcan
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$240,000 (2014)

PROGRAM SCOPE

The stated objectives of this project are: 1) To elucidate and control the bottom-up assembly of 0-, 1-, 2- and 3D nanoscale protein superstructures/arrays, and to functionalize them toward energy-related applications. 2) To construct redox-active copper centers in the interfaces of protein superstructures. These goals combined will lead to the chemically controllable self-assembly of well-ordered superstructures under ambient conditions that will be used for light-harvesting and redox catalysis. These structures also will provide a framework for a fundamental understanding of protein self-assembly as well as crystal nucleation and growth.

FY 2014 HIGHLIGHTS

We have made excellent progress in the past year on several fronts, both in terms of building structural complexity and diversity using proteins as synthons for self-assembled systems and in terms of controlling metal reactivity within these assemblies. Excitingly, entirely new research areas and possibilities (related to Biomaterials) emerged from our recent studies, which we had not foreseen when we were formulating our plans for 2013-2015. These include: 1) Construction of *de novo* helical protein nanotubes with tunable diameters, 2) Metal-mediated assembly of 2- and 3D crystalline protein lattices with novel protein building blocks and new bonding strategies, 3) Programmable assembly of DNA-protein hybrids, 4) Construction of protein assemblies with redox-active Cu centers.

Self-Assembly of PI-Conjugated Peptides in Aqueous Environments Leading to Energy-Transporting Bioelectrical Nanostructures

Institution: Johns Hopkins University
Point of Contact: John Tovar
Email: tovar@jhu.edu
Principal Investigator: John Tovar
Sr. Investigator(s): Howard Katz; Johns Hopkins University
Andrew Ferguson; Illinois-Urbana Champaign, University of
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$270,000 (2014)

PROGRAM SCOPE

The realization of new supramolecular pi-conjugated organic structures as driven by peptide-based self-assembly will offer a new approach to interface with the biotic environment. Previously, we developed pi-conjugated peptides that undergo supramolecular self-assembly into one-dimensional (1-D) organic electronic nanomaterials under benign aqueous conditions. The intermolecular interactions among the pi-conjugated organic segments within these nanomaterials lead to defined perturbations of their optoelectronic properties and yield nanoscale conduits that support energy transport within individual nanostructures and throughout bulk macroscopic collections of nanomaterials. Our objectives for this project are to construct and study biomimetic electronic materials for energy-related technology where peptide-driven self-assembly enhances pi-stacking within nanostructured biomaterials. This project entails synthesis of new pi-electron units to embed within self assembling peptides, detailed characterization and molecular modeling of the resulting nanomaterial aggregates, exploration of the surface chemistry presented by these nanostructures as relevant for the development of optoelectronic interaction with cells or other biotic systems and development of new assembly paradigms leading to heterogeneous electronic properties (i.e. gradients and localized electric fields) within the nanomaterials. Collaborative molecular modeling and simulation closely integrated with experimental synthesis and characterization will reveal molecularly-detailed structures and assembly mechanisms to rationalize experimental observations, and present molecular-level guidance to inform peptide design. This research will lead to the continued development of a powerful materials set capable of making connections between nanoscale electronic materials and macroscopic bulk interfaces, be they those of a cell, a protein or a device.

FY 2014 HIGHLIGHTS

Research over the past year has advanced all of the major project aims. We synthesized peptidic nanostructures based on 2-D “graphitic” subunits and new donor-acceptor constructs capable of directed energy migration both lateral to and along the nanowire conjugation axis. We finalized and published studies related to the variation of peptide sequence and resulting impacts on photophysical properties. We investigated the capability of nanowire assemblies to transmit voltage and current by using them in two different functional parts of field effect transistors (FETs), as well as by simple sheet resistance measurements. Sequence composition impacted the magnitude of the electrical conductivities which were also higher than a control nanowire with no conjugated core. These conductive nanowires were effective in transmitting gate voltage to the gate dielectric of an organic FET. Both hydrocarbon and hydroxylated dielectric materials were used in these devices. Separately, we compared various nanowires as semiconductors in FETs with silicon-silicon oxide gates. The most important finding is that the control nanowire did not show a field effect when used as a semiconductor, while many other nanowires, with conjugated cores, did so. We have developed a coarse-grained solvent-free model of peptide assembly tuned against fully atomistic, explicit solvent simulations to understand monomer and dimer behaviors. This model provides access to assembly time and length scales inaccessible to the atomistic molecular dynamics, enabling us to simulate the assembly of hundreds of peptide monomers for hundreds of nanoseconds. Our results suggest the existence of two time scales for assembly: a rapid annealing phase where monomers aggregate into barrel-like groups of ~5 peptides, and a slow ripening phase wherein these barrels coalesce into larger ribbons and sheets. A manuscript is in preparation to be submitted early in the new year.

Dynamic Self-Assembly, Emergence, and Complexity

Institution: Harvard University
Point of Contact: George Whitesides
Email: gwhitesides@gmwgroup.harvard.edu
Principal Investigator: George Whitesides
Sr. Investigator(s):
Students: 6 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$900,000 (2014-2017)

PROGRAM SCOPE

This program focuses on the development of two areas. Both are dissipative systems. i) Biomimetic Actuators. We are studying the fundamental materials science of soft actuators and soft machines—that is, devices fabricated predominantly in elastomers and flexible sheets—under actuation (primarily by pressurization with gas). The model “machines” we are characterizing share with living systems an organization around soft materials; the mechanism of actuation of these “machines” (by muscle in the case of animals; by pneumatics in our biomimetic systems) are mechanistically different, but functionally similar. As with living systems, these biomimetic, but non-living systems have the remarkable property of displaying non-linearities in actuation (e.g., stretching or bending) that allow them to substitute the non-linear properties of the materials for sensors and controls: that is, the materials allow the devices to carry out complex functions such as gripping delicate objects almost autonomously. Biological systems have similar properties and functions. In neither living nor non-living systems is the underlying materials science well understood. This program will explore analogies, and try to embed functions and properties into non-living systems that are similar to those in living systems. ii) Flames. Flames are prototypical dissipative systems: they also convert one form of energy (usually chemical free energy) into another form (heat). This project is not concerned with the use of this heat (as in an engine), but with the characteristics of flames as non-linear and complex systems. We are currently focused on the tendency for some model systems, when burning, to show behaviors expected of so-called “folded bifurcations:” that is, to show transitions between basins of attraction that are not reversible, but involve paths “forward” and “backward” between different stable states of combustion that are quite different.

FY 2014 HIGHLIGHTS

We continue to focus on the development of soft actuators and machines – machines whose structure involves soft and/or flexible organic materials (polymers, elastomers), and whose actuation is pneumatic or hydraulic. Recently completed projects in this area have broadened the movement capabilities and material properties of soft machines and will, in future work, facilitate the construction of actuators and tools that mimic some of the behaviors (and underlying mechanisms) of living systems. 1.1 Soft Actuators. In the area of actuation, we have developed strategies for (i) controlling large numbers (>50) of independent soft actuators, (ii) actuating pneumatic networks rapidly, and (iii) constructing soft actuators that are resistant to mechanical damage. 1.2 Composites of Elastomers and Other Materials. Our recent work in this area has focused on the development of composites and/or devices that are compatible with the anisotropic motion and range of movements required by soft machines. 1.3 Reconfigurable Systems. Soft machines that rely on pneumatic actuators are, in principle, easier to reconfigure than hard machines that rely on electronic components. We have developed several methods for using reversible couplings—magnetic and mechanical—to rapidly assemble (and re-assemble) soft machines.

Directed Assembly of Bio-Inspired Supramolecular Materials for Energy Transport and Capture: Mesoscale Construction of Functional Materials I

Institution: Illinois-Urbana Champaign, University of
Point of Contact: William Wilson
Email: wlwilson@illinois.edu
Principal Investigator: William Wilson
Sr. Investigator(s): Charles Schroeder; Illinois-Urbana Champaign, University of
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$759,000 (2014-2017)

PROGRAM SCOPE

The mesoscale engineering of nanoscale building blocks holds enormous promise to catalyze a revolution in new functional materials for advanced energy technologies. Bio-inspired systems can play a key role in this effort due to their inherent “programmable” function. In this program, we explore the use of controlled hydrodynamic flows for the directed assembly of synthetic peptides in microfluidic devices as a path to new functional materials. This strategy offers repeatable, mesoscale compositional and structural control of the assembled materials, with the potential for scalability. We capitalize on tailored microscale flow dynamics and peptide precursor reaction kinetics to bias assembly of peptide monomers into nanoscale and larger constructs. The hydrodynamic assembly method holds strong potential to enable fabrication of assemblies and hierarchical constructs that cannot form spontaneously in solution. In this way, directed assembly of synthetic peptides using microfluidics allows for unprecedented control of materials structure and properties at the nano and mesoscale. The overall goal of this research program is to understand the basic scientific foundation and the mesoscale materials design rules. In summary, the proposed work aims to “engineer” a new class of mesoscale functional materials. This new assembly strategy will fundamentally impact work in chemistry, physics, and materials science that will profoundly change how we think about designing and manipulating biomaterials.

FY 2014 HIGHLIGHTS

We are developing microfluidic device based approaches for fabrication of self-assembled polypeptide “nanostructures” with tailored materials properties. In this approach, flow fields in microfluidic systems are controlled in order to generate hydrodynamic flows that drive assembly of peptide materials. We are quantitatively characterizing the first microfluidic devices used to drive assembly at the flow interface between a flow focused, pH buffered monomer stream and an adjacent acid stream. This strategy facilitates geometric control of mesoscale structure. This initial year we are quantifying the device flow dynamics and the overall assembly kinetics. We have confirmed spectroscopically, and using Atomic Force Microscopy (AFM), the hydrodynamic control on polypeptide structure. We have acquired the first nanoscale images of these engineered materials. Moreover we are modeling the tailored microscale flow dynamics and reaction kinetics these 2-D linear flows, via COMSOL. This microfluidic-based method continues to show the potential and enables fabrication of assemblies and hierarchical constructs that cannot form spontaneously in solution. Given the wide array of macrostructures that can have synthesized using this strategy, we are developing new optical methods to image and study the electronic properties of the synthetic hydrogels formed in-situ. We have built a confocal spectral imaging system which allows us to probe how differences in hierarchical structure impacts the optical/electronic spectral properties and map the assembly kinetics as a function of peptide monomer structure. We are using molecular dynamics (MD) simulations to explore structural impact on assembly

dynamics and products. Techniques including nano CD, time-resolved non-linear microscopy, and x-ray analysis in the microfluidic reactors are being used.

DOE National Laboratories

Dynamics of Active Self-Assembled Materials

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Igor Aronson
Sr. Investigator(s): Alexey Snezhko; Argonne National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$976,000 (2014)

PROGRAM SCOPE

Dynamics of Active Self-Assembled Materials research program is focused on the fundamental aspects of out-of-equilibrium dynamics and self-assembly of bio-inspired materials for emerging energy applications. It paves the way for the discovery of tailored self-assembled materials and structures that can self-heal, regulate porosity, strength, water or air resistance, viscosity, or optical properties. The program synergistically combines experiment, theory, and simulations. It emphasizes strong cross-disciplinary ties with other research programs in Argonne, the Institute for Molecular Engineering of the University of Chicago, and leading soft matter groups in the USA and worldwide. This program makes active use of Argonne's scientific user facilities: the Center for Nanoscale Materials and Advance Photon Source. Our long-term goals are to develop fundamental understanding of out-of-equilibrium self-assembly in synthetic and bio-inspired systems as it relates to BES missions in Biomolecular Materials and Mesoscale Science. In the next three years we will explore new approaches to synthesis and discovery of a broad class of self-assembled bio-inspired materials stemming from the advances of our program: functional 2D and 3D self-assembled tunable and permanent structures built from functionalized sticky colloidal particles energized by applied electric or magnetic fields, and novel dynamic biomechanical materials formed by active swimmers (bacteria) placed in structured liquids (liquid crystals). For all these complex out-of-equilibrium systems we will develop predictive theoretical multi-scale description; the mathematical models will be implemented on GPU computers.

FY 2014 HIGHLIGHTS

Surfaces decorated with dense arrays of microscopic fibers exhibit unique materials properties, including superhydrophobicity and low friction. Nature relies on 'hairy' surfaces to protect blood capillaries from wear and infection (endothelial glycocalyx). Here we report on the discovery of self-assembled tunable networks of microscopic polymer fibers ranging from wavy colloidal 'fur' to highly interconnected networks. The networks emerge via dynamic self-assembly in an alternating electric field from a non-aqueous suspension of 'sticky' polymeric colloidal particles with a controlled degree of polymerization. The resulting architectures are tuned by the frequency and amplitude of the electric field and surface properties of the particles. We demonstrate, using atomic layer deposition, that the networks can serve as a template for a transparent conductor. These self-assembled tunable materials are promising candidates for large surface area electrodes in batteries and organic photovoltaic cells, as well as for microfluidic sensors and filters. Source: Demortiere *et al*, Nature Communications, v 5, p 3117 (2014).

Active Assembly of Dynamic and Adaptable Materials

Institution: Sandia National Laboratories-Albuquerque
Point of Contact: Richard Schneider

Principal Investigator: George Bachand
Sr. Investigator(s): Erik Spoerke; Sandia National Laboratories-Albuquerque
Mark Stevens; Sandia National Laboratories-Albuquerque
Darryl Sasaki; Sandia National Laboratories-Livermore
Dominic McGrath; Arizona, University of
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 5 Undergraduate(s)
Funding: \$1,251,000 (2014)

PROGRAM SCOPE

The fundamental goal of this project is to understand and apply key principles used by living systems to develop materials whose transport, reconfiguration, and disassembly can be programmed or “self-directed” in controlled environments. Our long-term goal is to learn how to develop robust, energy-dissipative “nano-robots” that replicate many of the emergent behaviors of living systems (e.g., the ability to adaptively change color) within artificial nanocomposites. The scope of this program includes two primary themes: (i.) Active Protein Assemblies that involves the *ex vivo* use of kinesin and tubulin to assemble, manipulate, and dynamically organize hybrid and composite nanomaterials; and (ii.) Artificial Microtubules that is focused on the design and development of robust artificial analogues to the energy-consuming protein tubulin. Work on Active Protein Assemblies has focused on applying the work produced by kinesin and microtubules to actively assemble non-equilibrium structures such as ring nanocomposite, lipid nanotube networks, and heterostructured nanowires. Work on Artificial Microtubule has centered on using computational and synthetic approaches to develop peptide- and polymer-based “building blocks” capable of mimicking the structure and dynamic self-assembly of natural microtubules.

FY 2014 HIGHLIGHTS

Electrostatics and Microtubules – Understanding of how the electrostatic state of the C-terminal tubulin tails regulates the mechanical properties (i.e., persistence length) and polymer dynamics (i.e., dynamic instability) of microtubule filaments, as well as their interaction with kinesin motors. Directed Self-Assembly (DSA) – Combined experimental and theory (molecular dynamics simulation) approaches to describe the DSA of microtubule filaments into one-dimensional nano-arrays. CdS Nanotubes – Described a synthetic, biomimetic strategy to control the uniform growth of cubic zinc-blended cadmium sulfide (CdS) nanocrystals on microtubule (MT) templates, replicating the microtubule’s tubular morphology with dense CdS only a single nanocrystal thick. Microfluidic Protection – Developed novel PDMS microfluidic device to microfluidically deoxygenate reaction solutions, and regulate the formation of photo-oxidative byproducts that adversely affect kinesin motor transport and assembly of nanocomposite structures. Peptide Assemblies – Combined experiments and self-consistent field theory to study the role of amphiphilic character, hydrogen bonding behavior, and distribution of charges in the supramolecular self-assembly of asymmetrically functional, wedge-shaped peptides. Chirality in Tubules – Using molecular dynamics simulation, the essential, underlying interactions that regulate the self-assembly of tubular nanostructures with specific chirality were described. Thermally-regulated Assembly/Disassembly – Developed an efficient and practical synthetic protocol for N-alkyl bis-

maleimide crosslinkers using a reverse Diels–Alder reaction, enabling an approach for temperature-regulated assembly and disassembly of polymer filaments

Students: 5 Postdoctoral Fellow(s), 4 Graduate(s), 1 Undergraduate(s)
Funding: \$1,416,000 (2014)

PROGRAM SCOPE

The goal of the Molecular Nanocomposites project is to explore the assembly and unique emergent properties of bioinspired, nanocomposite materials created using solution-based processing methods. We seek to develop fundamental understanding and control of molecular assembly mechanisms on multiple length scales, the physical and chemical properties derived from such nanoscale assemblies, and the implications of these properties for DOE's energy mission. The Molecular Nanocomposites project is comprised of two tasks: Adaptive and Reconfigurable Nanocomposites (Task 1, PI Dale Huber) and Complex Nanocomposites (Task 2, PI Jeff Brinker). The goal of task 1, Adaptive and Reconfigurable Nanocomposites, is to explore the basic science associated with the use of energy consuming, switchable, and/or responsive components to create programmable and/or reconfigurable nanocomposites. The task aims to understand how responsive nanoparticles, surface functionalization, and organic overlayers can be used in concert to influence physical properties of both primary particles and assembled composites. The goal of Task 2, Complex Nanocomposites, is discovery and understanding of new chemically- and physically-based synthesis and assembly methodologies to construct and integrate complex porous and composite materials which exhibit structure and function on multiple length scales. It aims to establish processing-structure-property relationships for new nanocomposites prepared by self-assembly, directed assembly and templating procedures pioneered by the team members. Emphasis is on construction of 3D nanocomposites with dimensional scales and interfacial behaviors designed to allow energy conversion, transduction, or storage and/or enable biotic/abiotic integration and development of life-like structure and functionality.

FY 2014 HIGHLIGHTS

In the past fiscal year, a broad range of new approaches were developed to predict, program, control and observe the directed assembly of complex nanocomposites. FY 2014 highlights included several first demonstrations, including (a) use of switchable PNIPAM surfactants on nanoparticle arrays to reversibly actuate interparticle energy transfer, published by Dale Huber and Hongyou Fan in ACS Nano in 2014,

(b) development of pressure-directed assembly as non-chemical method for systematic tuning of interparticle distance for investigation of energy transfer and optical properties under stress, published by Hongyou Fan in Nature Communications in 2014, (c) development and characterization of surface functionalization for tethered and cushioned supported lipid bilayers to enable flexible control of lipid bilayer properties, published by Darryl Sasaki in Langmuir in 2014 and (d) development of curvature sensing molecular assemblies for the selective partitioning and attachment of proteins to structured lipid membranes, published by Darryl Sasaki, Dale Huber, and Carl Hayden in JACS in 2013. In addition, a new software release of the Tramonto-5.0 fluid density functional theory (F-DFT) code was delivered in October 2013. These theories compute fluid structure near surfaces or as a result of self-assembly, and v 5.0 includes updates to capabilities in grafting polymers to surfaces: https://software.sandia.gov//tramonto/release_notes.html. Overall, 12 publications were supported by this project, including papers in ACS Nano (2), Nature Communications, JACS, Accounts of Chemical Research, Nanoscale, Langmuir, and J. Phys. Chem. Letters. Work under this project received a spring 2014 Spring MRS Best Poster Award and 2013 Federal Laboratory Consortium "Notable Technology Development Award" for 'Self-Assembled Multifunctional Optical Coatings'.

Clathrin Biotemplating

Institution: SLAC National Accelerator Laboratory
Point of Contact: Thomas Devereaux
Email: tpd@stanford.edu
Principal Investigator: Sarah Heilshorn
Sr. Investigator(s): Sebastian Doniach; Stanford University
Nicholas Melosh; Stanford University
Andrew Spakowitz; Stanford University
Students: 1 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$335,000 (2014)

PROGRAM SCOPE

The focus of this multi-disciplinary research program is to characterize and exploit the tailored molecular interactions inherent in biological systems. Such understanding will enable deterministic formation of complex organic/inorganic constructs and engineering of responsive, biomimetic materials that exhibit self-healing and self-regulating transformations. These materials will lead to fundamentally new designs in biomimetic organic/inorganic devices for energy storage, catalysis, solar cells, and fuel cells. The team integrates a wide range of experimental and theoretical approaches to assemble, characterize, and model dynamic assembly. Our recent collaborative effort has focused on experimental and theoretical insights into the fundamentals of biomimetic self-assembly in two and three dimensions, investigating the effects of multivalency on hierarchical assembly processes, extending our strategy for non-covalent, site-specific functionalization of clathrin protein assemblies to template multiple inorganic species simultaneously on the same protein particle, and developing advanced x-ray characterization techniques for atomic scale resolution of biomaterials with local order but disorder at large length scales.

FY 2014 HIGHLIGHTS

(1) Correlated X-ray Scattering (CXS) of soft materials: Tools to study disordered systems with local structural order, such as proteins in solution, remain limited. The Doniach lab has recently achieved a breakthrough in X-ray science by demonstrating for the first time the feasibility of CXS to obtain structural information at atomic resolution for disordered systems of ordered objects. In our

publication, we report on experimental work in which CXS signals were obtained for an ensemble of 20 nm silver nanoparticles in three dimensions. (2) Theoretical modeling of clathrin structure and responsive transformations: We developed a theoretical model of a clathrin protein lattice on a flexible membrane. Through Monte Carlo simulations, we predict the equilibrium phase behavior of clathrin lattices at various levels of tension, predicting the conditions where the lattice exhibits solid and fluid phases. We address the impact of membrane fluctuations and nanoscale indentations in modulating the local phase behavior of the clathrin lattices. Our work provides a basis for utilizing local deformations in triggering 3-dimensional vesicle budding from reorganization of 2-dimensional clathrin lattices. (3) A biomimetic system for 2-dimensional assembly of multi-functional subunits: In order to extend the lessons learned about the self-assembly of clathrin, we have designed new systems that can be produced in larger quantities and tailored to our specific needs. We are employing lithography based nanofabrication techniques to create self-assembling particles across the 100 nm – 10 μm scale with several of the characteristics of clathrin (3-legged structure, localized binding sites, propensity to attach to 2D interfaces) in order to analyze their self-assembly dynamics. By selective functionalization of the particle faces, we can order them onto fluid 2D air-water interfaces and manipulate their self-assembly structurally and chemically.

Students: 3 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$643,000 (2014)

PROGRAM SCOPE

Nature is replete with hierarchically assembled hybrid materials where the multi-scale structures confer unique properties and functions. The objective of the Bioinspired Materials FWP is to explore biomimetic pathways for design and synthesis of hierarchically self-assembled functional materials with controllable properties for energy applications. Our approach mimics Nature using organic templates coupled to mineralization proteins to control the growth of the inorganic phase to form self-assembled nanocomposites. Magnetotactic bacteria with chains of magnetic nanocrystals serve as inspiration and sources of mineralization proteins. We are developing new methods to create dynamic tunable nanostructures using reversible linkages for assembly/disassembly of inorganic nanocrystals in response to environmental conditions. This highly interdisciplinary research is facilitated by FWP investigators with diverse backgrounds in several disciplines. The synergistic combination of synthesis, materials characterization and theory provides a powerful approach for understanding mineralization processes in Nature and for expanding on these processes to grow novel nanocrystals in organic matrices *in vitro*. This controlled bottom-up approach for materials design aligns well with DOE's proposed directions in "control science", allowing for the synthesis of nanostructures such as complex magnetic nanocrystals with potential energy relevance.

FY 2014 HIGHLIGHTS

We synthesized novel magnetic nanomaterials using magnetotactic bacteria as inspiration and as a source of the biomineralization protein Mms6. While the controlled, low-temperature fabrication of uniform superparamagnetic nanocrystals remains a challenge, bioinspired routes offer room-temperature pathways for the production of many complex magnetic nanocrystals with desirable shapes and sizes. We continue to develop experimental methods, guided by theory and computation, to control the placement and self-assembly of the nanocrystals into bioinspired mesoscale structures. To expand our knowledge of biomineralization proteins beyond Mms6, we have investigated proteins from different strains of magnetotactic bacteria and developed predictive models for assembly of such nanocrystals using DNA and polymer-based strategies. Operationally, we have developed methods to pattern surfaces with arrays of magnetic nanocrystals by selectively localizing the mineralization proteins on surfaces as well as developed scattering and spectroscopy methods to investigate the biomineralization process and the interaction of the biomineralization proteins with various monolayer surfaces and with iron.

Molecularly Engineered Biomimetic Nanoassemblies

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor

Hsing-Lin Wang; Los Alamos National Laboratory
Reginaldo Rocha; Los Alamos National Laboratory
Sunil Sinha; California-San Diego, University of
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$365,000 (2014)

PROGRAM SCOPE

We are rapidly approaching the next revolution in materials science where first principles design will yield the assembly of materials having specific emergent properties. An especially rich area for this transformation to be realized is in the assembly of materials that absorb, transport, or manipulate light energy. Natural light-harvesting systems provide exquisite examples of such materials through genetically encoded assemblies that are dynamic, repairable, and tunable in response to external stimuli. We can predictively create materials with similar functionalities if only we can develop: bright chromophores with broad spectral coverage, photostability, and high fluorescence quantum yields; predictive models for assembly of these chromophores to control light absorption, emission and energy transfer over defined distances; and control over the dynamics of assembly. Toward reducing those gaps in knowledge, we will mimic Nature and develop optically and electronically active molecular components with unique size and intermolecular optical phenomena, and then assemble these materials into complex architectures by taking advantage of recent advances in predictive *de novo* protein design and DNA assembly. This materials fabrication approach allows us to fine-tune the emergent optical and electronic properties. Interwoven through the entire project is a characterization effort that addresses both functional and structural characterization of the resultant materials. The targeted assembly types and methods also allow study of materials ranging from classic 2D self-assembled thin films systems to multi-layer and bulk materials. Overall, we anticipate gaining

fundamental knowledge of how to manipulate light energy using new types of chromophores and their assemblies, a consistent thrust throughout our program past and future.

FY 2014 HIGHLIGHTS

We aim to generate materials with characteristics inspired by the complex assemblies found in Nature, producing chromophores and their functional assemblies with both tunable and adaptive behavior, and producing materials capable of control of light harvesting. Toward mimicking Nature, we 1) develop new chromophores (fluorescent noble-metal nanoclusters and conjugated organic oligomers); 2) develop DNA and computationally designed peptide assemblies; and 3) apply a suite of characterization tools to understand their emergent properties upon assembly. 1) We have created a pH sensitive fluorescent and white light emissive chromophore of polyphenylene vinylene oligomer (OPP) that shows controlled intermolecular charge transfer; a fluorescent tyrosine-OPP; and redesigned a 2D conjugated thiophene polymer. 2) We have used Rosetta Design to create helical peptides that assemble into planar mesoscopic hexagonal arrays and have imparted those assemblies with temperature-dependent changes in hexagon size, through addition of a genetically engineering elastin polymer. 3) We have templated an Au₁₄₄ cluster within elastin peptides [Au₁₄₄ clusters are directly between the size of clusters (10s of metal atoms) and particles (100s of metal atoms, plasmonic)]. Additionally, we have utilized a previously created and highly stable fluorescent nanocluster (DNA templated) to study its photophysical behavior upon assembly through DNA base pairing or controlled aggregation. We find that the cluster undergoes a series of reversible energy transfer reactions between the monomer to dimer to trimer nanocluster, until finally the monomer is fully consumed and the remaining fluorescence is from the near-IR emitting trimer nanocluster (a first in the cluster community). Further, we have created a cationic OPP that takes on new emergent properties upon incorporation within genetically engineered elastin assemblies.

Directed Organization of Functional Materials at Inorganic-Macromolecular Interfaces

Institution: Lawrence Livermore National Laboratory
Point of Contact: Eric Schwegler
Email: schwegler@llnl.gov
Principal Investigator: Aleksandr Noy
Sr. Investigator(s): James De Yoreo; Pacific Northwest National Laboratory
Anthony van Buuren; Lawrence Livermore National Laboratory
Students: 10 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$631,000 (2014)

PROGRAM SCOPE

We are investigating controls on directed organization in biomimetic systems, and the links between organization and function that emerges from assembly of nanoscale components. In one study, we utilize phospholipid bilayers on Si nanowires as a basic bionanoelectronic device scaffold. The bilayer produces a barrier against ion transport and provides an artificial environment for membrane proteins. We are performing studies of protein and lipid assembly process, characterizing the atomic scale structure using x-ray scattering, and assessing energetic parameters controlling organization via kMC models. We are incorporating these structures in working multi-component bioelectronic devices and show how complex device functionality emerges from a combination of materials properties and targeted protein functionality. We have also been designing and building novel biomimetic components that could take over the role of membrane proteins in these structures. In a second set of studies, we are investigating the dynamics of macromolecular self-assembly into 1D and 2D ordered structures in

systems where required conformational changes limit assembly kinetics. We exploit variations in solvent composition and substrate chemistry to manipulate interactions and control the resulting architecture. We use *in situ* AFM and TEM investigate assembly dynamics, micro-Raman/FTIR and force spectroscopy to identify and quantify intermolecular interactions, and MD and kMC simulations to test mechanistic models of assembly. We are also utilizing DNA origami as a scaffold upon which to build heterostructures with Au nanoparticles and MS₂ viruses. The latter are modified to include light adsorbing centers for light harvesting. Light harvesting efficiency is measured as a function of virus-virus and virus-nanoparticle spacing and the results are compared to predictions based on finite-difference time-domain numerical simulations.

FY 2014 HIGHLIGHTS

(1) Demonstrated multicomponent assembly of bioelectronic devices involving ionophores and light-activated membrane proton pumps that perform biological regulation of device activity. (Advanced Materials, 2014). (2) Refined synthetic conditions for producing CNT porins- biomimetic analogs of ion channels. Characterized structure and transport properties of the CNT porins using cryo-TEM, single molecule transport studies, and bulk transport studies. (Nature, 2014; Nano Letters, 2014). (3) Used high-speed AFM for in-situ monitoring of dynamin protein assembly on lipid-coated nanowire templates. Obtained the first images of GTP-induced disassembly of the protein complex from a curved template. (Manuscript in preparation, 2014). (4) Used a combination of SAXS and STXM to determine atomic level structural ordering in lipid bilayers adsorbed on the SiNW surface. (submitted, Advanced Materials Interfaces). (5) Used SAXS to study the formation and bilayer structure of (DOPC) coating on Silicon nanowires (SiNWs) as a host matrix for self-directed reconstitution of Proteorhodopsin (pR) protein membrane. (6) Exploiting the ability of vicinal sapphire surfaces to induce block alignment in block copolymer films, we showed that S-layer protein assembly on such films is directed exclusively along the blocks. (7) Used *in situ* TEM and AFM to investigate both Ca-induced globule formation by polyelectrolyte polymers chosen to mimic protein scaffolds in biominerals and the subsequent mineralization of the globules (in revision Nature Materials). (8) Developed a new bioconjugation strategy that utilizes potassium ferricyanide-mediated oxidative coupling to attach aniline-functionalized AuNPs to o-aminophenol-containing oligonucleotides, peptides, and proteins. (Bioconjugate Chem, 2014). (9) MD simulations of a bead-spring model of collagen showed that all of the architectures observed experimentally could be reproduced with a periodic arrangement of strong and weak bead-bead interactions (Langmuir, 2014).

Soft Matter Physics

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Benjamin Ocko
Sr. Investigator(s): Antonio Checco; Brookhaven National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$699,000 (2014)

PROGRAM SCOPE

The primary goal of the group is to understand the effects of mesoscopic confinement and the role of self-assembly in soft materials through the use of nano-patterned templates and well-defined interfaces. We use synchrotron x-ray scattering and scanning probe techniques to study fundamental

properties of biomolecular materials, simple liquids, complex fluids, molecular and macromolecular assemblies, and polymers at liquid-vapor, liquid-solid and liquid-liquid interfaces. The challenges are (1) to understand interfacial and nanoscale confinement effects of liquids including the relationship between macroscopic phenomena and nanoscale behavior, (2) how templates, confinement and molecular anisotropy can be used to direct the assembly properties of soft matter including molecular orientations and long-range positional order, (3) to understand how similar self-assembly behavior arises for a wide variety of systems (4) how order correlates with function. Structural aspects of self-assembly in thin organic films underlie many emerging organic based devices and energy technologies. The Group has carried out measurements at NSLS (BNL) and APS (Argonne) and has an approved Partner User Proposal at the Soft Matter Interfaces Beamline at NSLS II.

FY 2014 HIGHLIGHTS

Superhydrophobicity, a bioinspired phenomenon, was investigated using x-ray diffraction in arrays of ~20 nm-wide silicon textures with cylindrical, conical, and linear features. The superhydrophobic state was found to vanish above critical pressures that depend on texture, shape, and size, in agreement with classical capillary theory. Fabricated superhydrophobic surfaces with well-defined geometries at the 10-nm scale using diblock-copolymer assisted lithography. The anti-icing properties of the surfaces have been characterizing using high-speed optical imagery, water droplet freezing, and ice adhesion experiments. The nanopatterned surfaces delayed ice formation and dramatically reduced ice adhesion. The analysis of the X-ray Reflectivity from a series of alkane-water interface show that the width of the potential hydrophobic gap at these oil-water interfaces is significantly smaller than the values previously reported. Demonstrated via *in situ* SAXS measurements the assembly of a body-centered cubic lattice of P22 virus-like particles (VLP) electrostatically induced by mixing peptide linker-tethered P22 VLPs with smaller and oppositely charged dendrimers in solution. X-ray reflectivity structural measurements of the of silicon oxide in contact with bulk liquid or vapor octadecanol. Over a range of temperature (~ 12 °C) above the freezing point of C¹⁸OH an extremely well defined monolayer forms at the solid interface that consists of well-packed, surface-normal molecules. X-ray reflectivity measurements of silicon substrates reveal for the first time the existence of a thin, low density layer intruding between the single-crystalline silicon and the amorphous native SiO₂ terminating it. The inclusion of this layer is essential for an accurate determination of the structure of soft materials on these interfaces. Octadecyltrichlorosilane self-assembled monolayers on sapphire (0001) show the existence of a pseudo-rotational epitaxial monolayer.

EARLY CAREER: Real-Time Studies of Nucleation, Growth and Development of Ferromagnetism in Individual Protein-Templated Magnetic Nanocrystal

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov
Principal Investigator: Tanya Prozorov
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The research of the Emergent Magnetic and Atomic Structures Group is aimed at determining the nature of macromolecule-mediated magnetic nanoparticle formation: i.e., the mechanism of particle

nucleation, growth, the emergence of crystal structure and development of ferromagnetism in the individual bio-templated magnetic nanocrystal by utilizing the advanced electron microscopy techniques. Uniform magnetic nanoparticles with large magnetic moment and controlled magnetic anisotropy have important technological applications from data storage, to catalysis and drug delivery. Biomimetic synthetic routes offer room-temperature pathways to placement control, formation, and assembly of a variety of magnetic nanostructures with unique shapes and sizes. We work on gaining a better understanding on how the assembly of biomacromolecules dictates nanoparticle formation and functional properties. Magnetite biomineralization by magnetotactic bacteria is used as model system with the individual microorganisms monitored throughout the various steps of the biomineralization process.

FY 2014 HIGHLIGHTS

Iron biomineralization can be induced and tuned to yield a variety of biogenic magnetic materials. Iron can be biomineralized by many different microorganisms, and tweaking this process exerts control over the magnetic properties of biogenic materials. Biomioneralization can be induced and/or tweaked to yield nanocrystals with tunable composition and magnetic properties. Moreover, comprehensive characterization of biominerals has revealed the key factors affecting bacterial iron biomineralization.

Electron and Scanning Probe Microscopies

Principal Investigator: Philip Batson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$360,001 (2014-2015)

PROGRAM SCOPE

This project explores dielectric response in nano-structured materials, using inelastic and elastic scattering of an Angstrom-sized kilo-volt electron beam. This information will be useful for better understanding of light-matter interaction in wide ranging fields such as photo-catalysis, energy harvesting of sunlight, and information transmission in semiconductor structures using optical waveguides. Electron beams are particularly useful for this exploration, because they are capable of applying very wide bandwidth driving fields into very small volumes, revealing electronic behavior that could be put to practical use in an appropriately engineered structure. As we extend the energy scale of these studies into energy extremes, ranging from vibrational and plasmonic modes in the 10-300 meV range on the low end, and out to core losses and multiple single particle excitations in the KeV energies, we are seeking to interpret energy loss spectral information in terms of a time domain summary of specimen behavior from attosecond to picosecond time scales.

FY 2014 HIGHLIGHTS

During the present award period, we have largely completed our understanding of repulsive lateral forces on nanoparticles created during the close passage of a KeV electron. The results are surprising, and so we have been making extensive checks during this year to verify and begin exploration of implications. First, we have found that repulsive forces in nanoparticles are multipolar in character and occur during atto-second time of the very close approach of the swift electron. A key feature of our understanding is that magnetic interactions with nano-particle surface currents are necessary to understand the behavior. We find also very large forces in short wavelength patterns on the surface and within the nano-particle. Finally, in Au, we also notice evidence for collective behavior of 4d electrons, resulting in a high energy plasmonic mode near 25 eV. Dipole, optical energy plasmonic interactions do contribute to lateral forces, but at levels much smaller than the close-in multipolar modes. A manuscript is completed and being readied for submission. With the arrival of the Nion Ultra-STEM with the Hermes monochromator, we have spent extensive effort in initial instrumental operation, learning, and environmental work. We have demonstrated a 9 meV energy resolution -- a world record result -- and have begun studies of vibrational and interband excitations in various materials in collaboration with other workers. Results have appeared in Nature Letters, 514 209-212 (2014). The theoretical understanding accomplished here, together with the instrumental work to push the energy resolution and acquisition accuracy in the new instrument, provides a strong footing to accomplish the goal of

deriving time domain information from EELS spectra as promised in the Program Scope. This activity has also resulted in three invited presentations at international meetings.

EARLY CAREER: Mapping Interactions in Hybrid Systems with Active Scanning Probes

Institution: Case Western Reserve University
Point of Contact: Jesse Berezovsky
Email: jab298@case.edu
Principal Investigator: Jesse Berezovsky
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 3 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal of this research is to explore nanoscale interactions in hybrid systems by harnessing the precision and flexibility of scanning probe microscopy. Projected applications in areas such as energy conversion, opto-electronics, and spintronics will involve hybrid nanosystems composed of two or more materials or nanostructures which interact electrically, optically, or magnetically. Progress in understanding these interactions has been held back by cumbersome and/or imprecise fabrication methods. To overcome this challenge, this work will employ cantilevers with integrated active magnetic and optical components. These active probes will be controllably scanned in proximity to metal or semiconductor nanoscale structures, essentially creating a highly tunable and versatile hybrid system. This technique will allow detailed studies of interactions between optical resonators and plasmonic or spintronic nanostructures, or between dynamic ferromagnetic elements and quantum-confined electron spins. Scanned probes with an integrated optical resonator will be used to spatially map the coupling of the resonator's evanescent modes to nanoscale emitters, such as semiconductor quantum dots. Probes with radio-frequency-driven ferromagnetic microstructures will allow us to study the effect of a highly localized, dynamic magnetic field on confined electron spins. The planned research offers a significant increase of flexibility and efficiency for investigating hybrid systems over traditional nanoassembly, accelerating progress towards future technology.

FY 2014 HIGHLIGHTS

As we move towards the objective of coupling nanostructures to optical and magnetic devices fabricated on scanned cantilevers, we have obtained results on the individual components separately, before they are ultimately combined. We have constructed a combined confocal optical/scanned probe microscope, and have used optical microscopy capabilities to study photoluminescence dynamics of individual nanocrystal quantum dots. We have measured the absorption spectrum of single quantum dots at room temperature, and extracted information about broadening mechanisms [1]. We have also studied magnetization dynamics of driven ferromagnetic microstructures using a sensitive double-modulation technique. These results provide a detailed look at how magnetic domains dynamics are affected by disorder [2]. We have currently begun combining the optical and scanning probe microscopy capabilities of our setup, measuring the effect of a local electric field on quantum dot emission dynamics. Application of STEM/EELS to Plasmon-Related Effects in Optical Spectroscopy

Institution: Tennessee, University of
Point of Contact: Jon Camden
Email: jon.camden@gmail.com
Principal Investigator: Jon Camden
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

We are currently studying the (1) plasmonic energy transfer from metallic nanoparticles to neighboring materials and (2) Localized surface plasmon resonance (LSPR) and plasmon coupling in alloy nanoparticles. Understanding plasmonic energy transfer is important for developing superior photocatalytic and photovoltaic devices. Using our monochromated STEM/EELS, we are able to probe the energy transfer process at the single-particle level with high energy resolution (~120meV). The second program is based on alloy nanoparticles synthesized via pulsed laser induced liquid thin film dewetting. With this method, we can control the mole fractions of the metal and perform comprehensive studies on the tuning effects of the alloy compositions on LSPRs. Also, we are able to design and pattern nanoparticle arrays to study the collective properties of the LSPRs.

FY 2014 HIGHLIGHTS

In the first year of this proposal we have concentrated on the observation of Fano interferences using optical and electron energy-loss spectroscopies (EELS). Our experimental observations were fully correlated with continuum electrodynamics simulations and demonstrate that the mechanism responsible for optically-driven Fano resonances is similar to the EELS counterpart. As a follow-up to our work on the observation of Fano interferences in silver nanocubes, we are currently investigating the effects of substrates with varying refractive indices on the hybridization and damping of the LSPRs in silver nanocubes with 3D STEM/EELS tomography.

Nanoscale Properties of Novel Materials

Institution: Northwestern University
Point of Contact: Venkat Chandrasekhar
Email: v-chandrasekhar@northwestern.edu
Principal Investigator: Venkat Chandrasekhar
Sr. Investigator(s): Chang-Beom Eom; Wisconsin-Madison, University of
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The conducting interface that forms between the two band insulators LaAlO₃ (LAO) and SrTiO₃ (STO) has attracted a lot of interest since its discovery almost a decade ago. In the past few years, this system has proved to be a trove of interesting new physics, showing a gate-tunable conductance, superconductivity, and magnetism, among other effects. Particularly intriguing is the superconductivity and ferromagnetism, normally antagonistic phenomena, which we discovered can coexist at the interface in

appropriately grown samples. The major part of this project is devoted to investigating the nature of both the magnetism and the superconductivity at the LAO/STO interface, using electrical transport and eventually low temperature scanning probe techniques. The epitaxial films used in these studies were synthesized in the group of Prof. Chang-Beom Eom at the University of Wisconsin, Madison. The transport experiments focused on measuring the resistance of gated LAO/STO interface structures as a function of magnetic field at temperatures ranging from 25 millikelvin to room temperature in order to study the interplay between superconductivity and magnetism. These experiments involved both large two-dimensional films, as well as smaller, sub-micron structures defined by electron-beam lithography. The scanning probe work has been devoted to the development of a millikelvin range scanning probe microscope capable of performing atomic force microscopy, electrostatic force microscopy and magnetic force microscopy. Once operational, this microscope will enable us to correlate the magnetic and electronic properties of LAO/STO interface devices on the scale of a few hundred nanometers.

FY 2014 HIGHLIGHTS

The LAO/STO interface system offers a unique platform to study the superconductor-to-insulator transition (SIT), as the interface can be tuned from the superconducting state to the insulating state by means of an electric field applied by putting a voltage on a back or top gate. As with other disordered superconducting systems, it can also be tuned out of the superconducting state by applying a magnetic field, the so-called field-tuned SIT. Recently, we studied the field-tuned SIT in back-gated LAO/STO interface structures, and found a critical exponent product $z\nu \sim 7/3$, indicating that the transition is governed by quantum percolation effects. While such critical exponents have been reported previously for high resistance films, they have not been reported for a low resistance system like ours, with a maximum sheet resistance of ≈ 1.5 kohms much less than the quantum of resistance $R_Q \sim h/4e^2 = 6.45$ kohms. [Phys. Rev. B 90, 100506(R) (2014).] Scanning probe microscopes that use quartz crystal tuning forks as force transducers require instruments that can measure frequency shifts with a resolution of a few millihertz. Typically, this is done with a phase-locked loop (PLL), but to obtain the required frequency resolution, a digital signal processor (DSP) is required, greatly increasing the complexity of the instrument. We have designed and developed a hybrid analog-digital PLL that combines the simplicity of an analog front-end with the frequency resolution of a direct digital synthesis (DDS) chip that is controlled by a simple microprocessor. This has been successfully used in our home-built scanning probe microscope. [Rev. Sci. Instrum. 85, 013707 (2014).]

Structure and Dynamics of Domains in Ferroelectric Nanostructures

Institution:	Pennsylvania State University
Point of Contact:	Long-Qing Chen
Email:	lqc3@psu.edu
Principal Investigator:	Long-Qing Chen
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$160,000 (2014)

PROGRAM SCOPE

The program is centered on investigating the formation of mesoscale domain structures and their evolution in ferroelectric thin films and nanostructures under an electric and/or mechanical stress field. The main objective is to understand the fundamental thermodynamic stability of ferroelectric domain walls and multi-domain configurations as well as dynamic mechanisms of domain switching using the

phase-field method. The focus will be on BiFeO₃ and PbZr_xTi_{1-x}O₃ (PZT) systems. BiFeO₃ is one of the most promising single-phase candidates for magnetoelectric device applications and one of the most scientifically fascinating materials that may exhibit electric polarization, oxygen octahedral rotation, antiferromagnetic order, strain, and significant ionic/electronic charges while PZT is currently the most widely utilized class of ferroelectrics for piezoelectric device applications. The research is being carried out in close collaboration between the PI's group and a number of world-class experimental groups who use High Resolution Transmission Electron Microscopy (HRTEM), *in situ* TEM with Scanning Probe Microscopy (SPM), or Piezoresponse Force Microscopy (PFM) to characterize the domain structures and dynamics in high-quality ferroelectric BiFeO₃ and PZT thin films.

FY 2014 HIGHLIGHTS

(1) Fundamental Understanding of BiFeO₃ Domain Wall Energies and Structures: We determined the atomic structures and energies of domain walls in BiFeO₃, combining DFT+U calculations and aberration-corrected TEM images. The calculated wall energies (γ) follow the sequence $\gamma_{109^\circ} < \gamma_{180^\circ} < \gamma_{71^\circ}$ for the 109°, 180°, and 71° walls. We attribute the high 71° wall energy to an opposite tilting rotation of the oxygen octahedra and the low 109° wall energy to the opposite twisting rotation of the oxygen octahedra across the domain walls. We quantitatively analyze the domain walls (DWs) in BiFeO₃ and successfully explain the unusual ferroelectric DW width and energy in BiFeO₃. (2) Understanding Ferroelastic Domain Switching Dynamics under External Excitations: We analyzed the microscopic behavior of individual ferroelastic domains under electric fields and mechanical stress in a thin PbZr_{0.2}Ti_{0.8}O₃ film using *in situ* transmission electron microscopy and phase field modeling. We found that the mobility and switching behavior significantly depends on specific microstructures. Our results provide new insights into understanding of polarization switching dynamics and suggest a route to engineer electromechanical devices. (3) Discovered a First Order Morphological Transition of Ferroelastic Domains in Ferroelectric Thin Films: Ferroelastic domains in epitaxial films are often pinned by interfacial dislocations. The morphology of a pinned ferroelastic domain in Pb(Zr_{0.2}Ti_{0.8})O₃ (PZT) thin films is investigated as a function of film thickness using phase field modeling in combination with transmission electron microscope (TEM) observations. It is found that the ferroelastic domain undergoes a first-order morphological transition from a domain fully extended through the film thickness to one terminated inside the film as film thickness increases. It is demonstrated that this transition is first-order associated with abrupt changes in thermodynamic properties of the domain structure at the transition.

Combined Microscopy Studies of Complex Electronic Materials

Institution: Washington, University of
Point of Contact: David Cobden
Email: cobden@uw.edu
Principal Investigator: David Cobden
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

Many interesting electronic materials have very complex microstructure and exhibit high sensitivity to experimental conditions such as strain. Studies of small homogeneous single crystals under carefully controlled conditions are therefore needed for determining their fundamental properties. The goal of this program is to understand key aspects of important materials by combining multiple microscopy,

scanning probe and transport techniques with simultaneous control of temperature, strain, magnetic field, and vapor environment. We focus on VO₂ as a prototypical strongly correlated material, and monolayer dichalcogenide semiconductors of formula MX₂ as examples of a rich new class of electronic materials that are only available as small crystals and are susceptible to substrate, strain and environmental influence.

FY 2014 HIGHLIGHTS

A strain-controlled microscopy technique was developed with the initial aim of establishing the phase diagram of vanadium dioxide in the vicinity of the metal-insulator transition. It allowed us to determine the equilibrium boundaries between the three solid phases with unprecedented control and precision as a function of temperature and axial stress, and to locate the triple point, which coincides with the transition temperature at 65.0°C, to within a measurement accuracy of 0.1°C. In collaborative work, analysis of the scanning photocurrent microscopy of suspended single-crystal nanobeams showed that the photoresponse of vanadium dioxide is photothermal. Transmission infrared micro-spectroscopy on vanadium dioxide plates yielded the anisotropic phonon parameters and low frequency optical conductivity. Ultrafast pump-probe reflection measurements revealed that the electronic response time scale varies from just 40 fs to 200 fs between individual crystals. We also grew high quality monolayers of molybdenum disulfide and tungsten diselenide, as well as in-plane lateral monolayer heterojunctions. We created the first light-emitting diodes from lateral p-n junctions in monolayer tungsten diselenide. Bright electroluminescence was obtained with 1000 times smaller injection current and 10 times smaller linewidth than in earlier structures. By increasing the injection bias we could tune the electroluminescence between regimes of impurity-bound, charged, and neutral excitons. Using polarization-resolved photoluminescence we showed that in bilayers the emitted polarization can be continuously tuned through zero as a function of gate voltage, constituting the first demonstration of electric field control of orbital magnetic moments. We also observed linear splitting of the circularly polarized photoluminescence peaks in perpendicular fields up to 7 T, as well as magnetic tuning of the polarization, representing the first successful magnetic manipulation of valley pseudospin.

Development and Application of *In Situ* Nanocharacterization to Photocatalytic Materials for Solar Fuel Generation

Institution: Arizona State University
Point of Contact: Peter Crozier
Email: crozier@asu.edu
Principal Investigator: Peter Crozier
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

We are developing a fundamental understanding of heterostructured semiconductor-based photocatalysts for H₂ generation via water splitting. Our catalysts are composite materials consisting of light harvesting semiconducting oxides supporting catalytic nanoparticles that facilitate the transfer of excited electrons/holes for water reduction/oxidation. We are working on titania and tantalate light harvesting oxides which are functionalized with metal and metal oxide nanoparticles yielding model systems which are active under ultraviolet light. The H₂ evolution is measured in a photoreactor and advanced electron microscopy techniques (including *in situ* and *operando* approaches) are employed to

elucidate structure-reactivity relations. We are also developing and employing high energy resolution electron energy-loss spectroscopy to obtain new insights from high spatial resolution vibrational spectroscopy and band gap determinations.

FY 2014 HIGHLIGHTS

There have been three major accomplishments within the current fiscal year: (1) Instrumentation – We have completed the design and construction of a gas handling system for our newly installed aberration corrected environmental transmission electron microscope. This is required to carry out *in situ* studies on water splitting catalysts. We are now designing and constructing a light illumination system for the same electron microscope so that we can perform *in situ* and *operando* studies on photocatalytic water splitting materials. We have also completed construction of the first phase of an *ex situ* water splitting test reactor for testing novel photocatalysts. This is a critical step for testing materials that will be suitable for *in situ* and *operando* TEM studies of photocatalyst. (2) Structure-Reactivity Relations – We have completed a series of experiments on titania and tantalate based systems for solar water splitting. These two semiconducting oxides are functionalized with Ni/NiO core-shell structures which serve as water reduction and oxidation sites. We found that for the tantalate-based systems, increasing the thickness of the NiO shell increases the hydrogen production rate by almost a factor of 4 due to suppression of the back reaction. The core-shell structure gradually degrades and this is correlated with a reduction in the hydrogen production. For the titania based system, the activity is much lower and is associated with a photochemical reaction between the Ni metal and OH radical. The core-shell structure changes due to the Ni component undergoing photocorrosion into solution. (3) Vibrational Spectroscopy in the TEM – We have been able to detect vibrational excitations in the transmission electron microscopy for the first time using monochromated electron energy-loss spectroscopy. We have successfully observed optical phonons and molecular vibrational signatures on the surfaces of nanoparticles.

Tomographic Techniques for Electron Microscopy Vector Field Reconstructions

Institution: Carnegie Mellon University
Point of Contact: Marc De Graef
Email: degraef@cmu.edu
Principal Investigator: Marc De Graef
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$109,000 (2014)

PROGRAM SCOPE

In this project, we explore the use of forward modeling techniques in combination with Lorentz and STEM diffraction contrast transmission electron microscopy observation modes to determine quantitatively the 3-D spatial variations of vector-type physical quantities, such as magnetization and lattice displacement, and derived quantities, such as the magnetic vector potential and lattice strain, in modern engineering materials. The recent availability of spherical aberration correction combined with Lorentz transmission electron microscopy (LTEM) at both Carnegie Mellon University (CMU) and the Argonne National Laboratory (ANL) as well as at the Center for Electron Microscopy and Analysis at the Ohio State University (OSU) opens the door to quantitative 3D high resolution studies of both magnetic material systems and complex microstructures in materials of importance for power generation and propulsion. We build upon our earlier work in vector field electron tomography to expand the

reconstruction of 3D vector fields to the case of displacement fields in multi-phase engineering materials. We aim to create a framework for the forward modeling of tomographic image series which will be capable of dealing with both Lorentz and defect contrast images. This will then allow us to integrate the forward models with model-based tomographic reconstruction algorithms that are currently being developed. This program will result in an efficient, modular, accurate, iterative tomographic reconstruction technique, which can be used for the reconstruction of 3D vector fields, in particular magnetization and defect displacement fields. Our work will lay the foundation for the eventual routine determination of 3D vector fields by TEM techniques.

FY 2014 HIGHLIGHTS

We have created a flexible numerical approach that allows us to consider a magnetic sample as a superposition of magnetized spheres, whose projections can then be superimposed to obtain the magnetic phase shift for an arbitrary magnetization configuration. This approach allows us to create an accurate forward model that will be part of the model-based iterative reconstruction (MBIR) approach for vector field electron tomography. We have also created a flexible algorithm for the numerical simulation of STEM diffraction contrast images of defects in thin foil samples; this algorithm will form the basis for a new MBIR algorithm that will eventually allow us to reconstruct the 3D displacement field around lattice defects,

EARLY CAREER: In-situ TEM Observations of Degradation Mechanisms in Next-Generation High-Energy Density Lithium-Ion Battery Systems

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Shen Dillon
Email: sdillon@illinois.edu
Principal Investigator: Shen Dillon
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project seeks to characterize nanoscale processes associated with the degradation of next-generation high energy density lithium-ion battery electrodes via in-situ transmission electron microscopy (TEM). Dynamic processes active in the electrodes, electrolyte, and intervening interfaces, which are chemical, electrical, and mechanical in nature, have been correlated with capacity fade in lithium ion batteries. Absent direct observation with high spatial, temporal, chemical, and crystallographic resolution, limited understanding of the complex interactions occurring between these multiple processes may be derived. This work will develop a fundamental understanding of degradation mechanisms in representative environmental conditions using commercial electrolytes and electrode designs that mimic commercial electrodes, as well as in idealized solid-state batteries that will enable in-situ atomic-resolution imaging. The research will also develop the experimental techniques necessary for investigating electrochemical systems by in-situ transmission electron microscopy and will provide a framework for distinguishing and limiting electron beam effects that could potentially influence experimental results.

FY 2014 HIGHLIGHTS

In-situ electron microscopy was used to demonstrate unambiguously, for the first time, that power-law deformation creep dominates the mechanical response of high capacity alloying electrodes based on low melting temperature systems, such as Sn-Li, Al-Li, etc. The insight was gained through the ability to dynamically track the local strain rate during lithiation of individual particles and correlate this with the critical condition for particle fracture. Similar studies have found that the fracture behavior of lower diffusivity materials such as Si is insensitive to strain rate. Until now, the importance of lithiation rate on fracture of high capacity electrodes has not been appreciated or reported in the community, and the insight provides new opportunities to engineer failure resistant high capacity electrode materials. Related in-situ TEM techniques were also utilized to study dealloying in model Cu-Au systems that are similar to prior work, completed in this project, investigating dealloying of Li-Sn. The results enable us to understand the role of microstructure in affecting porosity evolution during dealloying, and also provide additional insights into the role of surface diffusion in mediating strain relaxation, which shares similarity with the power law creep described above. The project also contributed to the development of in-situ TEM techniques. We designed, fabricated, and tested the first in-situ environmental TEM platform with low temperature capability. We demonstrated the platform in experiments characterizing phase selection during ice crystallization, but it can be similarly applied to characterizing battery cycling at low or high temperatures relevant to real world applications.

EARLY CAREER: the Nature of the Spin Dependent Surface Chemical Bond: Spin Polarized STM Studies of Metal-Organic Interfaces

Institution: North Carolina State University
Point of Contact: Daniel Dougherty
Email: dbdoughe@ncsu.edu
Principal Investigator: Daniel Dougherty
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

New approaches to spin electronics envision using organic molecular films to control spin polarized carrier flow in devices. This requires the creation of interfaces between organic molecular solids and magnetic electrodes. The spin-dependent electronic coupling at such interfaces is a challenging problem not easily amenable to computational modeling. This project applies sophisticated spin polarized scanning tunneling microscopy and spectroscopy to directly measure the spin-dependent electronic coupling in concert with single molecule imaging. Attention is focused on organic semiconductors interacting with traditional magnetic metal electrodes as well as with more exotic substrates such as magnetic oxides and topological insulators. Important topics include whether covalent chemical bonds are created between the substrate and the molecule, which molecular orbitals are involved in interactions, and to what extent orbitals can be spin polarized by interacting with spin-split substrate states. The end goal is to identify the most important spin-dependent interactions at typical interfaces of interest for the emerging technology of organic and molecular spintronics.

FY 2014 HIGHLIGHTS

In 2014, the project reconstructed the spin polarized STM instrument for more rapid experimental throughput. This included upgrades to sample and tip preparation and particularly the development of bulk Cr tips that can be extensively processed during the experiment to optimize magnetic contrast in the microscope. In addition, we identified the importance of considering magnetic surface states in understanding coupling to molecules. This was particularly evident in our observations of a remarkable long range and indirect coupling between a magnetic surface state on a Cr substrate and the molecular orbitals in an organic semiconductor, PTCDA. This situation arises when the molecule couples to the non-magnetic sp bulk band that determines indirectly the lifetime of the magnetic surface state. Such a subtle effect indicates new complexities in organic spintronic interfaces and new opportunities for designing interfacial interactions by indirect means. Related to this topic of magnetic surface states was our exploration in FY 2014 of the coupling of molecules to topological insulators with spin textured surface states. These states have been recently identified as promising for spintronic applications and we think that molecular films may be valuable for spin injection. Beyond this, we also realized that specific predictions related to the breaking of time reversal symmetry with magnetic molecules can be tested with our spin polarized scanning tunneling microscope. In FY 2014, we learned to create and image topological insulators and made initial explorations of molecular film growth that are important for doping control.

EARLY CAREER: Quantum Control of Spins in Diamond for Nanoscale Magnetic Sensing and Imaging

Institution: Pittsburgh, University of
Point of Contact: Gurudev Dutt
Email: gdutt@pitt.edu
Principal Investigator: Gurudev Dutt
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal of this research is to develop a magnetic field imaging technique with nanoscale resolution that would allow for non-invasive, non-destructive probing of a variety of important physical phenomena such as quantum tunneling in single molecule magnets and quantum bits encoded into spins in quantum dots. Diamond single spin magnetic sensors are a highly promising material platform featuring high magnetic field sensitivity, nanometer spatial resolution and the important ability to operate under ambient or harsh environmental conditions required to study many material systems. The proposed work will take a multi-faceted approach toward improving the accuracy, sensitivity and robustness of this platform through a unique combination of fundamental investigations into quantum control and precision quantum metrology coupled tightly to innovative design, sophisticated nano-fabrication and advanced measurement techniques.

FY 2014 HIGHLIGHTS

Our group had invented a method for achieving accurate high dynamic range magnetometry with a precision beyond the shot-noise limit and showed significant improvement for both DC and AC fields through the use of novel quantum phase estimation algorithms (PEAs). Our latest experimental results were published in Phys. Rev. B (Rapid Comm.), and our theoretical analysis exploring both DC and AC

field sensing with PEAs was published in Phys. Rev. B. Both papers are also available on the arxiv pre-print server. We have carried out new experiments to explore the possibility of using geometric phase rather than dynamical phase for magnetic sensing, and for other applications such as gyroscopes. These results mark the first observation of geometric phase in a single solid-state spin system. The paper is available on the arxiv pre-print server.

EARLY CAREER: Time-resolved electrical, optical, and thermal probes of topological spin textures in magnetic nanostructures

Institution: Cornell University
Point of Contact: Gregory Fuchs
Email: gdf9@cornell.edu
Principal Investigator: Gregory Fuchs
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

The goal of this program is to investigate the dynamics of topological spin textures in chiral magnetic systems using a combination of electrical, optical and thermal probes. Nanoscale magnetic configurations with a non-zero topological winding number, also known as magnetic skyrmions, are of particular interest because they are expected to be protected from magnetic pinning defects and they can be moved under tiny applied currents through spin-transfer torques. Additionally, theory suggests unusual dynamical properties for individual skyrmions, including response to an electrically-driven Magnus force and behavior as a massless Dirac particle. Taken together, these topological spin textures are interesting for fundamental science and potentially as a platform for ultra-low power memory and logic devices. One challenge for this research is that magnetic materials that support stable skyrmion phases have a strong Dzyaloshinskii-Moriya interaction. This interaction is achieved in the bulk with a non-centrosymmetric crystal structure such as B20 chiral magnetic materials, or at interfaces between heavy metals and conventional magnetic materials. This program seeks to experimentally develop skyrmion containing magnetic materials and probe their behaviors using a combination of high-frequency magneto-transport, magneto-optical microscopy, magneto-thermal microscopy, and high resolution Lorentz contrast transmission electron microscopy (LTEM). We focus on understanding dynamics of individual skyrmions in magnetic nanostructures using a combination of techniques to access the relevant short length and time scales.

FY 2014 HIGHLIGHTS

This program was launched in summer of 2014. In that time we have made progress on two fronts. In the first, we have been developing a fabrication procedure capable of making lateral magnetic nanostructures with electrical contacts that are compatible with LTEM imaging. In the second, we have been developing the material synthesis of B20 chiral magnetic materials. We have succeeded in growing B20 phase FeGe thin films on Si [111] using a combination DC magnetron co-sputtering and thermal annealing. These films have been characterized using x-ray diffraction and found to be single crystal.

Polarization-Coupled Tunable Resistive Behavior in Oxide Ferroelectric Heterostructures

Chang-Beom Eom; Wisconsin-Madison, University of
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$246,338 (2014)

PROGRAM SCOPE

The main objective of this research is investigation of the physical mechanism of the electrically and mechanically tunable nonvolatile resistive behavior in oxide ferroelectric heterostructures with engineered interfaces realized via a strong coupling of ferroelectric polarization with tunneling electroresistance and metal-insulator (M-I) transitions. This proposal builds up on the breakthrough scientific results achieved during the previous DOE-supported research, which include: (1) observation of electrically tunable low-resistance state in ferroelectric tunnel junctions (FTJs); (2) demonstration of voltage-free ferroelectric and resistive switching induced by application of a localized mechanical stress gradient; (3) demonstration of a new mechanism of electrical control of 2D electron gas (2DEG) at oxide interfaces related to a switchable electrically-induced polarization in nominally non-ferroelectric oxide layers. The research goals will be achieved by creating strong synergy between cutting-edge fabrication, characterization and modeling capabilities. Extensive expertise of the PIs team (Gruverman, Eom and Tsymbal) creates a unique combination of complementary cutting-edge research approaches and provides the best opportunity for ensuing success. Using theoretical predictions, the project will identify perspective materials and structures for implementation of tunable resistance by electrical and mechanical stimuli. Furthermore, the concept of the ferroelectric junctions with electrically and mechanically tunable nonvolatile resistance represents a new paradigm shift in realization of the next-generation of non-volatile memory devices and low-power logic switches.

FY 2014 HIGHLIGHTS

Ferroelectric Tunnel Junctions with Graphene Electrodes We demonstrated a first use of graphene as electrodes in ferroelectric tunnel junctions (FTJs) – bistable resistance devices, where switching from the low (ON) to the high (OFF) resistance states is controlled by electrically induced polarization reversal. FTJs have a high potential for use in nonvolatile memory and logic devices due to their speed and low power consumption. The developed approach provides a simple and straightforward method for significant enhancement of the FTJ performance, i.e. its retention and OFF/ON ratio. A key concept of our work is introduction of a molecular layer at the graphene/ferroelectric interface by transferring graphene in different solvents on the surface of the ultrathin ferroelectric BaTiO₃ film. We show that polarization stability and resistive switching behavior of the FTJs are strongly affected by the molecular structure of this layer. Specifically, we find that the interfacial ammonia layer results in strong polarization retention and boosts the OFF/ON resistance ratio by almost three orders of magnitude. The reported results were published in Nature Communications 5, 5518 (2014).

Understanding Microscopic Mechanism of Spin Pumping and Magnetization Dynamics in Novel, Tailored Magnetic Material

Institution: Ohio State University
Point of Contact: P Chris Hammel
Email: hammel@mps.ohio-state.edu
Principal Investigator: P Chris Hammel

Sr. Investigator(s):

Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 1 Undergraduate(s)

Funding: \$185,000 (2014)

PROGRAM SCOPE

Spin pumping—the transport of spin angular momentum into neighboring material from a ferromagnet (FM) driven out of equilibrium by microwave excitation—is receiving a great deal of attention because of its potential technological importance and the richness and breadth of the science involved. A powerful diagnostic for spin pumping is the transfer of energy from the precessing magnetization that accompanies the angular momentum transport. This energy transfer is evident in measurements of the damping of the mode, damping which is in addition to the better understood intrinsic damping. This damping is unusual because it is non-local making it an exciting scientific topic in its own right. The mechanisms underlying conventional, local damping, including Gilbert-damping and spin wave emission in isolated FM films, have been extensively studied. Non-local damping is associated with transfer of angular momentum to an adjacent non-magnet (NM) layer. There is now broad agreement that spin pumping (transfer of angular momentum) and enhanced damping are two aspects of the same phenomenon and their relationship has been studied in metallic FM/NM bilayer and multilayer systems in which itinerant electrons interact across an abrupt interface. However, a quantitative description of the dependence of the spin-mixing conductance, the key parameter that quantifies spin pumping and non-local damping, on microscopic characteristics of the interface is lacking. Beyond this, and contrary to expectations from models, experimentally determined values of the spin mixing conductance are found to vary only slightly across a large variety of disparate FM and NM materials ranging from metals to semiconductors to insulators. We are studying these phenomena using microscopic scanned probe techniques and with magnetic-field defined boundaries that avoid complexities associated with material interfaces.

FY 2014 HIGHLIGHTS

Our multi-pronged approach to understanding the mechanisms by which angular momentum is transferred from the excited magnetization of a ferromagnet into adjacent material has generated 8 publications including 3 in Physical Review Letters. Using FMR spin pumping we have extensively studied the transport of spin through a variety of materials by means of the inverse spin Hall effect (ISHE) and measured the damping of the magnetization that arises specifically in association with these spin currents, and we have used FMR microscopy to study spin transport from microscopically confined spin wave modes in the absence of any material interfaces. Our scanned probe FMR measurements of the damping of spin wave modes confined solely by a strong, local magnetic field gradient have observed non-local damping. This damping is due to the transfer of angular momentum, that is spin pumping, from the confined mode into the ferromagnetic material in the surrounding film which serves as an equilibrium spin reservoir. We have explored spin transport through materials ranging from insulating oxides to transition metals to insulating ferromagnets and antiferromagnets. These studies reveal the sensitivity of spin transport to details of the interface and to the magnetic character of the material itself. We observed 1000-fold exponential decay of spin pumping across insulating barriers underscoring the importance of exchange coupling at the interface. In studies of diverse 3d, 4d and 5d metals we determined interfacial spin mixing conductances from measurements of Gilbert damping enhancement and ISHE to show that the spin Hall angle is dominated by the sensitivity of the d-orbital moment to the d-electron count. Our study of spin pumping into FM metals, including Py, Fe, Co, and Ni, revealed a high

effective spin mixing conductance. We discovered strain tuning of magnetocrystalline anisotropy over a range of more than 1000 G in epitaxial YIG films.

Switching in Solid State Memories via Nucleation and Growth Mechanisms: Causes and Effects at the Nanometer and Nanosecond Scale

Institution: Connecticut, University of
Point of Contact: Bryan Huey
Email: bhuey@ims.uconn.edu
Principal Investigator: Bryan Huey
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The development and optimization of applications comprising functional materials necessitates a thorough understanding of their static and dynamic properties and performance. While many experimental techniques are employed for such studies, high speed scanning probe microscopy is particularly suitable as it provides nanoscale maps of topographic features with simultaneous measurement of local functional properties. Leveraging such High Speed SPM and concepts enabled by it, efficient measurements and maps with nanoscale and nanosecond temporal resolution are thus uniquely feasible. This includes recent enhancements for topographic, conductivity, ferroelectric, and piezoelectric properties as originally proposed, as well as newly developed improvements to AFM-based mechanical, thermal, and photoconductivity maps. These capabilities are employed to gain novel insight into energy-efficient data storage systems such as phase change and ferroelectric memories, to map the influence of defects in energy-generation systems such as solar cells, and to guide the development of a new class of magnetoelectric switching for magnetic field sensing and data storage.

FY 2014 HIGHLIGHTS

A widely applicable modification to AFM imaging was devised that can greatly improve the accuracy of topographic and property maps, simplify AFM training and operation, and enable high speed AFM imaging even on legacy systems (Bosse et. al., *Nanotechnology*, 25, 2014). This is based on summing the traditionally measured height from AFM topography measurements with calibrated deflection (or amplitude) signals. These corrections have been overlooked essentially since AFM was invented more than 25 years ago. With suitable additional calibration steps, they are further shown to be applicable for improvements in a wide variety of property mapping variations of AFM. Leveraging high-speed imaging capabilities, multidimensional imaging with SPM was also widely implemented for mapping functional properties in phase change materials, microfabricated devices, and photovoltaics. This includes novel thermal characterization (Tovee, *JAP*, 116, 2014), ultrasound based mechanical modulus mapping (Bosse et. al., *JAP*, 115, 2014), friction mapping (Bosse et. al., *MST* 25, 2014), and conductance in photovoltaics (Kutes et. al., *Prog. Photovoltaics*, submitted, 2014). The first direct evidence of ferroelectric domains in the new class of solar cells known as perovskite thin films was also reported for polycrystalline MAPbI₃ thin films (Kutes, *J. Phys. Chem. Lett.*, 5, 2014). Multiferroics were intensively investigated as well, particularly the behavior of ferroelectric domains in poly-domain epitaxial films. This statistically revealed and spatially resolved full ferroelectric polarization reversals occurring via multiple ferroelastic switches. When coupled with overlaying ferromagnetic thin films, this allows previously

unexpected deterministic switching of magnetic domains, demonstrated with efficient room temperature control of spin valve states (Heron et. al., Nature, 516, 2014).

Vortex Matter in Confined Superconductors and Mesoscopic Hybrid Heterostructures

Institution: Temple University
Point of Contact: Maria Iavarone
Email: iavarone@temple.edu
Principal Investigator: Maria Iavarone
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$200,667 (2014)

PROGRAM SCOPE

The primary emphasis of this project is on the physics of vortices in confined superconductors and hybrid heterostructures such as superconductor-ferromagnet (S/F) systems. The goal is to understand how the physics of vortex matter changes in order to be able to predict and control the electronic properties of new hybrid systems. Vortices in superconductors can be probed with high spatial resolution by mapping the spatial variations in the electronic density of states with Scanning Tunneling Microscopy. The proposed program is divided in two parts. The first part focuses on studying the emergence of superconductivity and vortex matter in mesoscopic superconductors. Properties of superconducting materials differ greatly from the bulk properties when the size of the sample is small (compared to the coherence length and the London penetration depth). Critical parameters such as critical current and critical field can be greatly enhanced and the vortex configuration can be strongly influenced by the sample geometry. Despite many efforts over the last decade some fundamental issues are still open. In particular, we are still lacking a description of the emergence of superconductivity at the nanoscale. The second part of this program focuses on the investigation of hybrid nanostructures incorporating superconducting and ferromagnetic components. Understanding of the physics involved will be combined with searching novel guiding principles to enhance materials and devices functionalities by combining specific properties of ferromagnets and superconductors. In proximity coupled structures the interplay between magnetism and superconductivity leads to new physical phenomena with superconductivity coexisting with ferromagnetism at the interface. In magnetically coupled structures the stray field of the ferromagnet leads to an inhomogeneous superconducting state where superconductivity and vortices can be confined in channels determined by the underlying magnetic template.

FY 2014 HIGHLIGHTS

Magnetically coupled planar ferromagnet-superconductor (F/S) hybrid structures offer new avenues for manipulation of the superconductivity at the nanoscale and convenient means to control vortex dynamics. The nonuniform magnetic field produced by the ferromagnet spatially confines superconductivity. When the temperature is decreased below the superconducting critical temperature, the superconductivity nucleates first at the location where the stray field is minimum, i.e. at the domain wall, which is a realization of domain wall superconductivity. Therefore, the superconductivity is confined in tiny channels that can more or less interact depending upon the distance between them. These channels can be positioned at different locations in the superconductors by applying an external magnetic field. These effects known as domain wall superconductivity and reverse domain superconductivity were theoretically predicted and inferred experimentally only by global

measurements. Our measurements provided the first direct visualization of the nucleation of the superconductivity in regions above the domain walls. Moreover, we demonstrated that such F/S structures are attractive model systems that offer the possibility to control the strength and the location of the superconducting nucleus by applying an external magnetic field. We fabricated F/S structures consisting of Co-Pd multilayers having different stripe domains width and we found that the nucleation of superconductivity at the domain wall is critically dependent upon the domain width. Indeed, if the domains are too narrow the superconducting nuclei overlap and the superconductivity will nucleate everywhere with slight spatial inhomogeneity.

High-Resolution Photoemission Electron Microscopy on Femtosecond Time Scales

Institution: Portland State University
Point of Contact: Rolf Koenenkamp
Email: rkoe@pdx.edu
Principal Investigator: Rolf Koenenkamp
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$210,000 (2014)

PROGRAM SCOPE

The project seeks to improve the capabilities of photoemission electron microscopy (PEEM) through aberration correction and utilize these improvements in non-linear optical studies of surfaces at femtosecond time scales. A new electrostatic aberration corrector capable of simultaneous correction of chromatic and spherical aberration has been designed and is being tested and used in this project. A new approach for the determination of aberration coefficients for PEEM is developed to provide optimized corrector settings during microscope operation. The improved imaging capabilities are applied to microscopy work on ultrafast time scales. PEEM uses photo-excited electrons to generate electron micrographs from sample surfaces. In our case femtosecond multi-photon emission processes are utilized to study photon and plasmon dynamics. The goal of this work is to explore possibilities for a coherent control of the optical response in metals and transparent conductive media. The ultrafast imaging capabilities in PEEM allow us to stay within the coherence times of typical surface plasmon systems and hence study coherent control. With the direct (i.e. non-scanning) imaging capabilities in PEEM an in-situ approach appears possible and will be pursued. A detailed analysis of the correlations between optical input and sample response will allow us to establish guidelines and rules for this type of optical control. Aberration correction in this work is needed to bring the resolution into the true nanometer range and to obtain sufficient contrast at experimental photoemission yields which are customarily low.

FY 2014 HIGHLIGHTS

In the past year we have successfully developed a new method to determine the aberration coefficients in real-time, i.e. during the microscopy work on a given sample. This method is combined with a simulation-based procedure to deliver optimized corrector settings for that sample. In essence, the new method will render aberration correction in PEEM much more practical and also more precise. With further fine-tuning of the method we expect further resolution improvement in the near future. The instrument-related work on the microscope has significantly enhanced our experimental approach to image and analyze the optical response of surfaces. Using aberration correction we are now able to image photon and surface plasmon distributions at solid surfaces with a resolution of ~15nm.

Furthermore, with a two-dimensional modelling approach based on a Green's function method we are able to establish a precise simulation of the experimentally obtained images. From the comparison between simulated and experimental data we can extract the optical parameters in nanostructures on a similar spatial scale as given by the image resolution. With this information the dynamic interaction of plasmons and photons can be quantitatively evaluated, energy transfer and dissipation, coherence loss and other interactions can be analyzed directly from the images. Examples of coherent surface plasmon control have also been successfully established: In a ring-shaped gold/copper antenna of sub-micron dimensions we demonstrated, for the first time, precise and predictable position control for a localized surface plasmon resonance. Such control will be useful in many applications. Overall, our work shows quite clearly an emergent potential for applying electron imaging to light optics and plasmonics. In this project we literally observe light with electrons.

EARLY CAREER: Microscopy of Electrostatic Field Effect in Novel Quantum Materials

Institution: Texas-Austin, University of
Point of Contact: Keji Lai
Email: kejlai@physics.utexas.edu
Principal Investigator: Keji Lai
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,339 (2014)

PROGRAM SCOPE

The objective of this research is to explore the nanoscale electronic properties when charge carriers are electrostatically modulated in advanced quantum materials, such as complex oxides, layered chalcogenides, and organic semiconductors. By combining novel methods such as ferroelectric or electrolytic gating with scanning microwave impedance microscopy that probes sub-surface phenomena, this project aims to establish a new type of useful imaging methodology as well as to answer many key questions on technologically important materials. Specifically, the research will spatially resolve electronic phase transitions induced by density modulation, compare the underlying physics between bulk chemical doping and surface electrostatic doping, and investigate the microscopic origin of sub-threshold behaviors in various field-effect transistors.

FY 2014 HIGHLIGHTS

The microwave impedance microscope (MIM) is capable of detecting the nanoscale conductivity distribution in the buried semiconductor-dielectric interface through capacitive coupling. We have demonstrated the carrier density modulation at the strained BaTiO₃-Ge interface when the polarization is switched by the tip bias. To our knowledge, this is the first time ferroelectric field effect is reported on semiconductors. We have also studied electric-double-layer transistors (EDLTs) using electrolytes as gate dielectrics. Our results on ZnO substrates showed the metal-insulator transition in the EDLT structure with an ultra-thin (about 50nm) ion gel film. At the same time, successful MIM conductivity imaging has been demonstrated below the glass transition temperature of 200K. With instruments successfully installed and preliminary data obtained, we expect to enter an exciting and unexplored regime through the unique MIM measurements.

Scanning Quantum Gas Atom Chip Microscopy of Strongly Correlated and Topologically Nontrivial Materials

Institution: Stanford University
Point of Contact: Benjamin Lev
Email: benlev@stanford.edu
Principal Investigator: Benjamin Lev
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014-2016)

PROGRAM SCOPE

Microscopy techniques co-opted from nonlinear optics and high energy physics have complemented solid-state probes in elucidating exotic order manifest in condensed matter materials. Up until now, however, no attempts have been made to use modern techniques of ultracold atomic physics to directly explore properties of strongly correlated or topologically protected materials. We will continue to develop the SQCRAMscope, a novel Scanning Quantum Cryogenic Atom Microscope technique for imaging magnetic and electric fields near cryogenically cooled materials. With our SQCRAMscope, we aim to image inhomogeneous transport and domain percolation in technologically relevant materials whose order has evaded elucidation.

FY 2014 HIGHLIGHTS

Our new DOE funding began at the end of FY 2014, so we don't have as much to report as we will for FY 2015, but we can state that we have pushed the resolution of the microscope to below 1 um and increased the robustness of the BEC production apparatus. We are working on a manuscript reporting our characterizations of the sensitivity and resolution of the SQCRAMscope.

Tailoring the Electronic Properties of Graphene via Nanostructuring: An Integrated Atomic Resolution STM and Non-Contact AFM Study

Institution: Wisconsin-Milwaukee, University of
Point of Contact: Lian Li
Email: lianli@uwm.edu
Principal Investigator: Lian Li
Sr. Investigator(s): Michael Weinert; Wisconsin-Milwaukee, University of
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$186,000 (2014)

PROGRAM SCOPE

The underlying theme of the project is the study of graphene in the presence of confinement and varied boundary conditions. A necessary step is the preparation of nanostructured graphene. Work carried out during the current DOE support has demonstrated the feasibility of several routes for nanostructuring graphene, including Fe nanoparticle assisted hydrogen etching, and the growth of quantum dots on epitaxial graphene SiC. The formation of nanostructures of this 2D material necessarily leads to the existence of edges with significantly modified electronic properties. Edge states and energy level quantization are the intrinsic and interrelated consequences of the broken symmetry and quantum confinement. As the inherent boundaries of graphene quantum dots, edge structures impose potentials

that vary at the nanometer scale, representing a model system to explore relativistic quantum systems in condensed matter experiments under conditions unreachable for truly massless particles. The proposed research in the edge stability and reconstruction will lead to new discoveries in graphene such as chaotic energy level quantization, edge spin-polarization, and Anderson localization induced by edge disorder. Furthermore, our research addresses the pseudo-magnetic fields associated with the strained graphene nanostructures. To tackle these challenging tasks, a highly interactive team has been assembled, integrating the Pls' strengths in material synthesis and imaging (Li) and calculations (Weinert). With our *in situ* growth capability, unique combination of low-temperature atomic resolution STM and AFM, accompanied by density functional theory calculations, we are well positioned to conduct this research. The successful execution of the research plan will expand our knowledge base of the exotic properties and potentially enhanced functionalities of graphene, a material system that may significantly impact the fields of nano electronics and spintronics.

FY 2014 HIGHLIGHTS

During this 2014 budget period, (1) We have fabricated and demonstrated tunable bandgaps in semiconducting zigzag nanoribbons with hydrogen edge termination. (2) We have demonstrated for the 1st time metallicity in O-terminated zigzag nanoribbons. (3) We have shown that fluctuations in Schottky barrier height at the graphene-semiconductor (SiC, Si, and GaAs) junctions are directly related to the spatial and charge density variations in the graphene layer. (4) We have theoretically investigated the impact of Ag substrate on the band structure of silicene, a Si analog of graphene. (5) We have determined the atomic structure of graphene grain boundaries. These findings have led to the following publications: 1. (cover article) "Determining charge state of graphene vacancy by noncontact atomic force microscopy and first-principles calculations", Y Liu, M Weinert and L Li, *Nanotechnol.* 26, 035702 (2015). 2. "Direct experimental determination of onset of electron-electron interactions in gap opening of zigzag graphene nanoribbons", Y. Y. Li, M. X. Chen, M. Weinert, and L. Li, *Nat. Commun.* 5:4311 doi: 10.1038/ncomms5311 (2014). 3. "Transport and photoconduction characteristics of metal-graphene-4H-SiC(0001) heterojunction devices", T. Hosseini, D. Tomer, S. Rajput, L. Li, and N. Kouklin, *Appl. Phys. Lett.* 105, 223107 (2014). 4. "Intrinsic inhomogeneity in barrier height at monolayer graphene/SiC Schottky junction", D. Tomer, S. Rajput, L. J. Hudy, and L. Li, *App. Phys. Lett.* 105, 021607 (2014). 5. "Revealing the substrate origin of the linear dispersion of silicene/Ag(111)", M. X. Chen and M. Weinert, *Nano Lett.* 14, 5189 (2014). 6. STM Studies of Spin-Orbit Coupled Phases in Real- and Momentum-Space

Institution: Boston College, Trustees of
Point of Contact: Vidya Madhavan
Email: vm1@illinois.edu
Principal Investigator: Vidya Madhavan
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$154,000 (2014)

PROGRAM SCOPE

The recently discovered class of spin-orbit coupled materials with interesting topological character is fascinating both from a fundamental as well as an application point of view. One striking example is the

class of materials called 3D topological insulators (TIs). These materials host linearly dispersing (Dirac like) surface states with an odd number of Dirac nodes and are predicted to carry a quantized half-integer value of the axion field. The non-trivial topological properties of TIs arise from strong spin-orbit coupling leading to an inverted band structure; which also leads to the chiral spin texture in momentum space. In an entirely different class of topological systems, (MnSi, or Fe/Ir(111) for example) similar chiral spin texture in the form of Skyrmions is observed, but in real space. In this proposal we describe our plans to use low temperature scanning tunneling microscopy (STM) and spectroscopy (STS), back-gated STM, and spin-polarized STM to study materials with topological phases in real- and momentum-space. The materials we propose to study include 3D topological insulators, Skyrmion systems and 2D topological insulators. Using low temperature scanning tunneling spectroscopy and related techniques, our objectives answer fundamental questions such as: What is the influence of the position of the Fermi energy on the properties of topological insulators doped with magnetic and non-magnetic impurities? How far does the single particle picture apply? What are the new phases that emerge as correlations are strengthened? What are the consequences of electron-phonon coupling on the prototypical 3D TIs Bi_2X_3 ($\text{X}=\text{Se}, \text{Te}$)? How do we realize 2D topological insulators in mono- or bi-layer thin films? Can we see the edge modes in 2D topological insulators? In addition, we will use our techniques to visualize and uncover the physics of interesting new phases in topological materials such as: Landau level stripes, quantum spin Hall effect, and 1D chiral spin modes.

FY 2014 HIGHLIGHTS

A fundamental property predicted for topological crystalline insulator (TCI) family of materials is that due to symmetry constraints the orbital character of the surface state (SS) bands is different above and below the Dirac point. Both orbital- and spin-texture are therefore essential for a complete description of the TCI SS band structure. To experimentally probe this, we measured the interference patterns of $\text{Pb}_{1-x}\text{Sn}_x\text{Se}$ in the topological regime by scanning tunneling spectroscopy (STS). We find that the intensity and energy dependence of the FTs show distinct characteristics, which by comparison with theory can be attributed to orbital effects. Another central question in the field of topological insulators involves the fate of the Dirac surface states when band inversion is undone and the material becomes non-topological. Here, we use scanning tunneling microscopy to track the quantum phase transition in a topological crystalline insulator (TCI), $\text{Pb}_{1-x}\text{Sn}_x\text{Se}$, tuned by Sn content. We discover the existence of surface states in the trivial phase that have the characteristics of gapped, double-branched Dirac fermions. We demonstrate how these states induced by proximity to the topological phase, morph into robust topologically protected Dirac surface states across the critical composition. In a different study we developed a new technique to characterize electron-phonon coupling using Landau level spectroscopy. Quantifying the interaction between phonons and electrons is of immense importance for complete understanding of materials. Nearly all information about electron-phonon coupling (EPC) is contained in the Eliashberg function of the material, but its precise extraction has in part been limited due to the lack of local experimental probes. In this work, by utilizing Landau level spectroscopy, we construct a method to directly extract the Eliashberg function, and demonstrate its applicability to lightly-doped thermoelectric bulk insulator PbSe.

New Methods of Imaging Surfaces

Institution: Northwestern University
Point of Contact: Laurence Marks
Email: L-marks@northwestern.edu
Principal Investigator: Laurence Marks
Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Oxide surfaces are an important frontier, with numerous energy-related applications in areas ranging from catalysis to the emerging field of oxide electronics. Despite this, our understanding of the atomic structure of oxide surfaces is relatively primitive and it is hard to probe in detail the local atomic structure with available experimental tools. It has recently become apparent that the latest generation of aberration corrected transmission electron microscopes can image oxide surfaces in plan view with signals which are surprisingly strong and with resolutions of at least 1.5 Angstroms and probably better. It is also possible to obtain surface images not just using conventional high-resolution imaging, but also with annular dark-field and by detecting secondary electrons, again with atomic resolution. The focus of this research is to exploit this type of imaging information to improve the understanding of oxide surfaces, using both the unique UHV microscope at Northwestern University as well as advanced microscopes elsewhere in the US. This will involve both developing the methods as a tool as well as exploiting the information to solve surface structures previously unsolved (and perhaps unsolvable by existing techniques). The imaging information will be combined with other information, including direct-methods analyses based upon the use of transmission electron diffraction data, surface chemical analyses using XPS and advanced density-functional calculations including exact-exchange hybrid methods and more chemical approaches such as bond valence analyses. The last two provide energetic and chemical information which is central to understanding the thermodynamics and kinetics factors determining which surface structures form. A longer-term aim is to develop the methods so they can be used to obtain local information from the surfaces of inhomogeneous nanoscale objects such as SrTiO₃ nanocuboids.

FY 2014 HIGHLIGHTS

This period has seen substantial progress in a number of areas: 1) For SEM imaging of surfaces we now understand the details of what matters, what does not and there are some surprises such as an unexpected importance of dielectric screening at the surface. 2) We have now determined in some detail what matters for obtaining HREM images of surfaces in plan view, better than the early work from more than a decade ago. Modern aberration corrected microscopes matter. 3) We have solved quite comprehensively a large set of structures on the SrTiO₃ (111) surface including a new approach to understanding them based upon a Potts model approach. 4) We have determined a new range of structures on the SrTiO₃ (110) surface joint with collaborators in the UK and Austria. 5) We have broken new ground with KNbO₃ and NdGaO₃, oxides of technological importance for thin film growth about which nothing was previously known.

EARLY CAREER: Electron Microscopy with Vortex Beams Carrying Orbital Angular Momentum

Institution: Oregon, University of
Point of Contact: Benjamin McMorran
Email: mcmorran@uoregon.edu
Principal Investigator: Benjamin McMorran
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal of this project is to use a novel type of electron beam carrying quantized orbital angular momentum for new electron microscopy capabilities. The electron vortex beam is composed of free electrons with helical wavefunctions, analogous to optical vortices in beams of light (also known as twisted light). Unlike light, electron vortex beams also have unique magnetic properties, can be focused to atomic dimensions, and can interact with matter in unique new ways. The beams can be generated in conventional electron microscopes using a new technology: coherent electron wavefront engineering using nanofabricated diffraction holograms. This provides a way to upgrade existing instruments with electron vortex probe beams. In this project the unique orbital angular momentum, helical phase, and magnetic properties of the electron vortex will be applied to image magnetic and biological materials with unprecedented resolution using existing electron microscopes. The major objectives of the project are to (1) develop and refine diffractive electron optics for use in existing microscopes, (2) apply this new technology to image magnetic phenomena at nanometer length scales and below using scanning transmission electron microscopy (STEM) with vortex probe beams, (3) image low-scattering, normally-transparent soft materials in (S)TEM using electron vortex spiral phase filtering to provide enhanced contrast, and (4) explore and develop lower-energy scanning electron microscopy (SEM) capabilities using electron vortex beams.

FY 2014 HIGHLIGHTS

In FY 2014, we completed a study to maximize the diffraction efficiency and quality of nanofabricated diffractive optics for electrons. We wrote and published an article detailing these studies [New J. Phys. 16, 093039 (2014)]. Based on this research, we fabricated a grating for producing electron vortex beams and installed it in the TEAM I instrument at the National Center for Electron Microscopy (NCEM). We used this capability to demonstrate atomic resolution STEM images using a vortex beam [Microsc. & Microanal. 20, 84 (2014)]. After equipping a STEM instrument at University of Oregon with a highly efficient phase grating, we performed low-loss EELS measurements of a vortex beam incident upon spherical gold nanoparticles. We were able to demonstrate transfer of quantized orbital angular momentum from the beam to a surface plasmon resonance in the nanoparticle [Microsc. & Microanal. 20, 68 (2014)]. We also demonstrated initial results of chiral plasmons induced by vortex beams of a particular handedness. This is an initial demonstration of electron dichroism using vortex beams.

In Situ Analytical Electron Microscopy for Probing Dynamic Nano-Scale Electrochemistry

Institution:	California-San Diego, University of
Point of Contact:	Shirley Meng
Email:	shirleymeng@ucsd.edu
Principal Investigator:	Shirley Meng
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding:	\$180,000 (2014)

PROGRAM SCOPE

In this project, we focus on the development and optimization of *in situ* analytical electron microscopy to quantitatively understand the dynamic changes in the bulk and interfaces of electrodes and electrolytes within all solid state batteries. The objectives of the proposed research are 1) to design and fabricate all solid state batteries with a new electrochemical materials family; 2) to develop the

fundamental understanding of the dynamic chemical and electronic processes at the solid/solid interfaces of electrode/electrolyte; and 3) to make significant inroads towards understanding the basic science of ion transport and related phase transitions in electrochemical systems at the nanometer scale.

FY 2014 HIGHLIGHTS

We have successfully optimized the Focused Ion Beam (FIB) fabrication procedures used to preserve the electrochemical activity of nanobatteries and we succeeded in in-situ TEM biasing of nanobatteries. Through quantitative electron energy loss spectroscopy (EELS) characterizations we observed novel interfacial phenomena at the LiPON/LCO interfaces. We successfully correlate the phenomena to the electrochemical properties of the energy storage solid state batteries. This is the first time such interface phenomena has been observed in all solid state battery. Thin-film $\text{Li}_4\text{Ti}_5\text{O}_{12}$ (LTO) as anode material for lithium ion battery was studied using conductive atomic force microscopy (cAFM) in order to elucidate aspects of its reversible phase transition to $\text{Li}_7\text{Ti}_5\text{O}_{12}$ upon cycling. This allows us to directly observe the formation of a percolation network of electronic conductive phase and its eventual deterioration, which may be a possible degradation mechanism not yet reported before. Our work provides critical insights in designing and optimizing the next generation solid state batteries for ultra safe and long life energy storage technology.

Three-Dimensional Characterization of Nanomaterials at Atomic Resolution Using STEM Tomography

Institution: California-Los Angeles, University of
Point of Contact: Jianwei Miao
Email: miao@physics.ucla.edu
Principal Investigator: Jianwei Miao
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$195,000 (2014)

PROGRAM SCOPE

In this project, we propose to perform 3D characterization of nanoparticles at atomic resolution by using scanning transmission electron microscopy (STEM) tomography. Specifically, we will achieve the following three aims in this project. First, we will perform a comprehensive study of the non-linear diffraction and dynamical scattering effects by incorporating multislice STEM calculations into the equal slope tomography (EST) reconstruction. We will also use this simulation study to optimize the experimental parameters, including particle size, particle orientation, material composition, beam energy, defocus, and detector inner and outer angles, for 3D characterization of nanomaterials at atomic resolution. Second, we will develop methods for identifying all atoms in nanoparticles through a combination of high-quality tilt series, the EST reconstruction, 3D Bragg peak filtering and 3D atomic structure refinement. We will first verify the feasibility of locating all atoms in nanoparticles by using multislice simulations, and then optimize STEM experiments to achieve this goal. Third, we will address several outstanding materials science problems by using atomic resolution STEM tomography. Specifically, we will identify all 3D grains in Au nanoparticles at atomic resolution. We will perform 3D characterization of metallic nanocatalysts at atomic resolution, and resolve the location of all atoms and defects in core/shell structured quantum dots. Finally, we have formed an interdisciplinary team including Drs. Ulrich Dahmen and Peter Ercius of the NCEM, LBNL, Profs. Chris Regan and Yu Huang of UCLA, and Prof. Hao Zeng of University of Buffalo. We expect atomic resolution STEM tomography to

significantly expand our fundamental understanding of the structure and functions of nanoparticles and nanomaterials.

FY 2014 HIGHLIGHTS

We made the following accomplishments for the project within fiscal year 2014. First, we performed a series of STEM tomographic experiments on FePt nanocrystals. As synthesized, the FePt nanocrystals exhibit a chemically disordered face-centered cubic (FCC) phase. After thermal annealing at 600°C for ~30 minutes, the nanocrystals change to a chemically ordered face-centered tetragonal (FCT) phase and also show very strong ferromagnetism. A tilt series from an annealed FePt nanocrystal was measured. After performing an EST reconstruction, we performed the element-resolved 3D structure determination of the FePt nanoparticle at atomic resolution. Second, through numerical experiments, we demonstrate an electron tomography method for 3D structural determination of amorphous materials at atomic resolution. By combining multislice simulations of an aberration-corrected STEM with EST, we have determined the 3D atomic structure of a simulated glass particle, consisting of 334 Si and 668 O atoms, from a tilt series of 55 noisy projections. An atomic model refinement method has been implemented to locate the positions of the Si and O atoms in the reconstruction. Finally, we, together with collaborators from Fudan University in China, recently created freestanding atomic silver chains (ASCs) with more than a micrometer long that are suspended in the pores of the hollandite manganese oxide. These ASCs are very stable under ambient conditions with a wide range of temperatures. Our experimental results, including STEM images, indicate that the ASCs have tunable electronic states and exhibit exotic quantum effects such as Peierls distortions. Density functional theory calculations predict that the ASCs have one-dimensional monovalent single-atom quantized conductance.

Structure and Dynamics of Domains in Ferroelectric Nanostructures - *In Situ* TEM Studies

Institution:	Michigan, University of
Point of Contact:	Xiaoqing Pan
Email:	panx@umich.edu
Principal Investigator:	Xiaoqing Pan
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$185,000 (2014)

PROGRAM SCOPE

The main goal of the proposed research is to explore the structure and dynamic behaviors of ferroelectric domains in ferroelectric thin films and nanostructures by advanced transmission electron microscopy (TEM) techniques in close collaboration with phase field modeling. The experimental techniques used include aberration-corrected sub-Å resolution TEM and in-situ TEM using a novel scanning tunneling microscopy (STM) - TEM holder which allows the direct observation of nucleation and dynamic evolution of ferroelectric domains under applied electric field. Specifically, we propose (1) to study the roles of static electrical boundary conditions and electrical charge in controlling the equilibrium domain structures of BiFeO₃ thin films with controlled substrate constraints, (2) to explore the fundamental mechanisms of ferroelectric domain nucleation, growth, and switching under an applied electric field in both uniform thin films and nanofabricated nanostructures, and to understand the roles of crystal defects such as dislocations and interfaces in these processes, (3) to understand the physics of ferroelectric domain walls and the influence of defects on the electrical switching of

ferroelectric domains. The nucleation and dynamic evolution of ferroelectric domains observed by in-situ TEM under applied external electric field are quantitatively analyzed and directly compared with phase field simulations in Professor Long-Qing Chen's group at Penn State University.

FY 2014 HIGHLIGHTS

(1) Atomic-scale mechanisms of domain wall motion in ferroelectrics: Using unique in-situ TEM techniques, we performed the direct observation of ferroelectric domain wall motion under a probe induced electrical field with atomic resolution. The wall propagates through formation and growth of atomically thin step nuclei, in which the polarization is attenuated. The motion proceeds via a series of discontinuous jumps due to periodic lattice pinning effects. As the wall is moving away from the probe, dynamic transition from rough to smooth in wall motion is observed, along with a change of nucleation and growth rates. These observations coupled with phase-field simulations revealed how local electric fields interact with the lattice potential to enable domain wall propagation. This development offers a powerful means for exploring the physics of many types of topological defects in condensed matter systems. (2) Giant resistive switching via control of ferroelectric charged domain walls: Theoretical and experimental investigations have demonstrated that a quasi-two-dimensional electron gas can form at ferroelectric strongly charged domain walls (sCDWs) that break polarization continuity and enables formation of writable, metallicly conductive channels through the insulating bulk. Control of such sCDWs, however, has been a major challenge due to their instability. Here, using a novel *in situ* transmission electron microscopy combined with phase field simulations, we report controlled switching of resistivity in ferroelectric thin films by writing and erasing stable, nanoscale sCDWs. The switching process occurs through a novel mechanism of a transition between different lattice symmetries. The resistance can be read non-destructively and presents the largest off/on ratio ($\sim 10^5$) ever reported in room temperature ferroelectric devices, opening new avenues for engineering ferroelectric thin film devices.

Physics of Complex Materials Systems Through Theory and Microscopy/EELS

Institution: Vanderbilt University
Point of Contact: Sokrates Pantelides
Email: pantelides@vanderbilt.edu
Principal Investigator: Sokrates Pantelides
Sr. Investigator(s): Mark Oxley; Vanderbilt University
Kalman Varga; Vanderbilt University
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$280,750 (2014)

PROGRAM SCOPE

The main objective is to combine density functional theory (DFT) with Z-contrast imaging and electron-energy-loss spectroscopy, obtained with scanning transmission electron microscopes (STEMs), to elucidate structure-property relations in complex materials structures. A key subtask has been the development of computer codes that combine DFT calculations of electron excitations in solids with dynamical scattering theory that tracks the microscope's finely focused electron beam as it undergoes diffraction in the sample, exits, and gets collected in the detector, including all interference effects. These simulations are aimed at the new capabilities of aberration-corrected STEMs, which provide high-resolution two-dimensional maps of EELS spectral features, generated by collecting probe-position-dependent EELS.

FY 2014 HIGHLIGHTS

A major accomplishment during the present grant period is the joint theory/experiment demonstration that VEELS contains atomic-resolution contrast and thus can rival photon-based spectroscopies, which have low spatial resolution, for the study of complex, inhomogeneous structures. Despite long-held beliefs, based on qualitative arguments, that VEELS would not contain atomic-scale contrast, experimental data on monolayer graphene and matching theoretical simulations demonstrated the existence of atomic-scale contrast. A paper has been submitted for publication. In fiscal 2014, 10 papers have been published in premier journals. Highlights were: (1) A joint experiment-theory demonstration that stable, ultrathin (three atoms across), conducting nanowires can be fabricated in a single sheet of transition-metal dichalcogenides. (2) The discovery of a new form of crystalline order in CuInS₂ nanoparticles. All atoms reside at sites of a perfect lattice, but the Cu and In atoms, which share a sublattice, can order in several distinct ways, forming domains, without any strain or defects. These materials are expected to be suitable for thermoelectric applications. (3) The discovery that Si atoms can passivate nanoscale holes in monolayer graphene in a robust way, keeping them from filling up, so that they can be used for a variety of applications (molecular translocation, water filtering, DNA sequencing, etc). (4) A resolution of a long-standing puzzle about the magnetic properties of epitaxial lanthanum cobalt oxide thin films on different substrates. It was demonstrated that the strain is compensated by ordered oxygen vacancies, which make the films ferromagnetic and insulating, as observed.

Emerging Functionality in Transition-Metal Compounds Driven by Spatial Confinement

Institution: Louisiana State University
Point of Contact: Ward Plummer
Email: wplummer@phys.lsu.edu
Principal Investigator: Ward Plummer
Sr. Investigator(s): Jiandi Zhang; Louisiana State University
T. Zac Ward; Tennessee, University of / Oak Ridge National Laboratory
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$380,000 (2014)

PROGRAM SCOPE

The exotic properties displayed by correlated electronic materials (CEMs) such as the cuprates, manganites, ruthenates, Fe-based pnictides, and heavy-fermion compounds are intimately related to the coexistence of competing nearly degenerate states which couple simultaneously active degrees of freedom—charge, lattice, orbital, and spin states. This project focuses on the exploration of novel behavior induced by spatial confinement, strain, and chemical or physical modification of the surface or interface. Thin films will be grown and characterized *in situ* in an ultra high vacuum environment, using a combination of techniques, such as scanning tunneling microscopy and spectroscopy, low energy electron diffraction, high-resolution X-ray photoemission, angle-resolved photoemission spectroscopy, and low energy electron loss spectroscopy. High resolution scanning transmission electron microscopy, electron loss spectroscopy (BNL), x-ray diffraction, and electrical and magnetic transport measurements will be conducted *ex situ*. We focus on complex doped manganites and ruthenates, exploring the coupled structural, magnetic and electronic transitions. By combining local modifications to order parameters across the range of correlation length scales, we will investigate where the interplay of combinations of spin-charge-orbital-lattice contributions dominate or breakdown. New nanofabrication capabilities at the Center for Nanophase Materials Sciences at ORNL will be utilized to push the size of spatial confinement into the nanometer range. The electronic and magnetic properties can be tuned in

these spatially confined films by depositing electronic donors or acceptors or by patterning of magnetic nano-clusters. Strain also gives a non-thermal parameter to be use to tune electronic or magnetic phase transitions. In essence we are combining two of the grand challenges of the 21st century –Complexity and Nano-structured materials to explore and exploit emergent behavior.

FY 2014 HIGHLIGHTS

An intriguing property of many transition metal oxide thin films is that their physical properties are fundamentally different from what is observed for the bulk. One outstanding example is the nonmetallic behavior in ultrathin films of metallic oxides: a thickness-induced metal-nonmetal transition. We explore the origin of such transition by manipulating thin film growth and combining both macroscopic and microscopic characterization techniques, for $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$ (LSMO) ultrathin films. We have isolated several key driving forces -- lattice strain, oxygen vacancies, disorder, chemical segregation and interfacial charge transfer, all of which have noticeable contribution to the metal-nonmetal transition. We find that both tensile and compressive substrate strain increase the critical metal-nonmetal transition thickness. By minimizing strain effect through inserting strained buffer layers, we are able to approach the minimum critical thickness of 4 unit cell (u.c) for the transition. Further capping with a SrTiO_3 overlayer further reduces the critical thickness down to 3 u.c. However, the ferromagnetism of LSMO is more robust against reducing thickness. The ferromagnetic ground state persists down to 2 u.c. films. In particular, with decreasing film thickness, the film exhibits a weak to strong localization crossover behavior with a characteristic onset temperature (T^*) and such crossover is strongly tied with oxygen vacancies. As T^* increases and approaches to the Curie temperature (T_C), the film eventually becomes insulating. Scanning Transmission Electron Microscopy (combining atomically-resolved STEM imaging with electron energy loss spectroscopy) data confirms the surface of the film is terminated with a La/Sr-O layer rather than a MnO_2 -layer. ARXPS results also suggest that Sr segregation tends to be stronger with reduced film thickness, providing new aspects in understanding the metal-nonmetal transition.

Nano-Optical Imaging and Spectroscopy of Correlated Electron Materials

Point of Contact: Markus Raschke
Email: markus.raschke@colorado.edu
Principal Investigator: Markus Raschke
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$190,000 (2014)

PROGRAM SCOPE

The combination of optical spectroscopy with scanning probe microscopy has emerged as a new frontier of optical ultra-microscopy with a few nanometer spatial resolution. We have generalized this approach of scattering scanning near-field optical microscopy (s-SNOM) to any optical modality including linear (mid-IR to vis), inelastic (Raman), nonlinear (SHG), and ultrafast spectroscopy, and extended it to variable and cryogenic temperatures. On that basis we have demonstrated a unique application potential for probing nanoscale behavior in correlated, complex, and 2D materials. We pursue the multi-modal and multi-spectral nano-imaging of electronic and vibrational (including Drude and polaronic) resonances, structural symmetry, and ultrafast dynamics to gain insight into properties, mechanisms,

and functions of correlated electron materials (CEM), domain formation in multiferroics, polaronic thermal properties, and finite-size effects, and multivariable and optical control of 2D materials.

FY 2014 HIGHLIGHTS

Combining Drude response s-SNOM with femtosecond pump-probe microscopy we have identified a high degree of heterogeneity controlling the insulator-to-metal transition (IMT) in even single crystals of vanadium dioxide. From studies of the few 10's of femtosecond band structure collapse and nano-domain behavior during the thermally induced phase transition, a high sensitivity to local variations, such as doping, defects, and strain is suggested. This obscures the microscopic mechanism underlying the IMT raising the question on the general role of heterogeneities in correlated electron materials. In studies on graphene, we used phase-resolved surface plasmon interferometry to probe spatial variations of its underlying electronic structure due to edges, defects, and grain boundaries. Charge pooling and local variations in Fermi level, doping, and damping help understand limitations in performance of graphene based devices. Using thermal infrared near-field spectroscopy we investigated phonon-polariton coherence and control associated with the enhanced electromagnetic density of states of phonon polaritons in the thermal near-field. In collaboration with EMSL/PNNL and ALS/LBL we pursue the dissemination of s-SNOM through its implementation at DOE user facilities.

Four-Dimensional Characterization of Dislocation-Defect Interactions in Aggressive Environments - A New Approach

Principal Investigator: Ian Robertson
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$40,000 (2014)

PROGRAM SCOPE

Electron micrographs provide two-dimensional information of a specific state in time in the evolution of the microstructure. Information in the electron beam direction is missing from the micrograph as is insight to the pathway by which the evolved microstructure developed. This program addresses both issues by advancing the technique of electron tomography of defect structures in metallic systems such that it can be implemented in conjunction with dynamic experimental capabilities in the electron microscope such as straining. The ability to perform experiments in real time with three-dimensional analysis is required to enable advances in mesoscale science. Approaches to minimize the number of micrographs needed to reconstruct the tomogram along with methods to include all defects and the real space coordinate system in the tomogram have enabled quantitative quasi-four-dimensional studies of dislocation interactions with grain boundaries in FCC, BCC and HCP metals as well as dislocation-precipitation interactions in BCC metals. The combination of techniques has provided new insights to the mechanisms of slip transmission across grain boundaries in metals with different crystal structures and the mechanisms by which dislocations bypass large plate-like carbides in body-center cubic systems. Understanding these processes is essential to determining the link between atomic scale processes and macroscale assessment of mechanical properties of pure metals and alloys.

FY 2014 HIGHLIGHTS

The ability to predict the mechanical properties of polycrystalline metals and their alloys depends on determining how dislocations interact with each other and self-organize; how they interact with other obstacles; and how these processes are influenced by external variables such as stress, strain rate, strain and temperature. By combining in-situ TEM straining with electron tomography, the controlling mechanism of slip transmission as a function of temperature has been identified and shown to be the same in face-centered cubic, FCC, and hexagonal close packed, HCP, metals. The magnitude of the Burgers vector of the dislocation left in the grain boundary by the act of transmission determines the slip system activated by the grain boundary to transfer slip. Increasing the deformation temperature enhances the transfer rate but the activated system is still determined by this condition. It has been found that with increasing strain the transfer mechanism can change, the regular boundary structure can be destroyed, and the required change in misorientation across the boundary can generate a discontinuity. It has been found that slip transmission across grain boundaries in body-centered cubic systems appears to involve dislocation emission generally along the boundary. This is in contrast to FCC and HCP metals in which dislocation emission occurs from a specific volume element of the boundary. This dependence of the transmission process on the crystal structure implies differences in dislocation accommodation in the grain boundary as well as the nature of grain boundary dislocation sources. Dynamic studies of the interaction of dislocations with large plate-like carbides in bcc alloys have identified a new mechanism by which the dislocations “feel” the presence of the precipitate and cross slip to avoid interacting with it. The unanticipated finding is that the distance at which cross slip initiates appears greater than the calculated stress field of the precipitate.

Dynamical Nanoscale Electron Crystallography

Institution: Michigan State University
Point of Contact: Chong-Yu Ruan
Email: ruan@pa.msu.edu
Principal Investigator: Chong-Yu Ruan
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$183,000 (2014)

PROGRAM SCOPE

This research seeks to employ ultrafast electron crystallography to investigate the complex materials processes of nanoscale correlated oxides and plasmonics-enhanced surface nanoreaction dynamics on metal nanoparticles, with atomistic spatial and temporal resolutions. These efforts build on recent successful ultrafast electron diffraction investigations of vanadium dioxide nanobeams and the surface supported nanocrystals. The proposed research will further benefit from a recent upgrade of the system that incorporates a higher repetition rate (a factor of ten improvement) and an emerging ultrafast electron microscope with radiofrequency (RF) recompression system to significantly enhanced the probe's brightness (>100 improvement) to reach a very high level of signal level and resolution to elucidate the key mechanisms proposed to investigate here. While rather different in their respective applications, a common theme exists in the two: enhanced functionality is enabled on the nanometer scale where selectivity and strong correlations between multiple degrees of freedom play a central role. In particular, in the research of complex materials as realized by microbeam transition metal oxides (VO₂), we are investigating a novel interface-controlled metal-to-insulator transition, which potentially would permit ultrafast manipulation of the electronic state beyond the phonon timescale; on the other

hand, these states can be sustained for long-term storage by coupling the metal-to-insulator transition with structural phase transition. In the case of plasmonics-enhanced photoreactions, the key reaction coordinates to elucidate are the charge-mediated and thermally mediated channels for enhanced photoreactions. By manipulating the local morphology, we aim to control the field-enhancement and prioritize either local charge-transfer-induced or remote resonance-transfer-mediated reaction channels.

FY 2014 HIGHLIGHTS

(1) Optical control of phase transition in strongly correlated electron crystal without lattice entropy: We applied the fs optical doping and temperature control to map out the phase diagram of VO₂ polycrystalline film. By comparing different critical doses from mid-infrared and far-infrared photons, we show that the absorbed photon density rather than the enthalpy is the unifying figure of merit, and hence provided the first direct evidence demonstrating that the optically induced phase transition is driven by the photodoping effect. (2) Correlation-driven dynamics and optical tuning of CDW states in 1T-TaS₂: We report the first comprehensive studies of optical-doping-induced emergence of quantum phases and metastable states in strongly correlated electronic crystal. We showed that optical doping induced phase diagram mimics those under chemical doping and electrostatic charge carrier tuning. We also identified the subtle features unique to fs optical doping, including the induction of the hidden states which may be thermodynamically unstable under most steady-state approach, demonstrating the capabilities of high-speed non-thermal switching at meso-scales based on correlated crystals. (3) Using a high-brightness electron beam system we demonstrated for the first time ultrafast electron micro-diffraction on a single domain in HOPG at single-shot level sensitivity, and diffractive imaging at the scale of 20nm to image the large near commensurate domain dynamics in 1T-TaS₂. (4) Plasmonic enhancement effect at ice-nanocrystal-semiconductor interface: Photocarrier generation quantum yield was investigated using the ultrafast electron diffraction in reflection geometry. In addition to a single-photon enhancement at near surface plasmon resonance frequency, an enhancement at a high frequency dark mode has been established, demonstrating the unexpected complexity at the nanointerface triggered by surface plasmon resonance excitation.

Study of Energy Transport at the Nanoscale

Institution: Michigan, University of
Point of Contact: Pramod Sangi Reddy
Email: pramodr@umich.edu
Principal Investigator: Pramod Sangi Reddy
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014-2016)

PROGRAM SCOPE

The proposal seeks to experimentally investigate radiative and conductive thermal transport as well as heat dissipation (generation) at the nanoscale. In macroscale devices, heat transport via radiation and conduction is well described by the Stefan-Boltzmann law and the Fourier's law, respectively. However, recent studies have highlighted that both these laws fail to adequately describe heat transport at the nanoscale. For example, recent computational studies of nanoscale radiative heat transport have suggested that the radiative heat flux in a one-nanometer sized gap between suitably chosen planar dielectric surfaces could be five orders of magnitude larger than what is predicted by the Stefan-

Boltzmann law! This large deviation arises primarily due to contributions from evanescent waves that decay exponentially on a length scale comparable to their wavelength. Proposed Research and Methodology: Several questions regarding nanoscale heat transport and dissipation remain largely unanswered. Some of the most important questions include: 1) How do the radiative transport properties of nanometer-sized gaps (1 - 10 nm) depend on the dielectric properties of the surfaces? 2) Can radiative heat transport be enhanced by orders of magnitude in the extreme near-field? 3) What are the heat transport characteristics of atomic and molecular junctions? 4) Are quantum limited thermal transport properties realizable at room temperatures in metallic atomic chains? 5) What are the heat dissipation characteristics of atomic and molecular scale junctions? 6) Can Peltier cooling be experimentally realized in molecular junctions? Lack of progress in elucidating these nanoscale transport phenomena is primarily due to the experimental challenges in performing measurements with the desired resolution. In this project, we will systematically answer these questions by leveraging the novel scanning probe picowatt-resolution heat-flow calorimeters that were recently developed in our lab.

FY 2014 HIGHLIGHTS

We have recently leveraged the scanning probe techniques developed in this project to establish temperature differentials across nanoscale gaps of novel three terminal devices. Using these devices we demonstrated electrostatic control of thermoelectric properties in molecular scale junctions. Our results provide a rational approach for potentially achieving high efficiency thermoelectric energy conversion using molecular junctions. These results were reports in Nature Nanotechnology. Y. Kim, W. Jeong, K. Kim, W. Lee, P. Reddy, "Electrostatic Control of Thermoelectricity in Molecular Junctions" Nature Nanotechnology (2014)

Using Interfaces to Create Strongly-Coupled Magnetic-Ferroelectrics via Atomic-Scale Heteroepitaxy

Jointly funded by "Electron and Scanning Probe Microscopies" and "Synthesis and Processing Science"

PROGRAM SCOPE

Our objective is to create a ferromagnetic ferroelectric that can be deterministically switched between symmetry equivalent states using an electric field. The electric-field switching of a magnetization between 180° symmetry equivalent states has not been demonstrated in any material. The required coupling between ferroelectric and ferromagnetic domains allowing such switching is a missing feature in most multiferroics and is key to advancing the field both scientifically and technologically. Starting at the level of electrons and atoms our goal is to rationally design complex oxide heterostructures and interface-materials with this targeted emergent behavior. Using a combination of symmetry arguments and first-principles calculations to explore the connection between structural distortions and ferroelectricity in the perovskite family of materials, we have predicted electrical control of magnetism in the hexagonal rare earth ferrites. These realizations are created with atomic-layer precision, microscopically interrogated to see if there are competing mechanisms to the intended realization, and

finally their macroscopic properties are measured. Here we will develop the scientific ideas and experimental tools necessary to apply this design paradigm to the creation of multiferroics with unprecedented coupling between ferroelectric and magnetic order parameters.

FY 2014 HIGHLIGHTS

We have studied, both theoretically and experimentally, the properties of metastable hexagonal rare-earth ferrites with the $YMnO_3$ structure. In the hexagonal rare-earth manganites ($RMnO_3$), improper ferroelectricity (trimerization) leads to a network of coupled structural and magnetic vortices that induce domain wall magnetoelectricity and magnetization (M), neither of which, however, occurs in the bulk of these materials. It is relegated to the domain walls. Through a combination of first-principles calculations, group-theoretic techniques, and microscopic spin models, we have shown how the trimerization not only induces a polarization (P), but also a bulk M and bulk magnetoelectric effect. This results in the existence of a bulk linear magnetoelectric vortex structure or a bulk magnetoelectric coupling such that if P reverses so does M. We determined the intrinsic properties of the metastable hexagonal polymorph of $LuFeO_3$. We find that hexagonal $LuFeO_3$ is a canted antiferromagnet with $T_N=147$ K and a saturation magnetization, $M_s=0.018 \mu_B/Fe$. We have combined $LuFe_2O_4$ which is ferrimagnetic below 240 K, although it is not ferroelectric, with hexagonal $LuFeO_3$ that is a robust high-temperature ferroelectric with a closely related structure. The resulting precisely engineered $(LuFeO_3)_n(LuFe_2O_4)_m$ superlattices are strong ferrimagnet-ferroelectrics with the highest-known simultaneous transition temperatures. Using scanning transmission electron microscopy imaging and spectroscopy we have mapped the structure, chemistry, and polarization of these artificial multiferroics. Our results show that the superlattices have a higher ferrimagnetic ordering temperature (T_C) than either of the end members, $LuFe_2O_4$ and $LuFeO_3$, from which they are created. T_C increases to nearly room temperature with simultaneous ferroelectricity, suggesting the tantalizing prospect of the existence of the world's first single-phase room-temperature ferrimagnetic ferroelectric.

Spin-Polarized Scanning Tunneling Microscopy Studies of Nanoscale Magnetic and Spintronic Nitride Systems

Institution: Ohio University
Point of Contact: Arthur Smith
Email: smitha2@ohio.edu
Principal Investigator: Arthur Smith
Sr. Investigator(s): Jeongihm Pak; Ohio University
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

Jointly funded by "Electron and Scanning Probe Microscopies" and "Experimental Condensed Matter Physics"

PROGRAM SCOPE

Taking advantage of electron spins in gallium nitride (a Nobel prize-winning technology) is desirable in order to develop its even greater potential as a spintronic material. This project seeks to investigate spin properties in nitride-based material systems down to ultimately small spatial length scales (such as atomic dimensions), using the advanced technique of spin-polarized scanning tunneling microscopy (SP-STM). Using this method, it is possible to obtain information directly about the polarized and unpolarized spin densities of states at surfaces. We have shown through publications the promising spin properties occurring in nitride systems, such as: manganese, manganese gallium, and iron layers

deposited onto semiconducting gallium nitride; manganese and chromium doped gallium nitride layers; and layers of pure manganese and chromium nitrides. We synthesize ultra-thin films of these systems using molecular beam epitaxy (MBE), allowing us to tailor the spin properties with atomic layer precision. The magnetic/spintronic systems are then explored using both STM and SP-STM in which a magnetically functionalized needle-sharp probe is brought to within just a few atomic diameters away from, and then scanned across, the sample surface. Structural, electronic, and spin magnetic properties can be directly obtained as topographical, electronic conductance, and spin conductance images (dI/dV maps), respectively. Correlations among these interrelated properties are provided as the images are simultaneously acquired pixel by pixel. By manipulating tip and sample magnetization using an applied magnetic field, it is possible to deduce 3-dimensional spin information for complex material structures. Such information is also combined with results from different complimentary experimental techniques, and with theoretical calculations as well, in order to address a wide range of fascinating phenomena related to the growth and properties of these materials.

FY 2014 HIGHLIGHTS

Highlights related to the stated program scope include first of all, our work on manganese gallium ultra-thin films (1-25 nanometers) grown on Ga-polar GaN, which was recently published in Applied Physics Letters. We have shown that for the case of slightly Mn-rich growth conditions that there are predominantly three surface reconstruction patterns occurring, including 1x2, 2x2, and 2x3. The most commonly seen 2x2 corresponds to a manganese rich surface having a 3:1 Mn:Ga ratio, in agreement with theoretical calculations; whereas, the film is overall stoichiometric (having a 1:1 Mn:Ga ratio), indicating that excess Mn tends to segregate to the surface of the growing film. Ongoing work is extending to the gallium-rich side of growth, which will ultimately allow a comprehensive understanding of these important magnetic alloys. Secondly, we highlight our discovery of a novel 6x6-patterned surface structure induced by sub-monolayer iron deposition on the atomically smooth, Ga-polar GaN surface. These highly periodic 6x6 structures decorate the surface step edges. First principles calculations find a Ga dimer model consisting of 2/9 monolayers of iron embedded within 7/3 monolayers of Ga, resulting in a relaxed but distorted structure. These results have been published in Applied Physics Letters. Further extension of this work to the N-polar GaN case has also been carried out, which results in completely different structures forming. A final highlight of our recent work is our publication in Review of Scientific Instruments demonstrating the design and capabilities of our low-temperature SP-STM/MBE facility which also includes pulsed laser deposition. This system enables the growth of a wide variety of spintronic materials and their investigation down to the atomic scale under variable magnetic fields at low temperatures. Initial results on the N-polar GaN surface reveal novel features not previously observed in any room-temperature STM images.

Funding: \$450,000 (2014-2016)

PROGRAM SCOPE

The goal of this project is to develop a multifrequency atomic force microscopy (AFM) method, with which it will be possible to perform rapid measurements of the conservative and dissipative forces between a sharp probe and a nanoscale sample surface, simultaneously as the sample topography is recorded. The new technique will have four-dimensional capabilities, allowing force measurement as a function of the three spatial coordinates and vertical velocity of the probe. The method will be applied primarily to characterize the deformation-dependent electromechanical response of fuel cell ion exchange membranes under accelerated degradation conditions as a function of temperature, relative humidity, and mechanical strain (this work will be conducted in air environments). Additionally, the method will be extended to liquid environments and applied to study the formation process of solid electrolyte interfaces in lithium ion batteries and their evolution during cell cycling. The project will include both experimental and multi-scale simulation activities.

FY 2014 HIGHLIGHTS

We have developed and commissioned a single-pass, trimodal (3-eigenmode) multifrequency AFM methodology that enables simultaneous topographical imaging, modulation of probe-sample indentation and compositional/nanomechanical mapping of soft samples. Within this method, each vibrational eigenmode of the probe serves as a nearly independent 'control knob' that carries out a different function. The new technique is useful for rapidly visualizing and characterizing the subsurface of materials such as polymer composites and biological structures. By varying the indentation depth, the user is able to gradually reveal buried features and create 3-dimensional images of the subsurface. Additionally, we have carried out a variety of bimodal and trimodal multifrequency AFM studies that provide guidance to the user with regards to selecting optimized conditions for maximizing the image contrast without compromising the accuracy of the results (this is often a delicate trade-off in AFM). These studies have been illustrated and disseminated along with measurements performed on commercial and spin-coated proton exchange films.

Probing Correlated Phenomena in Oxide Structures with Quantitative STEM

Institution: California-Santa Barbara, University of
Point of Contact: Susanne Stemmer
Email: stemmer@mrl.ucsb.edu
Principal Investigator: Susanne Stemmer
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

The project seeks to further our understanding of atomic structure in strong electron correlation phenomena in complex oxide materials, and to advance quantitative methods for atomic scale imaging of functional oxide materials and interfaces. The project utilizes advances in quantitative scanning transmission electron microscopy (STEM) techniques and in the synthesis of oxide to heterostructures to establish quantitative relationships between atomic structure and the electrical and magnetic properties of correlated oxide interfaces. Experimental techniques include STEM-based diffraction techniques that allow for mapping of small lattice distortions and changes in the oxygen octahedral tilt patterns, with unit cell spatial resolution, at oxide interfaces. These are correlated with phenomena caused by strong

electron correlation physics that occur in these structures, such metal-insulator transitions and magnetism. Methods for quantitative analysis of STEM image intensities to elucidate local arrangements of point defects and nonstoichiometries are being developed in the project.

FY 2014 HIGHLIGHTS

We showed that quantitative HAADF-STEM can be used to obtain complete three-dimensional information about the location of individual Gd dopant atoms in a thin foil of SrTiO₃ [1]. Information is extracted from a single image, thereby avoiding alignment issues of approaches that require multiple images. We show that uncertainties in the depth positions of individual dopants are less than one unit cell in many cases, and that the method provides fully quantitative information of expectation values and establishes a quantitative criterion for the dopant visibility. The overall dopant concentration measured from atom column intensities agrees quantitatively with electrical measurements. Sufficiently thin TEM foils are key for unambiguous interpretation. We investigated the strongly modified octahedral tilts in RTiO₃/SrTiO₃ (R = Gd or Sm) heterostructures (superlattices and quantum wells), and correlated them with phenomena such as magnetism and metal-insulator transitions. Column displacements are measured using HAADF-STEM [2]. Symmetry-lowering structural distortions, measured by quantifying the Sr-column displacements, are present in the insulating quantum wells, but are either absent or very weak in metallic quantum wells, regardless of whether they are embedded in SmTiO₃ or in GdTiO₃. We showed that SrTiO₃ quantum wells embedded in SmTiO₃ remain metallic down to a single SrO layer thickness. The results provided insights into the roles of orthorhombic distortions and electron correlations in the transition to the insulating state. By combining position-average convergent beam electron diffraction (PACBED) with STEM-HAADF imaging, the R-site displacements and oxygen octahedral tilts are measured independently from each other. Principal Investigator: Paul Voyles
Sr. Investigator(s): Dane Morgan; Wisconsin-Madison, University of
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$218,000 (2014)

PROGRAM SCOPE

The goal of this project is to develop methods for characterization of single point defects using quantitative scanning transmission electron microscopy (STEM) imaging. Imaging of high atomic number (Z) substitutional impurities and interstitials has been previously demonstrated; the new challenge is to image low-Z impurities, anti-site defects, and especially vacancies. We are working towards imaging vacancies from the decrease in image intensity they create and from the distortions they impose on the positions of neighboring atoms. Both methods are made possible by our recent development of sub-picometer precision, extremely high signal-to-noise STEM imaging using non-rigid registration of a series of STEM images and by detailed, quantitative comparisons to state-of-the-art image simulations of structures derived from density functional theory. We will apply the methods we develop to problems arising from point defects in complex oxide materials relevant to solid oxide fuel cells, starting with the

prototype material (La,Sr)MnO₃. We will use simulations to guide experiments demonstrating the ability to image cation vacancies and cation vacancy / anion vacancy clusters. We will compare the density and spatial distribution of these vacancies and clusters to the predictions of a thermodynamic point defect model based on density functional theory energies, especially near surfaces and interfaces relevant to fuel cell performance.

FY 2014 HIGHLIGHTS

We have demonstrated reproducible sub-picometer precision in STEM images through non-rigid registration of a series of short acquisition time images of the same sample area. The non-rigid registration procedure corrects the instabilities that otherwise limit STEM imaging, enabling image with extremely high signal to noise ratio (SNR). High SNR enables us to locate the positions of atomic columns in the image less than 1% of spatial resolution of the image and to make detailed, quantitative comparisons of experimental image intensities to simulations. We have used high precision imaging to characterize the lattice distortions on the surface of a Pt nanocatalyst. Distortions at edges and corners of such small particles may play an important role in their catalytic activity. We have used DFT calculations to show that cation vacancies and anion vacancies have large binding energies, >1 eV as nearest-neighbor and next-nearest-neighbor clusters for both A-site and B-site cation vacancies. Since (La,Sr)MnO₃ can support both cation vacancies and anion vacancies simultaneously, bound vacancy clusters are likely to occur. STEM image simulations from DFT-derived structures predict that single La vacancies will be detectable in most samples and that single Mn vacancies will be detectable under favorable conditions. Experiments to test these predictions are underway.

Beneath and Between: Structural, Functional, and Spectroscopic Measurements of Buried Interfaces and Interactions

Institution:	California-Los Angeles, University of
Point of Contact:	Paul Weiss
Email:	psw@cnsi.ucla.edu
Principal Investigator:	Paul Weiss
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding:	\$200,000 (2014)

PROGRAM SCOPE

Spectroscopic imaging tools and methods, based on scanning tunneling microscopes (STMs), are being developed to examine buried layers and interfaces with ultrahigh resolution. These new methods will measure molecule-substrate bonds, buried dipoles in molecular layers, and key structural aspects of adsorbed molecules, such as tilt angles. We will develop the ability to locate lateral projections of molecular parts as a means of determining the structures of molecular layers. We are developing the ability to measure the orientation of buried functionality.

FY 2014 HIGHLIGHTS

We have found that we can measure and change the valency of the interactions between bifunctional carboranebithiol/selenol molecules on Au{111}. The STM can be used to measure the number of surface bonds, once calibrated with X-ray photoelectron and infrared spectroscopies. The interconversion between one and two surface bonds can be performed through protonation and deprotonation with

acid-base reactions. We have developed methods, in collaboration with Bertozzi, Gilles, and Osher, for the segmentation of domains of carboranethiols, which form two-dimensional plastic lattices. We have ascertained that proximate domains often have aligned dipoles. Thus, having real-time analysis tools has been critical for testing whether the offset between maxima in topographic, which follows the exposed molecular in this case, and in barrier-height imaging, which measures the largest buried dipoles (due here to the dipole of the cage), are due to artifacts or dipole alignment. We have found alignment both within and between domains. Molecular dynamics simulations are consistent with our results. These segmentation and analysis methods are now being applied elsewhere in our laboratory. We have used the segmentation methods, both total variation and empirical wavelets in the analysis of amyloid-forming peptides. We have accelerated the methods such that analyses now take place in real time (our first such structural analysis took two years!) such that missing information can be collected while the sample is still present. We have now advanced this work to the point where we are able to locate metal ions associated with the peptides, which cannot be done crystallographically, because these ions are not arranged periodically. We have used chemical lift-off lithography to produce metal monolayers. We are studying these monolayers, elucidating their chemistry, electronic, and optical properties as well as their potential as substrates for scanning probe and electron microscopy.

Electron Density Determination, Bonding and Properties of Tetragonal Ferromagnetic Intermetallics

Institution: Pittsburgh, University of
Point of Contact: Jorg Wiezorek
Email: wiezorek@pitt.edu
Principal Investigator: Jorg Wiezorek
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The project uses quantitative convergent-beam electron diffraction (QCBED) by transmission electron microscopy (TEM) and density functional theory (DFT) to study the electron density and nature of bonding in transition metal based alloys and intermetallics. The methods developed here focus on the bonding charge distribution as one of the quantum mechanical characteristics central for understanding of properties and validation of DFT calculations. The differences between the QCBED measured or DFT calculated electron density and those based on the independent atom model (IAM) can be visualized electron density difference maps (EDDM) which facilitate elucidating details of interatomic bonding in the transition metal based crystals. Multiple structure and temperature factors are measured simultaneously from high-quality crystal volumes by QCBED with sufficient accuracy and precision for comparison with electron density calculations by DFT. The often anisotropic temperature factors for the different atoms and atom sites in chemically ordered phases can differ significantly from those known for relevant pure element crystals due to bonding effects and thus need to be measured, ideally from the same crystal volumes as the structure factors, to facilitate robust electron density determination. The ferromagnetic ordered intermetallic phases FePd and FePt are selected as model systems for 3d-4d and 3d-5d electron interactions, while the intermetallic phases NiAl and TiAl are used to probe 3d-3p electron interactions. Additionally, pure transition metal elements up to Ta with 5d electrons are studied. This effort advances the state of the art in quantitative TEM experimentation, provides original experimental data uniquely suited for new validation approaches of DFT calculations of d-electron affected transition metals and intermetallics.

FY 2014 HIGHLIGHTS

High quality QCBED experiments and associated EDDM enabled study of details of bonding for FCC, BCC and HCP transition metals, FePd (intermetallic and solid solution), as well as for TiAl with slightly Al-rich composition. FCC metals exhibit well defined delocalized bonding charge in tetrahedral sites, while less directional, more distributed bonding charge attains in BCC EDDM's. Agreement between DFT calculated and QCBED EDDM's degrades as d-electron levels fill in the elements, and for intermetallics as d-d interactions dominate over p-d interactions. Utilizing the LDA+U approach enables inclusion of onsite Coulomb-repulsion effects in DFT calculated EDDM's, which can afford improved agreements with QCBED results [1, 2]. This implies that onsite Coulomb repulsion effects become non-negligible as the d-orbitals fill. The use of easily measured low-order structure factors as an additional experimental metric in validation of DFT calculation offers potential to capture better both total energy related properties and details of the interatomic bonding in system with d-electron orbital contributions. Relative to the CBED results the DFT EDDM for the transition metals showed slightly enhanced bonding related delocalized charge between nearest neighbor atoms [2]. QCBED experiments determined differences in the EDDM for the Al-rich and equiatomic composition intermetallic TiAl. Substitution of excess 2at.% Al on the Ti sites appears to redistribute charge from the tetrahedral sites of the FCC related structure to enhance charge delocalization to octahedral sites. QCBED of the equiatomic composition chemically disordered FCC solid solution Fe-Pd delivered isotropic temperature factors about 60% larger than for the chemically ordered intermetallic FePd which has been rationalized in terms of lattice distortion theory. [1] X. Sang, *et al*, Journal of Chemical Physics (2013) Vol. 138, 084504 [2] X. Sang *et al.*, Microscopy and Microanalysis (2014) 20 (S3) 1822.S

EARLY CAREER: *In Situ* Scanning Force Microscopy Studies of Cross-Coupled Domains and Domain Walls

Institution: New Jersey-Rutgers, State University of
Point of Contact: Weida Wu
Email: wdwu@physics.rutgers.edu
Principal Investigator: Weida Wu
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of this project is to explore the nanoscale emergent phenomena and to understand the unconventional properties of cross-coupled domains and domain walls in multiferroics, where both ferroelectricity and magnetism coexist. The giant magnetoelectric effect due to coupled ferroic orders in multiferroics is of both fundamental and technological interest and is promising for energy-efficient multifunctional applications. The presence of domains and domain walls is a distinguishing feature of any ferroic order; their responses to external stimuli determine the macroscopic properties and the functionalities of ferroic materials. To address the challenges and to directly visualize the cross-coupled domains and domain walls and their responses to the applied electric and magnetic fields, this project will develop a unique, high-resolution and high-sensitivity *in situ* scanning force microscopy (SFM). The real space imaging of domains and domain walls by SFM aims to fundamentally understand the nature of magnetoelectric cross-coupling in representative multiferroic and magnetoelectric materials.

FY 2014 HIGHLIGHTS

We developed a novel Magnetoelectric Force Microscopy (MeFM) technique that combines Magnetic Force Microscopy with in-situ modulation of high electric fields. This microscopy technique enables direct visualization of the magnetoelectric response of the domains in multiferroic materials (e.g., hexagonal manganites). The interesting observation of the sign change of magnetoelectric response at each structural domain wall was explained by theorists at Cornell and Groningen (Netherlands) using symmetry analysis and phenomenological modeling, which provides compelling evidence that the magnetoelectric coupling is mediated by a periodic lattice distortion. Furthermore, the MeFM results revealed a gigantic enhancement of magnetoelectric effect when the magnetic order can rotate freely, suggesting a viable way to enhance magnetoelectric couplings for potential multifunctional applications. The detection of magnetoelectric response at mesoscopic scales not only allows direct visualization of magnetoelectric domains, but also opens up explorations of exciting emergent phenomena in multifunctional materials with multiple coupled orders. In addition to MeFM, we developed a Background-Free Piezo-response Force Microscopy (PFM), which effectively removes the “system inherent” background, allowing high sensitivity PFM measurements of new dielectric materials such as multiferroics and improper ferroelectrics.

Transport and Imaging of Mesoscopic Phenomena in Single and Few Layer Graphene

Institution: Harvard University
Point of Contact: Amir Yacoby
Email: yacoby@physics.harvard.edu
Principal Investigator: Amir Yacoby
Sr. Investigator(s): Pablo Jarillo-Herrero; Massachusetts Institute of Technology
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 1 Undergraduate(s)
Funding: \$400,000 (2014)

PROGRAM SCOPE

The research objective of this project is to investigate novel quantum phenomena in single and few layer graphene. Special emphasis is given to the role of Coulomb interactions and to spatially varying phenomena where geometry and boundary conditions play an important role. Our experimental approach consists of both conventional transport methods as well as sophisticated local probe techniques capable of imaging the local thermodynamic and transport properties of these spatially varying quantum phenomena. We explore both naturally occurring inhomogeneities due to intrinsic disorder as well as spatially dependent phenomena arising from patterning graphene into nanostructures, introducing inhomogeneous charge densities or magnetic fields using local electrostatic gates, superconducting contacts, and contacting graphene with novel materials. Our focus is on extremely high quality few layer graphene fabricated either by suspending above a substrate or using h-BN as a support structure. Such devices have very small disorder where mesoscopic and relativistic-like phenomena in the ultra-low density regime may be studied. A few examples include the investigation of the fractional quantum Hall effect and the effects of screening on such correlated phenomena, and the investigation of hybrid superconductor-graphene devices.

FY 2014 HIGHLIGHTS

(1) We have observed an anomalous fractional quantum Hall (FQH) effect in bilayer graphene. Our measurements use a scanning single electron transistor to image the local compressibility of bilayer

graphene on h-BN. The observed sequence of FQH states and the background inverse compressibility pattern break particle-hole symmetry and instead follow a $\nu \rightarrow \nu + 2$ pattern. The $\nu \rightarrow \nu + 2$ symmetry that we observe indicates that the orbital degeneracy uniquely present in bilayer graphene is playing an important role. (2) We have induced a quantum spin Hall (QSH) state in monolayer graphene by subjecting a high quality graphene sample to a large magnetic field angled with respect to the graphene plane. Unlike previous realizations of QSH states observed in HgTe and InAs/GaSb quantum wells, this graphene QSH state is fundamentally built upon the graphene quantum Hall effect and the effects of electron-electron interactions. This approach is inspired by the similarity between the quantum spin Hall state and overlapping electron and hole-like copies of the quantum Hall effect, with the two copies having opposite spin polarizations. We have demonstrated that such a state can be induced in graphene by inverting its electron- and hole-like Landau levels through the effect of Zeeman splitting, which is induced by a large in-plane magnetic field and exchange interactions.

Probing Correlated Superconductors and their Phase Transitions on the Nanometer Scale

Institution: Princeton University
Point of Contact: Ali Yazdani
Email: yazdani@Princeton.edu
Principal Investigator: Ali Yazdani
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$240,000 (2014)

PROGRAM SCOPE

Our experimental program provides an atomic scale perspective of unconventional superconductivity – how it evolves from an unconventional conducting state, and how it competes with other forms of order in correlated electronic systems. Such phenomena are at the heart of some of the most debated issues in condensed matter physics, and their understanding is an intellectual driver for many of the DOE-BES projects for the development of novel materials, including the search for higher temperature superconductivity. Our aim is to provide a microscopic view of these exotic materials and their phase transition into the superconducting state using some of the most sophisticated scanning tunneling microscopy (STM) and spectroscopy techniques. The results of the experiments proposed here provide important evidence that will help constrain theoretical models of unconventional superconductivity, the normal states from which it emerges from, and electronic states with which it competes. The proposed program is divided into three parts. The first part will focus on examining how heavy electron states emerge in compounds in which the f orbital interacts with more itinerate electronic states and the process by which such heavy electronic states give rise to unconventional superconductivity. The second part of the proposed program will focus on how charge ordering competes with superconductivity in high- T_c cuprates. One of the key questions is to determine whether there is universality in the way charge ordering occurs in doped Mott insulators and the connection between different forms of charge ordering now observed in different cuprate families. The third, and more exploratory part of this program, will focus on the development of techniques for local Josephson tunneling with superconducting STM tips at millikelvin temperatures.

FY 2014 HIGHLIGHTS

Science 343, 393 (2014). For each of the past several years, our group has accomplished a major breakthrough in understanding the properties of high- T_c cuprate superconductors. This past year, our

group demonstrated the major experimental results showing the ubiquity of charge ordering in cuprates and its competition with superconductivity. To put this work in context, we should first note that in 2004 (M. Vershinin *et al.*, Science 2004), our group established the observation of a charge ordering signal in the temperature range above T_c in underdoped Bi-based cuprates. In the interim years, we went on to establish that this signal could be detected at the onset of the pseudogap state at T^* as well as it having the strongest signal near 1/8 doping, similar to the stripe phase in La-based cuprates found in late 1990s. In a recent combined study of charge ordering using both high-resolution, temperature-dependent spectroscopic mapping with the STM, as well as resonant elastic x-ray scattering (REXS) on the same sample, we have made several important contributions. First, we have established that the charge ordering seen with the STM is present at the same wavevector in the REXS measurements. Depending on the doping, we find this wavevector to be the same as that of Y-based cuprates or La-based cuprates, thereby establishing universality of a charge ordering mechanism across all families of cuprates. Second, we find that both the STM and REXS signals confirm that the charge ordering competes with superconductivity as it becomes weaker with decreasing temperature below T_c , where superconductivity gets stronger. Third, using the energy resolution of the STM together with its ability to obtain information about the momentum of the quasiparticles by using their interference, we established a connection between the end of the arcs of a pseudogap in momentum space and the charge ordering wavevector.

Electron Nanocrystallography of Complex Materials and Processes

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Jian Min Zuo
Email: jianzuo@illinois.edu
Principal Investigator: Jian Min Zuo
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$460,000 (2014-2016)

PROGRAM SCOPE

The project is to develop a quantitative and spatially-resolved characterization approach that will enable the study of evolution of polarization domains and symmetry in complex piezoelectric crystals. A new and quantitative method for the determination of local polarization and crystal symmetry will be developed and validated, and the method will be applied together with in-situ experiments to the study of relaxor-ferroelectric crystals. Polarization determination is based on the measurement of local structure factors by recording a large number of convergent beam electron diffraction (CBED) patterns using a scanning electron nanoprobe. To achieve this, an advanced automated refinement procedure will be developed using electron multiple scattering theory. It is anticipated that through the proposed new approach, critical data will be obtained about polarization rotation and domain wall dynamics and their correlation with external forces. The outcome of the research will make it possible to predict quantitatively domain evolutions under force and to shed new light on the mechanisms of high performance piezoelectric crystals. The local structure factor measurement method developed here is also general; applications of this method will have significant impacts on the study of local structures, especially in highly doped materials. The experiment will be carried out using advanced imaging and diffraction techniques, such as a direct electron detection camera to reduce the electron dose in order to minimize the electron beam effect on polarization switching, to enable fast diffraction pattern acquisition rate up to 1600 frames per second for time dependent study. In-column energy filter will be

employed for quantitative CBED. The in-situ experiments will be helped by a Hysitron PI95 TEM Picoindenter.

FY 2014 HIGHLIGHTS

(1) Symmetry determined in ferroelectric single crystals of PMN-PT: By quantifying the symmetry recorded in the experimental CBED patterns, we show that the symmetry of PMN-31%PT is triclinic at few nm length scales, and becomes monoclinic (MB)-like symmetry at the length scale of few tens of nm. The macroscopic symmetry determined by X-ray diffraction suggests multiple domains of different sizes in PMN-31%PT single crystal. Thus, the high piezoelectric response of PMN-31%PT single crystal at the morphological phase boundary (MPB) region is underlined by the structure that lacks local symmetry, which has an averaged monoclinic symmetry over tens of nanometers in some regions of the crystal. By comparing the experimental and the calculation results, therefore, the lack of local symmetry observed in the experimental CBED patterns is not a result from the R- and T-nanodomain structures but a result from an intrinsic structural property of PMN-31%PT single crystal. (2) Fluctuations in local symmetry revealed by CBED: Direct evidence for the volume dependence and spatial dependence of symmetry fluctuations was obtained in PMN-31%PT by CBED with help of energy dispersive x-ray (EDX) spectroscopy. Fluctuations in symmetry were determined by using different electron beam probe sizes ranging from ~2 to 25 nm from a crystal ~62 nm thick. The symmetry of PMN-31%PT was found to increase linearly as the average volume increased, and the local symmetry fluctuated from one location to another at the nanoscale. The EDX spectroscopy results indicate chemical fluctuations are significant only when the probe size decreases to ~2nm. We attributed the symmetry fluctuation to locally varying composition, composition dependent ionic displacements, and spontaneous polarization.

DOE National Laboratories

Soft Matter Electron Microscopy Program

Students: 2 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$969,000 (2014)

PROGRAM SCOPE

Our objective is to reshape the way microscopy and scattering techniques are used to investigate structure, composition and transport properties of soft matter used in emerging clean energy-related applications including lithium batteries and hydrogen fuel cells. We will study a wide array of materials ranging from sequence-specified bio-inspired polypeptoids to synthetic block copolymers made by anionic polymerization. The proposed electron microscopy work focuses on determining the morphology of ion-containing nanostructures, maximizing spatial and energetic resolution while minimizing radiation exposure and damage. This will be achieved by using novel techniques to

manipulate and detect the incident, transmitted, and scattered electrons. We pay particular attention to determination of both the 'average' morphology and statistical fluctuations around the average; fluctuations are an essential property of soft matter. We will combine hard X-ray and electron tomography to obtain high-resolution images of dendritic structures that are the root cause of failure of batteries with lithium metal anodes. This combination of techniques is needed because the dendritic structure is an isolated object, like the proverbial 'needle in a haystack'. Energy-resolved soft X-ray scattering will be used to determine the local chemical environments around the ions. The relationship between molecular structure, morphology, and ion transport on the mesoscale will be clarified by the use of polymer chains with precisely specified sequences and through the use of molecular simulations with validation through simulated characterization. Included in this effort is the first theoretical attempt to quantify observed shifts in low loss electron energy loss spectra from first principles.

FY 2014 HIGHLIGHTS

We have produced the first electron micrographs demonstrating the presence of pure water channels in hydrated fuel cell membranes. An important barrier in enabling hydrogen fuel cells is the availability of a suitable electrolyte membrane for proton transport between the electrodes. Designing ideal membranes, however, requires a fundamental understanding of the mechanism of proton transport in the membranes which requires the development of new characterization tools. The importance of water-rich channels for proton transport is well-established but little is known about the structure of these channels. We obtained high resolution images of these channels in the model polymer electrolyte membrane. Equilibration of the membrane in humid air resulted in homogeneous water-rich channels. In contrast, equilibration of the membrane in liquid water resulted in the formation of a heterogeneous proton-conducting channel comprising a central layer of pure water enveloped within polyelectrolyte brushes. The formation of the pure water layer coincided with a significant increase in proton conductivity. In fact, the estimated conductivity within the layer was comparable to that of an equivalent hydrochloric acid solution. Filtering of the raw electron micrographs within certain spatial frequencies, and our use of model block copolymers with well-defined periodic morphologies were essential for determining the presence of water-rich channels.

Probing Phase Transitions, Chem. Reactions, and Energy Transfer at the Atomic Scale: Multifunctional Imaging with Combined Electron and Scanning Probe Microscopy

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris

Sokrates Pantelides; Vanderbilt University
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$721,000 (2014)

PROGRAM SCOPE

The focus of the program is on probing the mechanisms of reversible and irreversible bias-induced transformations in solids at the atomic level of individual defects using a combination of scanning transmission electron microscopy (STEM) and local-field confinement in ex-situ and in-situ active device configurations. We aim to unravel the complex interplay between order parameter dynamics, ionic flows, electrochemical reactions, and mechanical behavior by studying three classes of phenomena: (a)

irreversible electrochemical processes including oxygen vacancy injection and vacancy ordering; (b) hysteretic processes including electrostatically-driven structural changes and phase transitions in ferroelectrics and at ferroelectric interfaces; and ultimately (c) kinetics of reversible electronic transfer, ionic polarization and interfacial reactions at oxide interfaces and oxide grain boundaries. We aim to uncover the mechanisms of these transformations at the nanometer-scale, and ultimately, the single-atom and single electron level, and link these to atomistic and mesoscopic models. The experimental and quantification approaches are developed for *ex situ* experiments, in particular systems with built-in electric fields or compositional gradients. They are subsequently used in *in situ* studies, where types of information inaccessible by other techniques can be obtained, such as direct images of metastable states and real-time compositional snapshots. The transformation mechanisms uncovered in this project will help establish a sound scientific basis for optimization and engineering of materials for a broad range of energy and information technologies from solid oxide fuel cells to memristive data storage and logic devices, as well as elucidate the role of vacancies in physical functionality of surfaces and interfaces.

FY 2014 HIGHLIGHTS

(1) DOE highlights submitted: “Direct observation of ferroelectric field effect and oxygen vacancy screening at ferroelectric-metal interface” (Aug. 2014); “Polar behavior induced by oxygen vacancy ordering” (May 2014). (2) Investigated unexpected polar behavior in $\text{LaFeO}_3/\text{SrFeO}_3$ superlattices made of two non-polar oxides, concluding that it is driven by the ordered oxygen vacancies. (3) Investigated surface-related effects in BiFeO_3 thin film, from the small reconstructed layer to domain wall widening on approach to the interface, directly determining a spectrum of length scales for different surface phenomena. (4) Developed image quantification approaches suitable for rapid analysis of multiple images and used it to investigate quantitative aspects of vacancy dynamics in $\text{LaCoO}_3/\text{SrTiO}_3$ multilayers, enabling tracking of the composition of each individual unit cell as the system converges to a vacancy ordered state. (5) Investigated vacancy distribution and interface structure in $(\text{La,Sr})\text{CuO}_2$ superconductors grown on different substrates and concluded that different levels of strain can lead films to adopt different oxygen stoichiometry, in turn affecting superconducting properties. (6) U.S. Patent No. 8,752,211, issued: June 10, 2014 “Real Space Mapping of Oxygen Vacancy Diffusion and Electrochemical Transformations by Hysteretic Current Reversal Curve Measurements”.

Fundamental Mechanisms of Transient States in Materials Quantified by Dynamic TEM

Funding: \$971,000 (2014)

PROGRAM SCOPE

The goal of this project is to investigate the fundamental physical mechanisms controlling transformation kinetics at the nanoscale, concentrating on the crystallization of amorphous solids. These kinetics are influenced by the initial amorphous structure, which can be controlled by processing. We

will use fluctuation electron microscopy (FEM) to characterize the structure of several model amorphous systems, including Ge, Si, and phase change materials, which have been formed under different conditions. We will use atomistic simulations to create structures that we will use to simulate the FEM signals to get a best match and then measure crystallization kinetics with those various structures in the simulations. We will then perform precise measurements of crystallization nucleation rates and growth rates in those films, which are enabled by the unique capabilities of the dynamic transmission electron microscope (DTEM). We will use phase field simulations at the mesoscale to connect the thermodynamic quantities from atomistic scale simulations to the microscopic observations from the DTEM. We will then compare the observed differences in the kinetics with the predictions of simulations to reveal fundamental controlling mechanisms for the transformation process.

FY 2014 HIGHLIGHTS

Conducted experiments on pulsed-laser dewetting in Co-Cu alloys to investigate the self-assembly of nanoparticle arrays on substrates. This work is in collaboration with Prof. Philip Rack at the University of Tennessee and makes use of the Center for Nanophase Materials Sciences, sponsored by BES at Oak Ridge National Laboratory. Performed movie-mode DTEM experiments to study rapid crystallization of amorphous Ge, measuring growth kinetics in the three different regimes of crystallization. We have also performed preliminary fluctuation electron microscopy experiments, which showed a distinct change in the medium-range order in amorphous Ge caused by sub-threshold laser annealing. Performed movie-mode DTEM experiments to study rapid crystallization of amorphous GeTe, thin film instabilities in GeTe, and unsteady propagation in reactive multilayer metal foils. Developed a phase-field model and a corresponding computer code for simulating microstructure evolution during a reactive phase transformation involving intermixing of layers and crystalline-amorphous-B2 structural transition in Al/Ni multilayers. Parameterized the phase-field model with thermodynamic and kinetic parameters computed by the classical molecular dynamics method. Conducted preliminary phase-field simulations to investigate the fundamental kinetics of interphase boundary evolution.

STEM: Atomic Structure and Properties of Materials

Beth Guiton; Kentucky, University of
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$2,508,000 (2014)

PROGRAM SCOPE

The mission of the STEM group is to develop instrumentation and techniques to advance atomic level characterization and to use these to explore the behavior of materials at the atomic scale. The successful correction of aberrations in our Nion UltraSTEM 200 scanning transmission electron

microscope now provides 0.57Å resolution imaging, combined with unprecedented sensitivity for spectroscopy. This instrument's resolution even at 200 kV is now limited by chromatic aberrations. With this tool, the group probes the connections between a material's spin, charge, orbital and structural degrees of freedom. This project primarily investigates critical issues in selected model materials systems; defect configurations in two-dimensional materials, complex oxide heterostructures, and materials for energy applications. Density functional theory is used to interpret the data and make the connections between the microscopic and macroscopic properties that are of interest for potential applications.

FY 2014 HIGHLIGHTS

The STEM group created, activated, observed and explained the ultimate miniaturization of a mechanical device (a terahertz rotor). This result obtained with theorists at Vanderbilt University (Lee and Pantelides), was published in *Angewandte Chemie*. The same team also demonstrated the existence of stable holes in graphene. This discovery is a major step toward the development of nanopore devices that could be used, for example, for DNA sequencing. In several papers published in high impact factor journals, the STEM group and collaborators have described novel charge and magnetic properties that develop at complex oxide interfaces. These include a charge profile tunable by strain, chemical doping or electron-lattice interactions and the development of interfacial ferromagnetic coupling that can be controlled by a voltage. We have quantitatively mapped dopant distributions and tracked dopant diffusion in three dimensions with single atom sensitivity. These achievements obtained from Se-doped MoS₂ and Ce- and Mn-doped AlN have been published in *Nano Lett.* and *Science Rep.* The group published 37 refereed journal articles and 5 refereed conference proceedings; Six of these were published in *Nature* journals and three in *PRL*. Maria Varela was awarded the Burton Medal for distinguished contributions to the field of electron microscopy. Matthew Chisholm was awarded a patent for band gap tuning in transition metal oxides.

Spectroscopic Imaging STM for Complex Electronic Matter Studies

Principal Investigator: JC Seamus Davis
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$620,000 (2014)

PROGRAM SCOPE

Everything around us, everything each of us has ever experienced, and virtually everything underpinning our technological society and economy is governed by quantum mechanics. Yet this most fundamental physical theory of nature often feels as if it is a set of somewhat eerie and counterintuitive ideas of no direct relevance to our lives. Why is this? One reason is that we cannot perceive the strangeness (and beauty) of the quantum mechanical phenomena all around us by using our own senses. In this program we develop techniques that allow us to image complex quantum electronic matter directly at the atomic scale. For example we visually explore the previously unseen and very beautiful forms of quantum matter making up electronic liquid crystals; hybridized heavy-fermions; topological-insulator surface states; and topological superconductors. We explore implications for fundamental research, and also for

advanced materials and new technologies, arising from the development and application of these novel techniques.

FY 2014 HIGHLIGHTS

(1) Imaging of Dirac-Mass Configurations in Ferromagnetic Topological Insulators: We recently introduced the Dirac-mass 'gapmap' technique to visualize the atomic-scale spatial conformations of Dirac mass. It reveals radically new perspectives on ferromagnetic topological insulators. We discover intense nanoscale disorder in the Dirac-mass and demonstrate that this is directly related to the magnetic-dopant atom density $n(r)$. This reveals how the percolating internal edge states at the $\Delta(r)$ domain walls can destroy all exotic topological insulator (TI) surface state phenomena. (2) Gap Structure of Topological Superconductor Sr_2RuO_4 : To establish the mechanism of topological superconductivity in Sr_2RuO_4 , a necessity is knowledge of the momentum-space structure of the energy gaps. Our measurements of the density of states in superconducting Sr_2RuO_4 for T between $0.1T_c$ and T_c demonstrate that the maximum value $2\Delta \sim 5kT_c$, plus our discovery of a $N(E)$ shape indicative of line nodes, are consistent with magnetically mediated quasi-one-dimensional superconductivity on two specific bands. (3) Visualization of Heavy Fermion Superconductivity: Cooper pairing of heavy-fermions was hypothesized as due to spin-fluctuation exchange but was impossible to prove because energy scales for both band and gap structures are so low (sub meV). To solve this challenge, we introduced Bogoliubov quasiparticle interference (QPI) imaging using millikelvin STM in CeCoIn_5 and revealed both the heavy-fermion band structure and superconducting $\Delta(k)$ of a heavy fermion compound for the first time. (4) Proof of Cooper Pairing Mediated by Magnetic f-Electrons in CeCoIn_5 : We invented a technique to measure the f-electron magnetic interactions of CeCoIn_5 . Solving the superconducting gap equations with these magnetic interactions mediate the Cooper pairing, we made quantitative theoretical predictions. We established agreement between these and measured characteristics of CeCoIn_5 indicating magnetically mediated pairing.

EARLY CAREER: Investigation of the role of inhomogeneities and phase segregation on correlated electron dynamics by optical spectroscopy and nano-imaging

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Adrian Gozar
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$2,500,000 (2010-2014)

PROGRAM SCOPE

The purpose of this project was twofold: a) to develop novel instrumentation which enables performing infrared optical spectroscopy measurements with nano-scale spatial resolution within a variable temperature environment. b) to use this tool either in order to address physics problems which are difficult/impossible by other type of instrumentation or for providing a complementary perspective in conjunction with other established techniques. Scanning Near Field Optical Microscopy (SNOM) has several key features among which: nano-scale spatial resolution; chemical sensitivity reaching the single molecule level, compatibility to time resolved methods; opportunity for finite-momentum optics. Our instrumentation goal was to add to this list SNOM operation in a 10 K – 300 K temperature range. These key advantages were aimed at studying competing phases in correlated systems (e.g. phase transitions,

the role of intrinsic/extrinsic inhomogeneities) and emergent phenomena associated with surfaces or buried interfaces in artificial structures. Our current work is focused on three main projects: 1) Electronic properties of graphene: Here we are interested in the origin of damping in a quasi-2D electronic gas with relevance for graphene-based electronics. We use near-field plasmon interferometry which allows us to extract temperature dependent energy-momentum information about collective electronic excitations. 2) Metal-Insulator transition and ferromagnetism in thin sub-surface EuO films. Can the metal-insulator (M-I) transition in thin subsurface EuO be detected optically by SNOM? Does the giant magneto-resistance exhibited by EuO belong to the paradigm of manganites? Can we offer insights for a roadmap to spintronics application? 3) High-temperature superconductivity. Here we exploit the capability of SNOM to image superfluid-polaritons in the superconducting states. We want to understand how can one use interface physics to further increase the maximum T_c in superconductors?

FY 2014 HIGHLIGHTS

The key project finalized during the last year is the successful and reproducible operation of our infrared cryo-SNOM at both room and low temperatures*. Other results: (1) Electronic properties of graphene. We performed real-space mapping of plasmon scattering in a single-layer of commercial graphene. We observed heavily damped plasmonic waves indicative of remarkable scattering efficiency of folds or sub-nanometer cracks. Discriminating between intrinsic and extrinsic damping mechanisms via temperature dependent studies requires a gated device: particle desorption in vacuum leads to drastic changes in the Fermi levels. We use ultra-high mobility samples consisting of single-layer graphene (SLG) sandwiched between boron nitride layers (ongoing collaboration with Philip Kim's group, Columbia/Harvard University). (2) Studies of thin EuO films. We studied 18 nm EuO thick films protected by a 23 nm a-Si. We found that the signal measured at $T > T_c = 69$ K is about 50% lower in intensity than below T_c and that the sample is optically homogeneous sample above and below T_c . Our results indicate that SNOM can probe the subsurface M-I transition in EuO and that the giant magneto-resistance is not related to inhomogeneous behavior. Our next set of measurements will be quantitative and will consist of SNOM data of EuO with in-situ Au reference as well as magnetic force microscopy (MFM) measurements (work in progress, collaboration with Darrell Schlom's group, Cornell University). (3) High- T_c superconductivity. We are just about to demonstrate cryo-SNOM operation in the 0.1 – 1 THz range. We acquired all equipment needed for these measurements and we were successful in producing and testing at all temperatures our AFM probes compatible with this operation: 65 kHz quartz tuning forks with W and Au etched wires (shaft lengths ≥ 500 μm).

Probing Coupled Metal-Insulator and Ferroic Transitions from the Atomistic to Mesoscopic Scales

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Sergei Kalinin
Sr. Investigator(s): Petro Maksymovych; Oak Ridge National Laboratory
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$775,000 (2014)

PROGRAM SCOPE

The coupling between electronic and ferroic behaviors has emerged as one of the most intriguing aspects of condensed matter physics, with examples including phase separation, metal-insulator transitions, and complex electronic ordering patterns. Both structural and electronic aspects of these

behaviors are currently of interest for energy generation and storage applications. The overarching goal of this project is to reveal the mechanisms of coupled electronic (metal-insulator) and ferroic (ferro- and antiferroelastic, ferro and antiferroelectric) transitions from atomistic to mesoscopic scales by exploring coupled electronic and atomistic structures on the length-scale of an individual unit cell, single domain, structural defect, and domain wall. The research will develop and exploit the synergy between advanced scanning probe microscopy, artificial-intelligence and multivariate methods for theory-experiment matching, and established methodologies of surface science and oxide growth. The SPM tip will act as a local probe of the ferroic and electronic state of matter, communicating local properties to the outside world through imaged structure and measured electronic current, dynamic and static electromechanical response, resonant frequency and quality factor of the cantilever, and microwave response, thus exploring and actively manipulating local order parameters in nanoscale volumes. Unraveling and subsequently understanding the energy balance between competing interactions and establishing the atomic configurations responsible for desired materials functionalities will reveal the key structural and electronic mechanisms involved in energy storage, generation and dissipation processes. This will provide a fundamental scientific basis for optimization and engineering of energy-related materials, with enormous potential benefits to fuel cells, batteries, solar energy, data storage, energy transport, and other vital energy technologies.

FY 2014 HIGHLIGHTS

In the concurrence period, we explored the coupled physical and chemical phenomena on the $\text{La}_{(0.625)}\text{Ca}_{(0.375)}\text{MnO}_3$ (LCMO). We identified preferred surface reconstruction during growth and demonstrated the influence of oxygen pressure and epitaxial strain on Mn adatom mobility and atomic-scale surface morphology of manganite thin films using atomically-resolved scanning tunneling microscopy and in-situ diffraction and spectroscopy methods. We further developed pathway to control surface reconstructions caused by oxygen vacancy ordering via silver-doping. Finally, we demonstrated feasibility of electrochemical single-atom manipulation on in-situ grown surface. To enable further progress, we developed a novel, big-data approach to analysis of reflection high energy electron diffraction (RHEED) data during epitaxial growth. The approach facilitates control over surface morphology, and in conjunction with in-situ STM will allow growth of films with controlled surface structures. In parallel, we explored emergence of ferroelectric domain structure and ferroelectric size-effect in an intrinsically layered ferroelectric material, CuInP_2S_6 as a model for atomically resolved studies of ferroic ordering. On the mesoscopic level, we demonstrated deterministic control over polarization orientation in-plane at any angle, by decoupling ferroelectric order parameter from crystallography on mesoscopic scale and thereby greatly increasing theoretical attainable densities for ferroelectric memory storage devices. We further performed disorder mapping and uncovered universal relaxation processes on surface of a relaxor ferroelectric through synergistic combination of multidimensional scanning probe techniques and multivariate statistical analysis.

Nanometer-Scale Surface and Interface Phenomena

Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$615,000 (2014)

PROGRAM SCOPE

The four tasks of this program study solid surfaces, internal interfaces and solid-liquid interfaces. The overarching goal is to achieve a fundamental understanding of the processes that control the static and dynamic properties of surfaces and interfaces and use this knowledge to provide the foundations for new energy technologies consistent with DOE's Office of Basic Energy Sciences mission. To achieve this goal, we apply a wide range of state-of-the-art experimental and tools and theoretical approaches to determine how atomic-scale processes relate to the longer-range interactions that control interfacial behavior. Specific materials systems are chosen for their relevance to national needs, notably energy-related materials. Our task structure is designed to investigate a set of increasingly reactive environments from clean surfaces in ultrahigh vacuum, to liquid-solid interfaces, to metallic and oxide nanostructures in electrochemical environments: Task 1 focuses on atomistic processes on surfaces; Task 2 describes the collective behavior that occurs on larger length scales; Task 3 deals with linking the results of Tasks 1 and 2 to macroscopic properties of technological importance; and finally Task 4 is concerned with explaining electrochemical processes in terms of nanoscale interfacial properties.

FY 2014 HIGHLIGHTS

- Characterized the structure of single-layer tungsten diselenide with low energy electron microscopy.
- Determined that surface oxygen is crucial to growing perfect graphene crystals on copper.
- Used low energy electron microscopy to show that 2-D boron nitride grows epitaxially next to graphene.
- Characterized the growth modes of various iron oxides on ruthenium surfaces.
- Determined how graphene grows on palladium.
- Explained how surface nucleation barriers determine the charging rates of batteries with LiFePO₄ battery electrodes.
- Successfully modeled experiments of Au diffusing into bismuth telluride.
- Showed that binding of graphene edges to the substrate determined the shape of growing graphene crystals.
- Explained at an atomic scale how magnetite converts to hematite in an oxygen rich environment.
- Made first real-time observation of graphene changing orientation while bonded to a substrate.
- Determined and modeled the structure of the surface of magnetite at high temperatures.
- Used low energy electron microscopy to probe the amount of disorder in bilayer graphene.

3D Visualization of Emergent Behavior in Nanoscale Functional Heterostructures

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Amanda Petford-Long
Sr. Investigator(s): Seungbum Hong; Argonne National Laboratory
Charudatta Phatak; Argonne National Laboratory
Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$969,000 (2014)

PROGRAM SCOPE

The properties of ferroic materials at the nanoscale are governed by their complex energy landscape, which must be understood if emergent behavior is to be controlled. Our goal is to gain a fundamental understanding of how the energy landscape can be influenced through geometric patterning or confinement and through interfacial interactions. We are focusing our research on heterostructure nanosystems whose building blocks show ferromagnetic, ferroelectric, and resistance switching properties. We aim to obtain a fundamental understanding of domain behavior and charge transport properties in these nanostructures through control of parameters that contribute to their energy landscape, such as interlayer coupling, geometric effects, and interactions between adjacent nanostructures. As the nanostructure dimensions approach the characteristic length scales of the order parameters and associated energy terms, novel distributions of spin and/or charge are created. Further degrees of freedom can be achieved in 'designer' heterostructures, in which there is coupling between the order parameters in materials with different ferroic order. Our approach involves an interwoven combination of aberration-corrected Lorentz transmission electron microscopy and advanced scanning probe microscopy that we use to address scientific questions related to ferroic nanostructure behavior, for example the competing effects of exchange-bias and interlayer exchange coupling in ferromagnetic nanostructures or the role of metastable ferroelectric domains on polarization switching in thin films. A particular focus is the use of three-dimensional analysis and imaging techniques that we have developed to visualize domain and transport behavior in nanostructures as a function of external stimuli such as applied fields, temperature and/or time.

FY 2014 HIGHLIGHTS

(1) We carried out the first observation of a volatile photovoltaic-like resistance change in Pt/TiO₂/Pt heterostructures induced by exposure to a synchrotron X-ray beam. A non-volatile effect was also observed, resulting from X-ray-induced defect generation and Joule heating, that led to the formation of conducting Ti₄O₇ channels. (2) We used Lorentz TEM and quantitative phase reconstruction to explore the energy landscape of Co nanospirals and determined that the shape anisotropy controlled the spin structure leading to uniform magnetization along the spiral. (3) We have developed a new technique - Charge Gradient Microscopy (CGM) – that can be used to reveal the underlying polarization domain structure in ferroelectric materials at high speeds by scraping off and quantifying the surface screening charge. We envision that CGM can be used to study the complex dynamics of domain nucleation and growth in different environments. (4) We investigated the origins of resistance changes in Pt/CuO_x/Pt nanostructures and correlated them with local changes in copper oxidation state, using x-ray nanoprobe spectro-microscopy and current-voltage characterization. (5) We developed a theoretical model to analyze the effect of shape on the ferroelectric polarization of nanoparticles in the absence of screening charges. Using this model, we determined the minimum aspect ratio of a triaxial allipsoid that can sustain ferroelectric polarization and visualized using phase retrieval methods in TEM.

Spin Physics

Institution: SLAC National Accelerator Laboratory
Point of Contact: Thomas Devereaux
Email: tpd@stanford.edu
Principal Investigator: Shoucheng Zhang
Sr. Investigator(s): David Goldhaber-Gordon; Stanford University
Hari Manoharan; Stanford University

Students: Joseph Orenstein; Lawrence Berkeley National Laboratory
4 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$804,000 (2014)

PROGRAM SCOPE

The main goals of this FWP are to discover new states of quantum matter and novel physical effects associated with the electron spin, to observe and to manipulate quantum spin degrees-of-freedom at the microscopic scale, and to design and predict materials with tailored functionality. The spin physics program investigates novel phenomena arising from spin coupling in solids. Recently, it was realized that spin-orbit coupling can lead to a fundamentally new state of matter, the topological insulator. These materials have an energy gap in the bulk, and a conducting topological state on the surface. The spin program develops theoretical concepts and experimental tools to investigate these novel effects.

FY 2014 HIGHLIGHTS

(1) A new platform for topological superconductivity. Manoharan, Orenstein, and Zhang actively worked together on the half-metallic surface state of NaCoO_2 as a platform for topological superconductivity and Majorana fermions through the mechanism of s-wave superconductivity proximity effect. Manoharan performed STM measurements on the surface states of NaCoO_2 , and distinguished the p-type doping surface region. The observed local density of states (LDOS) by STM experiments quantitatively agrees with Zhang group's *ab initio* calculations, indicating the single Fermi surface on NaCoO_2 . The single surface state was confirmed by ARPES experiments done by Yulin Chen. The magnetization of the surface states was confirmed by measurements of the magneto-optical Kerr effect by Orenstein group revealing a remnant magnetization of the state with a critical temperature $T \sim 15$ K, in agreement with T-dependent scanning tunneling spectroscopy performed by Manoharan group. (2) Quantum anomalous Hall effect theory. Zhang group has theoretically predicted the quantum anomalous Hall (QAH) effect in magnetic topological insulators. Recently, this theoretical prediction has been confirmed experimentally in Cr doped topological insulator $(\text{Sb,Bi})_2\text{Te}_3$. Zhang group published five papers on QAH effect. (3) Quantum anomalous Hall effect experiments. Orenstein, Goldhaber-Gordon, Manoharan, and Zhang actively worked together on the ferromagnetism of Cr doped topological insulator $(\text{Sb,Bi})_2\text{Te}_3$. (4) Quantum spin Hall effect. Zhang group has theoretically predicted the quantum spin Hall (QSH) effect in HgTe quantum well as well as topological insulators Bi_2Se_3 . (5) TRI topological superconductor prediction. Zhang group has theoretically proposed the concept of time-reversal invariant topological superconductivity.

EARLY CAREER: Real Time TEM Imaging of Materials Transformations in Liquid and Gas Environments

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Xiang Zhang
Email: XZhang4@lbl.gov
Principal Investigator: Haimei Zheng
Sr. Investigator(s):
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The aim of this project is to study the physical and chemical processes in materials with high spatial resolution using *in situ* liquid or gas environmental transmission electron microscopy (TEM). Understanding how materials grow and function at the nanometer or atomic scale in their working environments is essential to developing efficient and inexpensive energy conversion and storage materials and devices. With real time imaging in liquids or gases, this project will advance environmental cell TEM development and result in better understandings of growth, mass transport and chemical reaction induced structural changes of materials during energy applications.

FY 2014 HIGHLIGHTS

The reliance of future technologies on advanced materials has spurred intense interest in solution growth of nanostructured materials owing to the substantial advantages with respect to the massive scalability required for any global energy solution. An understanding of the solution growth mechanisms of nanocrystals is critical to the design of novel materials. *In situ* study of nanoparticle growth trajectories using liquid cell TEM is a unique approach. With our recent effort, breakthroughs have been made on the study of facet development of Pt catalytic nanoparticles. With the thin liquid cells and advanced imaging detector, we were able to capture the atomic development of each individual facet. We found the widely implemented surface energy minimization rule breaks down at the nanoscale. Instead, stochastic growth dominates and the facet development is strongly influenced by surfactant ligands. This work has been published in Science Aug. 2014. This work is an excellent extension of our previous effort on the study of shape evolution mechanisms of nanocrystals. Another highlight is the *in situ* study of dendritic growth in electrochemical processes with our development of electrochemical liquid cells. The electrochemical liquid cells allow us to monitor the electrode-electrolyte interfaces and reveal unseen materials dynamics at the nanoscale. Two papers on the formation of Pb dendrites and Li dendrites have been published in Scientific Report and Nano Letters. It opens the opportunities to study many other dynamic processes including electrodeposition, electrocatalysis and so on at a great level of details which were not possible before. Additionally, we have also made significant progress on the study of structural dynamics of nanocatalysts *in situ* using gas environmental cell TEM. The recent work has been published in Nano Letters and there are multiple news reports on the achievement.

Studies of Nanoscale Structure and Structural Defects of Advanced Materials

Institution:	Brookhaven National Laboratory
Point of Contact:	Peter Johnson
Email:	pdj@bnl.gov
Principal Investigator:	Yimei Zhu
Sr. Investigator(s):	Jing Tao; Brookhaven National Laboratory Myung-Geun Han; Brookhaven National Laboratory Lijun Wu; Brookhaven National Laboratory
Students:	1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding:	\$2,232,000 (2014)

PROGRAM SCOPE

The goal of this program is to understand the roles of property-sensitive nanoscale structures and defects of technologically-important materials such as superconductors, multiferroics, spintronics, and other energy related materials including thermoelectrics, batteries and catalysts. To gain a thorough

understanding we employ and advance quantitative electron diffraction, imaging, and spectroscopy techniques, including the pump-probe based ultrafast electron diffraction method. We aim at understanding the electron, spin, orbital, and lattice correlation and their interplay that control physical and chemical behavior of matter. One essential component of our program is developing advanced instruments and methods for direct measurement of materials' structural functionalities at nanoscales and comparing them with those obtained using neutrons and synchrotron x-rays. The progress of our research requires a significant resource suitable for a national laboratory setting, wherein applications to various model systems in strongly correlated oxides and energy-related materials can be demonstrated. Computer simulations and theoretical modeling are carried out to aid the interpretation of experimental data. Fabrication of thin films with tailored nanostructures is also incorporated.

FY 2014 HIGHLIGHTS

Direct observations of coherence and modality of driven interlayer-coupled magnetic vortices using high-frequency resonance current; Revealing the direct coupling between anion polarization and superconductivity in Co doped BaFe_2As_2 superconductors using quantitative electron diffraction and energy-loss spectroscopy; Revealing interface-induced nonswitchable domains in ferroelectric thin films; Direct imaging of vortex-core precession orbits and the interaction of double vortex-cores in strongly and weakly coupled tri-layered magnetic nanostructures; Identifying the origin of phonon glass–electron crystal behavior in layered thermoelectric materials; Understanding topological effect of surface plasmon excitation in gapped isotropic topological insulator nanowires; Imaging symmetry breaking of magnetic vortices before annihilation; Separating the electron and lattice contribution to the formation of charge-density-wave in TaSe_2 using ultrafast electron diffraction; Observing tunable THz surface plasmon polariton based on a topological insulator/layered superconductor hybrid structure.

EPSCoR

Institutions Receiving Grants

EARLY CAREER: Develop On-Demand Nanoplasmonic Device Concepts in a Semiconductor Compatible Hybrid System

Institution: West Virginia University
Point of Contact: Cheng Cen
Email: Cheng.Cen@mail.wvu.edu
Principal Investigator: Cheng Cen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2013-2017)

PROGRAM SCOPE

The objective for this project is to develop an on-demand nanoplasmonic platform that combines emerging oxide nanoelectronics with a low-loss semiconductor-friendly plasmonic material — graphene. In the heterostructures of Graphene/LaAlO₃/SrTiO₃, the nanoscale conducting structures at LaAlO₃/SrTiO₃ interfaces reversibly patterned by conducting atomic force microscope (c-AFM) will be used to spatially modulate the chemical potential in the top graphene layer and provide dynamic confinement and manipulations of plasmon modes in graphene. Various rewritable nanoplasmonic devices, including waveguides, active modulators, on chip light source and sensors, will be explored by c-AFM lithography and in-situ near field scanning optical microscopy. The successful development of such hybrid plasmonic platforms will enable creation of on demand nanoplasmonic devices in one single step and can potentially lead to tantalizing applications in single molecule spectroscopy, scalable solid state quantum information processing and novel plasmon probe for various interesting material quanta in condensed matter physics.

FY 2014 HIGHLIGHTS

A new material stack of Si/LaAlO₃/SrTiO₃/SiO₂/Si has been developed and studied. With thickness ratio of the stack designed by finite element simulation, the new heterostructure enhances the optical contrast of graphene by orders of magnitude comparing to the originally proposed LaAlO₃/SrTiO₃ substrate. In addition, the introduction of Si also allows the carrier density in graphene and LaAlO₃/SrTiO₃ interface to be tuned independently. A dry transfer method based on PDMS stamp has been developed to transfer a patterned graphene structure from copper foil directly onto a LaAlO₃ surface. This method eliminates the exposure of resist related chemicals to highly surface sensitive graphene or polar complex oxide (LaAlO₃), and allows high quality contacts to be formed to access graphene and LaAlO₃/SrTiO₃ interfaces separately. The reversible C-AFM lithography in presence of graphene has been successfully performed. The LaAlO₃/SrTiO₃ interface underneath single monolayer graphene can be reversibly switched between metallic and insulating states with biased conducting atomic force microscope (c-AFM) probe in contact with graphene. Small voltage applied to the conducting regions at the LaAlO₃/SrTiO₃ interface can effectively control the graphene transport with a large on-off ratio. Surface plasmon mode has been successfully observed in highly doped SrTiO₃ region by near field scanning optical microscope. The mechanism of the C-AFM lithography in the presence of

graphene as well as plasmon modes in graphene/oxide heterostructures will be the subject of next step investigations

Neutrino Oscillations in Supernovae

Institution: New Mexico, University of
Point of Contact: Huaiyu (Mike) Duan
Email: duan@unm.edu
Principal Investigator: Huaiyu (Mike) Duan
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2012-2017)

PROGRAM SCOPE

At the end of its life the core of a massive star collapses under its own gravity, and the star explodes as a supernova. Supernovae are crucial to the chemical evolution of the universe. They disseminate heavy elements into the Interstellar Medium inside which new generations of stars are born. Although supernovae have been observed in the last several decades, it is until recently, with the advances of computing technologies and the development of multi-dimensional supernova simulations, that the explosion mechanism of a supernova is finally (close to be) understood. However, the recent development of neutrino mixing adds a new twist to this puzzle. Neutrinos interact very weakly with ordinary matter but carry away 99% of the total energy of a supernova. The electron flavor neutrinos and antineutrinos play pivotal roles in supernova physics. It has been established by experiments that neutrinos and antineutrinos of the electron flavor can transform or oscillate into neutrinos of other flavors and vice versa. In this project we use both analytic and numerical methods, including large-scale numerical simulations, to find out the mechanism and conditions for neutrino oscillations to occur in supernovae and to study the potential impacts of neutrino oscillations on supernova physics. By understanding neutrino oscillations in supernovae we will complete an important piece for the puzzle of supernova physics and help answering some fundamental questions such as the origin of the elements.

FY 2014 HIGHLIGHTS

Two important progresses have been made in FY 2014 towards understanding (collective) neutrino oscillations in supernovae. We have developed a multi-purpose numerical package xFLAT to simulate neutrino oscillations in several physical models. Compared to the old package xFLAT is designed to utilize the vector engines of modern CPUs, and it runs efficiently on the 60-core Xeon Phi accelerator introduced by Intel recently on which we plan to run our future large-scale simulations. This numerical package was one of the highlights of the UNM booth during the SC14 conference. We have also developed a new approach, the moment expansion method, to compute neutrino oscillations in the one-dimensional (i.e. spherically symmetric) "neutrino bulb model". Compared to the traditional angle-bin method the new approach improves the efficiency by about 2 orders of magnitude. This improvement of efficiency can be essential for us to devise and carry out simulations of neutrino oscillations in multi-dimensional models. This work has been published by Journal of Cosmology and Astroparticle Physics.

Neutron Scattering Research Network for EPSCoR States

Principal Investigator: Takeshi Egami
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$1,666,000 (2012-2015)

PROGRAM SCOPE

With the completion of the Spallation Neutron Source (SNS) and upgrading of the High-Flux Isotope Reactor (HFIR) at the Oak Ridge National Laboratory (ORNL) the state of Tennessee now leads the world in the capability for neutron scattering research. This project aims at directing the great impact of these facilities to researchers in the EPSCoR states, Tennessee in particular, by creating a research collaboration network around these facilities. The plan consists of two parts: (1) Direct effort to increase the user base through the travel fellowship for graduate students and faculty from the EPSCoR states to use the neutron facilities at the ORNL, and through workshops and schools on the application of neutron scattering, and (2) Research collaboration among the core participants from UTK, ORNL and other states. The EPSCoR Travel Fellowship Program started in the Phase I of this grant (2008-2012) has supported a large number of neutron facility users and workshop participants. This program is highly popular particularly among young researchers, and is the foundation of this project. We supported several educational workshops, organized one by ourselves each year, targeting non-users of neutron scattering. The core research groups participating in this project include not only researchers from Tennessee but those from Kansas, South Carolina, Puerto Rico and Louisiana, making this project a national, rather than regional, enterprise. Collaborations that were seeded by this project have grown into two major projects, one in condensed matter physics and the other in soft matter sciences. Through this project we promote the use of neutron scattering, particularly in biological and life sciences and in energy sciences, and facilitate the DOE investment in this field to impact wide fields of science and engineering. This project is administered through the Joint Institute for Neutron Sciences (JINS) of the University of Tennessee (UT) and ORNL.

FY 2014 HIGHLIGHTS

The neutron travel fellowship program continued to grow, and supported 588 total users (370 distinct users) over 6 years. At the beginning of this program we estimated the number of neutron facility users from the EPSCoR states to be about 90, half of whom were from the state of Tennessee. Thus we have succeeded in increasing the number of neutron users by a factor of four. Actually less than 10% of the fellowship recipients are from the state of Tennessee, so the number of out-of-state users has increased by more than 7 times. In August we held the fourth workshop on “neutrons for novices”, which attracted nearly 50 participants. Through this series of workshops we introduced nearly 200 participants to neutron scattering, many of whom are new neutron facility users. In the research on condensed matter physics, through collaboration with subcontractors from Kansas, Louisiana, South Carolina and Puerto Rico we advanced the neutron scattering studies of the structure of new compounds, including frustrated magnets and complex hydride. We also made advances in the study of Fe-pnictide superconductors through the discovery of strong anisotropy in spin excitation and local lattice distortions larger than the average orthorhombic lattice distortion. In the field of soft-matter physics and biological science we advanced our understanding of the role of secondary structure in rigidity,

dynamics and function through the use of inelastic neutron scattering and modeling. Water is an extremely important substance in biology. Through inelastic neutron scattering, light scattering and dielectric spectroscopy the picosecond dynamics of water was studied, and elucidated the role of hydration on protein dynamics. A new effort on membrane dynamics was started a year ago, and resulted in major advances. In particular we identified the dynamic domain formation on asymmetric membranes through small angle neutron scattering and modeling.

Fundamental Investigations of Mechanical and Chemical Degradation Mechanisms in Lithium Ion Battery Materials

Institution: Brown University
Point of Contact: Pradeep Guduru
Email: pradeep_guduru@brown.edu
Principal Investigator: Pradeep Guduru
Sr. Investigator(s): Brett Lucht; Rhode Island, University of
Allan Bower; Brown University

David Heskett; Rhode Island, University of
William Euler; Rhode Island, University of
Students: 7 Postdoctoral Fellow(s), 8 Graduate(s), 1 Undergraduate(s)
Funding: \$6,000,000 (2014-2017)

PROGRAM SCOPE

We aim to understand the mechanical and chemical degradation mechanisms and improve the cycle and calendar life of lithium ion battery materials. Our effort consists of fundamental investigations of: (i) Mechanical properties, fracture and damage in electrode materials; (ii) Chemistry and Mechanics of Solid Electrolyte Interphase (SEI); (iii) Mechanical and Chemical Integrity of Solid-Solid Interfaces in Practical Electrodes. The research project consists of closely coupled experimental, theoretical and computational investigations that complement each other, in collaboration with DOE National Laboratories and industrial partners. The first focus area deals with mechanical degradation caused by the stress fields induced by volume expansion during diffusion, phase transformations and intercalation during Li insertion and removal. Continuum and atomic scale models will be developed and validated against the experiments in order to make them predictive in more general electrode architectures. The second focus area seeks to establish a rigorous relation between the electrolyte chemistry, structure & chemical composition of SEI and its mechanical properties. A suite of experimental techniques will be employed to gain unprecedented insights, which will be complemented by Density Functional Theory (DFT) simulations of the reduction reactions. The performance of practical electrode microstructures is critically dependent on the mechanical integrity of interfaces in electrodes, particularly the active-inert interfaces and active-active interfaces. The interface mechanics is often strongly influenced by chemical factors such as Li concentration and absorbed electrolyte in the binder. The third focus area will develop a detailed understanding of solid-solid interfaces in electrodes and how electrode expansion is accommodated at such interfaces. One of the objectives is to arrive at a rational materials design for composite electrode coatings.

FY 2014 HIGHLIGHTS

Phase boundaries in Li ion battery materials play a critical role in controlling the rates at which the material can be charged/discharged and the stress induced in the particle. We developed a theoretical model to describe the roles of solution thermodynamics, mechanical stress and kinetics on the behavior of electrode particles containing propagating phase boundaries. We also obtained analytical solutions for composition and stress in elastic-plastic electrode particles containing a propagating phase boundary. The most significant implication of these predictions is that chemistry can influence the stress state in electrode particles by controlling the relative contributions from solution thermodynamics and stress to the chemical potential. Tin forms multiple Li-Sn phases during lithiation; it is essential to characterize the thermodynamics and kinetics of the phase transformations and stress generation. We subjected thin films of tin to lithiation at specific constant potentials, thus allowing only a single phase transformation to proceed at each potential in a controlled manner. We employed a kinetic model to analyze phase boundary propagation and to extract the kinetic parameters such as mobility of Li atoms and reaction rate coefficients of phase transformations at steady state, which are essential for developing numerical models for more complex particle shapes and sizes. To understand the formation of the SEI, we employed electronic structure calculations of the initial surface reactions at the electrode. We use the “computational lithium electrode” technique to model the potential-dependent elementary steps of solvent degradation on Li. We have mapped out competing reaction pathways and incorporated the voltage dependence parametrically. We studied different configurations of common solvent molecules on the lithium battery’s negative electrode. These results help understand the early stages of SEI formation that are of prime importance to battery performance.

Building Neutron Scattering Infrastructure in Louisiana for Advanced Materials

Institution:	Louisiana Board of Regents
Point of Contact:	Michael Khonsari
Email:	michael.khonsari@la.gov
Principal Investigator:	Michael Khonsari
Sr. Investigator(s):	John DiTusa; Louisiana State University
Students:	0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding:	\$4,949,000 (2014-2017)

PROGRAM SCOPE

This project seeks to build a major neutron scattering infrastructure capable of treating both soft and hard materials. The objectives of this initiative include: building a base of users of the Spallation Neutron Source (SNS) and the High Flux Isotope Reactor (HFIR) in the southern region of the USA; training of talented students and postdocs in synthesis and neutron scattering techniques who will become the next generation of neutron users; and discovery of the role of coupling of degrees of freedom that determine the emergent properties of complex materials. The scientific focus of this program is to understand the role of coupling in emergent complex materials and its impact on the structure/property relationship, and to explore how this information can be utilized or applied in the guided-design of materials with the desired properties. Our goal is to tune dominant couplings to enhance a critical property in order to derive new functionality. In particular, many of the most interesting materials display coupling both in their static and dynamical behavior, making neutron scattering (elastic and inelastic) the ideal tool to elucidate fundamental relationships. This program takes advantage of the synergy between the expertise of Louisiana’s faculty and that of the Spallation Neutron Source (SNS) and High Flux Isotope Reactor (HFIR) staff to position the team as leaders in the exploration of complex

interactions that give rise to novel phenomena. The scientific team is exploring the static and dynamic properties of transition metal compounds including transition metal oxide, silicide, and selenide/telluride systems via neutron scattering techniques that emphasize the effects of uniaxial pressure. In the soft materials systems we are investigating the effects of secondary interactions using neutron scattering on the mesoscale structure in well-defined model polymer systems as a function of polymer system type and synthetic/processing route.

FY 2014 HIGHLIGHTS

The grant was awarded in August 2014. Work completed prior to September 30, 2014 includes the following: During the first six weeks of the project we have established much of the administrative structure of the program. This includes establishing an External Advisory Committee consisting of six highly accomplished researchers with great experience in the programmatic areas of the LaCNS. We have searched for and hired a highly experienced program coordinator, established hiring searches for several postdocs and a visiting professor, and identified three graduate students that are now receiving support from this program. We have begun the processes of purchasing all of the capital equipment supported by DOE funding including commencing a competitive bid process where appropriate. In addition, we have established several collaborations between faculty participants and ORNL staff that will prove highly beneficial to the goals of the program. A seminar program focusing on neutron scattering-relevant science which hosts speakers external to the program's institutions has also been established. Weekly and biweekly meetings of the soft and hard matter teams have been established. Two faculty members of the team attended and formally presented ideas and perspectives at the SNS workshop on "Neutrons and High Magnetic Fields" at ORNL in September 2014. In addition, materials synthesis for the experiments has begun with several polycrystalline and crystalline transition metal compound samples being produced and polymeric thin films being grown.

EARLY CAREER: Modeling of Photoexcited Process at Interfaces of Functionalized Quantum Dots

Institution:	North Dakota State University
Point of Contact:	Svetlana Kilina
Email:	svetlana.kilina@ndsu.edu
Principal Investigator:	Svetlana Kilina
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 2 Graduate(s), 4 Undergraduate(s)
Funding:	\$750,000 (2012-2016)

PROGRAM SCOPE

The long-term goal of this research is theoretically establishing the structure-property relationship of chemically functionalized semiconductor quantum dots (QDs) targeting chemical, structural, and size manipulation of their electronic and optical properties. In the realm of energy related research, advances that rely upon the use of QDs are currently limited by a lack of understanding of fundamental processes that occur at the surfaces and interfaces of these nanomaterials upon photoexcitation. The complexity of this task poses high demands on the experimental techniques used to characterize nanoscale systems. Computational modeling provides interpretations of experimental data and a better understanding of the material's properties at the atomistic level, while development of validated theoretical predictions could guide new experimental efforts. As such, this project aims to improve our understanding of the role of QD surfaces in light-driven physicochemical processes via developments and practical applications of reliable quantum chemical methodologies capable of modeling

photoinduced dynamics and spectroscopic observables in the nanosized systems and their interfaces. Specifically, it focuses on systematic computational studies of the effect that a soft layer of organic ligands, including metal-organic complexes, and a shell of a different semiconductor covering the QD surface have on the morphology, electronic structure, optical response, charge/energy transfer, and excitation dissipation in QDs. Density functional theory (DFT) and time dependent DFT (TDDFT) are coupled with quantum-classical non-adiabatic dynamics and used as the quantitative framework for computing ground and excited state electronic structures, photoexcited trajectories, and electron-phonon couplings responsible for energy-to-heat losses. Simulated results will allow for a better interpretation of experiments, and facilitate rational design of new nanostructures with desired properties.

FY 2014 HIGHLIGHTS

Our research aims to fill the gap in understanding of the role of QD surfaces in light-driven processes. Several steps were done toward this goal during this year. (I) We have benchmarked DFT methods and identified that PBE1 functional more accurately describes photophysics of functionalized QDs. (II) We revealed the role of QD-dye interactions on their electronic structure: Energy offsets in the QD/dye composites do not represent a simple difference of the isolated organometallic dyes and the QDs, which should be accounted for in experiments. (III) We determined the effect of the dye on mechanisms of the charge transfer in QD/dye composites. Change in a metal of the dye weakly affects the alignment of the electronic levels of the dye versus the QD's states. In contrast, negatively charged ligands and less polar solvents strongly destabilize the dye's occupied orbitals shifting them toward the edge of the QD valence band, thus, providing favorable conditions for the hole transfer. Thus we have determined thermodynamic conditions governing the direction of the charge transfer in photoexcited QDs passivated by Ru(II)-polypyridine dyes. (IV) Targeting design of metal-organic dyes with enhanced charge transfer properties, we have performed joined computational and experimental studies of optical properties of various Ir(III) complexes and demonstrated the practical realization of DFT predictions in rational structure-property design of molecular systems. These results were summarized in 4 journal publications and reported in 6 invited talks, plus 5 contributed presentations at the international scientific conferences. This conference was organized on topics closely related to the DOE funded project was organized. Two graduate students were distinguished by summer internships at National Laboratories. Three awards for excellence in science, including a Sloan Research Award in Chemistry, have been obtained, and two projects (one as PI) have been funded by NSF, plus one by ND EPSCoR NSF.

Resolving Reactor Antineutrino Anomaly with Strong Antineutrino Source

Institution:	Hawaii, University of
Point of Contact:	Jelena Maricic
Email:	jelena@phys.hawaii.edu
Principal Investigator:	Jelena Maricic
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding:	\$750,000 (2013-2018)

PROGRAM SCOPE

The scope of this project is search for the sterile neutrinos in 1 eV^2 mass range using a very strong antineutrino generator. For this purpose we are preparing 5 PBq ^{144}Ce - ^{144}Pr radioactive source (as a copious antineutrino source). The source will require a sizable tungsten shield to protect humans and

detector from high rate 2.2 MeV gammas, as they produce background for neutron capture on protons as second part of IBD interaction. The source will be placed below the Borexino antineutrino detector. This large antineutrino detector will allow us to observe distance dependent oscillation flux if it is there. We expect to observe around 12,000 antineutrinos in the course of 18 months. With this measurement we will be able to fully probe the preferred parameter space for $\sim 1 \text{ eV}^2$ sterile neutrinos indicated by RAA (Reactor Antineutrino Anomaly).

FY 2014 HIGHLIGHTS

During the course of FY 2014 there was significant progress on the shielding design. Two manufacturers have been identified that are capable of producing a 2.2 ton tungsten shield that can meet safety and background suppression requirements. PI has recently hired a postdoc Koun Choi to work on the CeSO_x and she will carry out simulations to ensure that the shield provides sufficient shielding against gammas in the Borexino detector. PI visited PLANSEE factory in Germany, one of the two companies that accepted the challenge of producing the shield. Another company is Xiamen in China. No company in the world has produced such a large tungsten part and there are technological challenges involved. The companies seem confident in their ability to produce the shield. Space under Borexino has been identified and prepared for receiving the source. Areva transportation company has taken over transportation of the source and a special B type container has been identified to carry the source from Sankt Petersburg to Gran Sasso in Italy. Finally, Mayak has carried a test production run for ^{144}Ce - ^{144}Pr with about 1/15 of activity and they have started the necessary modifications to upgrade the facilities needed to produce the source.

Atmosphere to Grid: Addressing Barriers to Energy Conversion and Delivery

Dan Trudnowski; Montana Tech
Students: 1 Postdoctoral Fellow(s), 17 Graduate(s), 0 Undergraduate(s)
Funding: \$4,250,000 (2014-2017)

PROGRAM SCOPE

This project addresses the barriers to incorporating renewable energy sources into the national energy infrastructure from both technical and economic points of view. This project adopts a comprehensive multi-scale and multidisciplinary approach that considers the complete energy conversion and delivery cycle, from continental atmospheric weather events, to wind farm power production and reliability, to power grid transmission issues, and including economic drivers and impact on local and regional scales. The project is centered around three principal interdependent thrusts: 1) the development and validation of a variable-fidelity multi-scale coupled atmosphere/wind-plant modeling and control capability, 2) the development of a measurement-based transmission grid modeling capability, and 3) the development of fully integrated economic models for more diverse and variable energy generation and transmission scenarios. Improved wind plant modeling capability will provide a better understanding of complete wind farm power responses to slow and rapid transient weather events, provide information for potential wind farm turbine siting in complex terrain, and allow the design and testing of control strategies for optimizing power output and reliability of entire wind farms. At the same time, measurement based transmission grid modeling capability will result in a better understanding of power system instabilities and congestion, which are current obstacles that are exacerbated in the presence of high wind energy penetration. Economic models will provide the necessary tools for measuring the overall benefit of improvements in wind energy and power transmission technologies, while at the same time enabling informed decisions regarding investment in conventional and renewable energy sources. This project includes collaboration with wind farm operators and power companies through extensive data sharing.

FY 2014 HIGHLIGHTS

Although the project began very late in the year (August 2014), there are a few accomplishments to point out. A successful kick-off meeting was held in September 2014. A review of the proposed work was provided by a team of external reviewers, and their suggestions promise to increase the value of the work to be done. Similarly, initial setup of administrative structure to support the research efforts has been started, and graduate students have been recruited.

EARLY CAREER: Examination of Actinide Chemistry at Solid-Water Interfaces to Support Advanced Actinide Separations

Institution: Clemson University
Point of Contact: Brian Powell
Email: BPOWELL@clemson.edu
Principal Investigator: Brian Powell
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$750,000 (2013-2017)

PROGRAM SCOPE

The study of the chemical and physical properties of actinide bonding and reactivity is essential for the development of an improved nuclear fuel cycle and to understand how the actinides move through the environment. This work will examine the fundamental chemical properties of actinide elements in aqueous solutions and at solid-water interfaces. Sorption of actinides to solid surfaces such as minerals and soils can limit the movement of actinides in the environment and sorption to engineered solids can

facilitate separation of actinides from other waste materials within the nuclear fuel cycle. Understanding and quantifying actinide bonding and reactivity at solid-water interfaces is needed for a wide range of applications such as advanced actinide separation schemes, waste treatment and disposal, understanding actinide behavior under geologic repository conditions, and determining the performance of actinide bearing wastes and waste facilities. A novel aspect of this work will be to examine sorption processes on a mechanistic basis and quantify the data using a standard thermochemical construct as opposed to the empirical methods commonly employed. The overarching objectives of this work are to provide a mechanistic conceptual model and a quantitative sorption model describing actinide behavior at solid-water interfaces based on a molecular level understanding of the chemical processes involved. Particular attention will be focused on understanding underlying mechanisms of actinide sorption to differing solid phases, understanding underlying mechanisms behind frequent observations of hysteretic sorption and understanding the potential formation of ternary actinide-ligand-surface complexes. The ability to predict distribution of the actinides between aqueous and solid phases will improve our overall understanding of actinide behavior in natural and engineered systems and facilitate prediction of actinide behavior in complex systems.

FY 2014 HIGHLIGHTS

Titanium-doped magnetite nanoparticles were synthesized to examine the effects of systematically increasing the Fe(II)/Fe(III) ratio in magnetite on the adsorption of light actinides with a range of oxidation states. Preliminary results indicate that increased Ti concentration (and the resulting increase in surficial Fe(II) and Ti(IV)) results in increased absorption of actinides in the pentavalent and hexavalent oxidation states at low pH (~3). These results demonstrate that 'tunable' solid phases provide control over actinide partitioning in complex aqueous solutions which may be useful in understanding actinide geochemical behavior and in the development of actinide separation processes. Graphene oxide (GO) has been explored as a novel radionuclide sorbent. Sorption of Tc(VII) is very weak in neutral pH solutions but increases drastically with increasing acid concentration up to 5M HCl. The stability of GO under these harsh conditions illustrates its potential use for Tc removal (potentially selective removal) from strongly acidic waste streams. Strong sorption of Eu(III), U(VI), Np(V), and Th(IV) to GO in solutions ranging from pH 1 to 9 have been examined using a variety of techniques including FTIR-ATR, High Resolution-TEM/EDX, and quantum mechanical modeling. The GO appears to be capable of profoundly high sorption capacities which are on the order of 10 to 100 mg actinide/g_{GO}. The results indicate sorption is likely driven by complexation with carboxylate functional groups and sequestration of trivalent and tetravalent species within the interlayers of GO sheets. Examination of actinide and Tc interactions with these two novel sorbents is providing high level detailed information regarding the chemical behavior of these ions at solid:water interfaces. Gaining a molecular level understanding of these solid:water interface reactions will help to improve our understanding of actinide behavior in natural and engineered systems.

Radionuclide Waste Disposal: Development of Multi-scale Experimental and Modeling Capabilities

Institution: Clemson University
Point of Contact: Brian Powell
Email: BPOWELL@clemson.edu
Principal Investigator: Brian Powell
Sr. Investigator(s): Timothy DeVol; Clemson University
Stephen Moysey; Clemson University
Lawrence Murdoch; Clemson University
Travis Knight; South Carolina, University of

Students: Zheng Chang; South Carolina State University
5 Postdoctoral Fellow(s), 15 Graduate(s), 10 Undergraduate(s)
Funding: \$5,250,000 (2014-2017)

PROGRAM SCOPE

The objective of this project is to address scientific issues limiting understanding of radionuclide behavior in natural and engineered systems. The key issues to be addressed include identifying source terms for contaminants in geologic disposal scenarios, determining the chemical speciation of contaminants, delineating the biogeochemical and physical processes through which contaminant transport is manifested, and predicting contaminant mobility across wide temporal and spatial scales. This will be accomplished through a collaborative effort between scientists and engineers at Clemson University, University of South Carolina, and South Carolina State University. The proposed research program consists of the following four integrated tasks: Task A: Origins of Radionuclide Source Terms in Legacy and Advanced Waste Forms; Task B: Biogeochemical Behavior of Radionuclides in Natural Systems: Mineral, Plant, and Microbial Interactions; Task C: Imaging and Meso-Scale Facilities to Support Radionuclide Transport Studies; Task D: Development of Advanced Reactive Transport Models. These tasks will utilize an imaging facility to be designed and implemented as part of this work. The imaging facility will provide pore to lab scale imaging of radionuclide transport through soils as well as monitor the chemical, biological, and physical changes occurring in the soils over time. Through this implementation grant, we will (1) develop an innovative, cross-disciplinary testing and imaging facility, (2) construct a meso-scale field lysimeter facility for long-term radionuclide release experiments (both of which will support of nationwide nuclear-environmental efforts), and (3) apply and experimentally verify highly integrated reactive transport models of radionuclide transport in natural and engineered systems, including vegetation. The end result of these efforts will be used to address nuclear waste issues arising from commercial nuclear energy and legacy weapons production.

FY 2014 HIGHLIGHTS

The start date for this project is August 15, 2014. Therefore, the project was only active for a few weeks of FY 2014. An all hands meeting was held August 19th and an onsite DOE review was held September 25-26th. The scope of the project was presented to DOE program managers and reviewers.

Center for Interfacial Reaction Engineering

Institution: Oklahoma, University of
Point of Contact: Daniel Resasco
Email: ouresasco@gmail.com
Principal Investigator: Daniel Resasco
Sr. Investigator(s): Jeffrey Harwell; Oklahoma, University of
Steven Crossley; Oklahoma, University of
Bin Wang; Oklahoma, University of
Sanwu Wang; Tulsa, University of
Jeffrey White; Oklahoma State University
Clinton Aichele; Oklahoma State University
Brian Neeley; Oklahoma State University
Students: 6 Postdoctoral Fellow(s), 14 Graduate(s), 3 Undergraduate(s)
Funding: \$3,160,699 (2013-2016)

PROGRAM SCOPE

Investigations focus on reactive interfaces in liquid/liquid/solid systems with impact in energy applications, including biomass conversion, catalytic upgrading in liquid biphasic systems, polarity-driven selectivity, generation of H₂ through photocatalysis, and subsurface conversion in oil reservoirs at the water/oil interfaces. The four interconnected research thrusts include (a) Dynamics and structure of emulsions stabilized by nanoparticles such as nanotubes, Janus particles, and nanohybrids. Characterization under varying particle concentration, temperature, pH, water/oil ratio, flowing conditions, etc. Gel formation at very low solid concentrations is conducted with binary particles of different isoelectric points. (b) Synthesis, functionalization, and characterization of amphiphilic nanoparticles. Functionalized carbon nanotubes with varying hydrophobic/hydrophilic balance, which allows us to precisely control the location and orientation of the particles at the water/oil interface. Precise silylation of external surface minimizes the high susceptibility of hydrophilic zeolites to hot liquid water while keeping the active acid sites unaffected. Unfunctionalized zeolites lose crystallinity rapidly, but after silylation stability greatly increases without losing catalytic activity. (c) Reaction kinetics and transport phenomena in biphasic systems catalyzed by solids. Water/organic biphasic media; Fischer Tropsch synthesis, hydrogenation, hydrodeoxygenation, alkylation, photocatalytic oxidation. By properly adjusting the chemical potential of compounds, the kinetics and rate of mass transport can be finely controlled, thus controlling the selectivity of reactions in each phase. (d) Theory and spectroscopy at the water/oil/solid interfaces. Combination of FTIR, Raman, and NMR spectroscopies with DFT calculations and MD simulation has allowed us to obtain mechanistic insight on reactions catalyzed by metals, oxides, and acids occurring in the aqueous/oil media.

FY 2014 HIGHLIGHTS

Important progress has been accomplished in all four CIRE research thrusts. As a result, several publications (some involving various groups) have been obtained from work conducted under CIRE. They include 1. Chen, Damron, Pearson, Resasco, Zhang, White. "Zeolite Catalysis: Water Can Dramatically Increase or Suppress Alkane C-H Bond Activation" *ACS Catalysis*, 4 (2014) 3039 2. Weston, Venkataramani, Aichele, Grady, Harwell, Resasco, "Pseudo-solid, shear-thinning gel formation in binary dispersions of metal oxide nanoparticles at low volume fractions" *Langmuir* 30 (2014) 14982 3. Venkataramani, Aichele, "Concentrated Emulsion Characterization in Flowing Conditions" *Energy & Fuels* (2014) - DOI: 10.1021/ef5020583 4. Gebreyohannes, Neely, Gasem, "Generalized NRTL interaction model parameters for predicting liquid-liquid equilibrium behavior" *I&EC Research* 53 (2014) 12445. Based on the work conducted under CIRE, several of the PIs have been invited to speak in important events (ACS symposia, several universities in the US and Europe, PANIC NMR meeting, etc.). Members of CIRE have made ten contributed presentations at ACS Annual Meeting (San Francisco) and AIChE Annual Meeting (Atlanta) and submitted for upcoming NAM and APS meetings. An important development from CIRE has been a proposal to STC NSF program including 7 CIRE participants and contributors from S. Barbara, Caltech, Washington, and Princeton.

Miracles in Scattering Amplitudes: from QCD to Gravity

Institution: Brown University
Point of Contact: Anastasia Volovich
Email: Anastasia_Volovich@brown.edu
Principal Investigator: Anastasia Volovich
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2011-2016)

PROGRAM SCOPE

Proposed research in the area of theoretical high energy physics is centered around both theory and phenomenology of scattering amplitudes in quantum field theories and gravity. Recently remarkable advances have been made in this area, with a broad spectrum of results ranging from new precision predictions in QCD which will be very important for understanding Large Hadron Collider LHC data to the miraculous structures in $N=4$ Yang-Mills and $N=8$ supergravity. The goal of my research project involves deepening our understanding of gauge and gravity theories by exploring hidden structures of scattering amplitudes (ranging from integrability to twistors to the theory of motives), and using these rich structures as much as possible to aid practical calculations relevant to collider physics. These hidden structures not only help us calculate and make predictions for experimentally relevant processes but also lead to deeper understanding of fundamental properties of field and gravity theories. The funds will be used to train graduate students and postdocs.

FY 2014 HIGHLIGHTS

We continued exploring beautiful structures in scattering amplitudes. Motivated by the cluster structure of two-loop scattering amplitudes in $N = 4$ Yang-Mills theory we define cluster polylogarithm functions. We find that all such functions of weight 4 are made up of a single simple building block associated to the A_2 cluster algebra. Adding the requirement of locality on generalized Stasheff polytopes, we find that these A_2 building blocks arrange themselves to form a unique function associated to the A_3 cluster algebra. This A_3 function manifests all of the cluster algebraic structure of the two-loop n -particle maximally helicity violating amplitudes for all n , and we use it to provide an explicit representation for the most complicated part of the $n = 7$ amplitude as an example. We also investigated soft theorems in both Yang-Mills and gauge theories, providing a universal formula in arbitrary dimension. Investigation of these theorems from Ward identities of Bondi-Metzner-Sachs symmetry is under way.

Quantum Dot Sensitized Solar Cells Based on Ternary Metal Oxide Nanowires

Institution: Wyoming, University of
Point of Contact: Wenying Wang
Email: wwang5@uwyo.edu
Principal Investigator: Wenying Wang
Sr. Investigator(s): Jinke Tang; Wyoming, University of
Yuri Dahnovsky; Wyoming, University of
Jon Pikal; Wyoming, University of
Milan Balaz; Wyoming, University of
TeYu Chien; Wyoming, University of
Students: 2 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$1,875,000 (2013-2016)

PROGRAM SCOPE

This joint research effort on renewable energy materials at the University of Wyoming investigates the application of novel nanostructures including ternary metal oxide nanowires and semiconductor quantum dots (QDs) in QD sensitized solar cells (QDSSCs), and aims at achieving a better understanding on carrier generation, transport, and recombination in these structures. In this renewal project our first major research goal is to investigate magnetically doped quantum dots and related spin polarization effect, which could improve light absorption and suppress electron relaxation in the QDs. We will utilize both physical and chemical methods to synthesize these doped QDs. We will also study magnetically modified nanowires and introduce spin-polarized transport into QDSSCs, and inspect its impact on forward electron injection and back electron transfer processes. Our second goal is to study novel solid-state electrolytes for QDSSCs. Specifically, we will inspect a new type of polymer electrolytes based on a modified polysulfide redox couple, and examine the effect of their electrical properties on QDSSC performance. These solid-state electrolytes could also be used as filler materials for *in situ* sample fracturing in STM and enable cross-sectional interface examination of QD/nanowire structures. Our third research goal is to examine the interfacial properties such as energy level alignment at QD/nanowire interfaces using the newly developed Cross-sectional Scanning Tunneling Microscopy and Spectroscopy technique for non-cleavable materials. This technique allows a direct probing of band structures and alignment at device interfaces, which could generate important insight into the mechanisms that govern QDSSC operation. These investigations will be carried out through a close collaboration between our experimental and theoretical efforts in this project.

FY 2014 HIGHLIGHTS

1. We have synthesized Mn-doped ZnO nanowire arrays by a modified chemical vapor deposition method in order to introduce spin-polarized transport into QDSSCs.
2. Our current approach to improving the QDSSC efficiency is to investigate QDs doped with magnetic ions like Mn. In this work, we have demonstrated that pulsed laser deposition is very effective to synthesize Mn doped CdSe QDs. Mn resides on the Cd sites inside the CdSe QDs as shown in the Raman spectrum as well as depth profile of XPS. As a result of collaborative effort, improved QDSSC device performance based on CdSe:Mn QDs was obtained compared to that based on undoped CdSe QDs. On the investigation of colloidal quantum dots, we have shown for the first time that cysteine capped CdSe QDs synthesized by ligand exchange exhibit circularly polarized luminescence.
3. The use of liquid electrolyte in quantum dot-sensitized solar cells (QDSSCs) has been primarily impeded by limitation on the stability issue. We have investigated a novel solid-state polymer electrolyte based on PEO-PVDF polymer that blends with thiosulfate ($S_2O_3^{2-}$) and polysulfide (S_x^{2-}) as redox couples, allowing for an interesting way to probe the solid-state QDSSCs with new kind of redox couple different from the traditional S_2^-/S_x^{2-} in S/Na₂S aqueous electrolyte.
4. We have done extensive optoelectronic characterization of the zinc tin oxide nanowires. There is no emission from the band edge states of the nanowires, indicating that they are a direct forbidden bandgap material. Also, there is a broad defect peak in the visible which appears to be two separate peaks. We found that the fastest time constant dominates at short wavelengths but mostly disappears by 500nm as the slower time constants increase in importance. This work has been written up and is in the final internal review stages prior to submission.
5. We have calculated optical spectra and densities of states (DOS) for various CdSe and PbS quantum dots depending of sizes and shapes.

Enhancing Metabolic Flux to Photosynthetic Biofuels

Institution: Vanderbilt University
Point of Contact: Jamey Young
Email: j.d.young@vanderbilt.edu
Principal Investigator: Jamey Young
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$750,000 (2012-2017)

PROGRAM SCOPE

The overall objective of the project is to test new metabolic engineering and systems biology approaches for maximizing metabolic flux to biofuels in cyanobacterial hosts. The central hypothesis is that combining directed metabolic engineering approaches with global rewiring of circadian transcriptional programs will lead to enhanced biofuel productivities. ^{13}C metabolic flux analysis and metabolomic profiling will be applied to optimize cyanobacterial production of isobutyraldehyde (IBA), which is a direct precursor of isobutanol, starting from several promising strains of *Synechococcus elongatus* PCC 7942 that have been recently constructed.

FY 2014 HIGHLIGHTS

- We applied ^{13}C labeling experiments to a wild-type *Synechococcus elongatus* PCC 7942 strain (WT) and an IBA-producing strain (IBA) to quantify photoautotrophic metabolism.
- We developed a custom MATLAB-based software package called INCA (Isotopomer Network Compartmental Analysis), which automates the model construction and numerical simulation of isotopomer balance equations required for isotopically nonstationary MFA (INST-MFA). The software is publicly available at <http://mfa.vueinnovations.com>.
- By analyzing the labeling trajectories obtained from the transient $^{13}\text{CO}_2$ labeling studies using INCA, we were able to map the flow of carbon in the WT and IBA strains.
- Based on the ^{13}C flux analysis results, we have identified a potential bottleneck in central carbon metabolism that limits IBA production.
- We have constructed several mutant strains that overexpress enzymes needed to bypass this potential bottleneck and are currently assessing the impact of these overexpressions on IBA production.

Principal Investigator: Joshua Zide
Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 3 Undergraduate(s)
Funding: \$750,000 (2012-2016)

PROGRAM SCOPE

Nanocomposites consisting of rare-earth monpnictide nanoparticles (e.g. ErAs) within III-V semiconductors represent a useful composite material for a variety of applications. The incorporation of nanoparticles into semiconductors can pin the Fermi level, drastically altering the electronic properties in ways that are fundamentally different from conventional doping. This can reduce carrier lifetimes and also controllably change electrical conductivity depending on the matrix and composition of the nanoparticle. Additionally, nanoparticles scatter phonons, reducing thermal conductivity. These materials have been studied using molecular beam epitaxy (MBE)-grown materials and have been shown to be promising for myriad (opto)electronic and energy conversion applications. The epitaxial relationship between the crystal structures of the nanoparticles and matrix creates high quality interfaces, allowing the study of charge transfer mechanisms in nanostructured electronic composites. While prior work by MBE has enabled significant advances in the understanding of a subset of this class of composite materials, the hallmarks of MBE-grown material are a lack of flexibility in composition, a slow growth rate, and very high cost. To these ends, this project is focused on creating epitaxial nanocomposites via a hybrid approach in which nanoparticles are produced using inert gas condensation (IGC) and incorporated epitaxially into semiconductor films using liquid phase epitaxy (LPE). This hybrid approach has several advantages. First, there is considerable flexibility in what materials are grown because the nanoparticles are produced separately. Many different compositions can therefore be explored. This new approach also allows growth rates of micrometers per minute rather than micrometers per hour, thus allowing thicker films and scaling of materials. Finally, this approach can be generalized; we hope to establish a new paradigm in nanocomposites for electronic materials.

FY 2014 HIGHLIGHTS

The past fiscal year was a critical time in this project, as the Inert Gas Condensation (IGC) system became fully operational. Accordingly, erbium arsenide (ErAs) nanoparticles were produced and characterized, and techniques to control particle production, collection, and characterization have been refined. Specifically, switching to a laser ablation approach for the evaporation of both the rare earth (erbium) and the group V species (arsenic) has permitted excellent control over relative evaporation rates by defocusing the laser spot. Under one set of growth conditions, we have obtained particles with a mean diameter of approximately 4nm with a standard deviation of approximately 1nm. Changing helium pressure and evaporation rate permits tuning of particle size distribution, but we are still working to thoroughly characterize this effect. Additionally, we have found that collected particles do not oxidize as readily as initially expected. This result is both fortuitous (as it permits more flexible characterization of particles) and also sensible given the quite small size of the particles. We are currently working on characterizing particle morphology and determining how to control size. Additionally, because ErAs is anti-ferromagnetic (albeit with a low Neel temperature of 4K), we are exploring opportunities to determine how magnetic properties of antiferromagnetic materials scale with particle size. In this past year, we have also rebuilt the liquid phase epitaxy system and determined the conditions required to grow high-quality GaAs. Our most recent growths appear to be high-quality, thick (>10 micrometer), epitaxial GaAs on GaAs, and we are therefore now ready to incorporate nanoparticles into films. We expect rapid progress to continue in calendar year 2015 building on our efforts from previous years.

Spin Effects in Magnetic and Non-Magnetic 2D Correlated Insulators

Institution: Louisiana State University
Point of Contact: Philip Adams
Email: adams@phys.lsu.edu
Principal Investigator: Philip Adams
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

Our experimental research program is focused on the magneto-transport, non-equilibrium relaxation, and spin-resolved density-of-states properties of highly disordered two-dimensional paramagnetic, ferromagnetic, and superconducting systems. The specific research agenda of the program is organized into three separate but related areas. The first is studies of disorder and correlation effects in superconducting Al and V films that have been subjected to high Zeeman fields. We are primarily interested in what role local spin-triplet fluctuations play in determining the nature of the superconductor-insulator transition in these systems. The second class of systems that we study is represented by ultra-thin CR₃ magnetic films (R = Ni, Co, Fe) formed via e-beam deposition from arc-melted buttons of these metastable, covalently bonded compounds. When made sufficiently thin, these films they exhibit a correlated insulator phase that is similar to what we have observed in homogeneously disordered, non-magnetic, Be films. In addition to the conductivity, we can follow the magnetic behavior via the anomalous Hall effect and spin polarized tunneling as the films are pushed to higher and higher sheet resistance. The third class of systems is proximity structures comprised of non-magnetic/ferromagnetic bilayers. We have developed spin-resolved tunneling probes that give us a direct measure of the proximity-induced exchange field in non-magnetic component of the bilayers.

FY 2014 HIGHLIGHTS

We have just completed a study of the non-equilibrium behavior of disordered superconducting Al films in high Zeeman fields. We find that, in moderately disordered films, with sheet resistances of a few hundred ohms, large avalanches occur on the superheating branch of the critical field hysteresis loop. In contrast, the transition back into the superconducting phase (i.e., along the super-cooling branch) is always continuous. The fact that the condensate follows an unstable trajectory to the normal state suggests that the order parameter in the hysteretic regime is not homogeneous. We believe that the asymmetric avalanche behavior may, in fact, be a manifestation of a disordered spin polarized superconducting phase. In a separate project, we documented a magnetic field-pulse memory effect in the temperature-dependent magnetization of Tb₃₀Ru_{6.0}Sn_{29.5}, a spin-glass material having a newly identified structure type. Tb₃₀Ru_{6.0}Sn_{29.5} exhibits a glassy magnetization component of 2290 emu/mol-Tb, which represents over 84% of its total saturation magnetization. We showed that when a magnetic field pulse of a few hundred gauss is applied to the sample as it is cooling, the system retains a memory of the temperature at which the pulse was applied. Upon warming, the imprinted memory is observed as a precipitous drop in magnetization at the pulse temperature. We believe that spin-glass behavior

arises from competing interactions between the many non-equivalent magnetic sites in the complex crystal structure. Indeed, this compound has more than 100 atoms in its unit cell, with 11 inequivalent Tb sites. Unlike more traditional spin-glasses, the dynamics do not appear to be related to geometric frustration and/or structural disorder.

Heavy Fermions, Quantum Criticality, and Unconventional Superconductivity in Filled Skutterudites and Related Materials

Institution: Florida, University of
Point of Contact: Bohdan Andraka
Email: andraka@phys.ufl.edu
Principal Investigator: Bohdan Andraka
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Performed research was on unconventional superconductivity and the relationship between superconducting and normal state properties. The focus was $\text{PrOs}_4\text{Sb}_{12}$, first discovered heavy fermion Pr-based superconductor which exhibits two superconducting transitions. This is one of two materials only known to have two superconducting transitions, and which remains a subject of a controversy and general interest of physics community. Existence of small crystals with a single superconducting transition leads to a consensus that the upper superconducting transition is extrinsic. We have continued broad material investigation and characterization of different $\text{PrOs}_4\text{Sb}_{12}$ samples to search for correlations between existence of the upper superconducting transition and quality of material. Specific heat, dc- and ac-magnetic susceptibility and electrical resistivity were primary experimental techniques.

FY 2014 HIGHLIGHTS

1. We were able to reproduce crystals with a single superconducting transition at T_{c2} (~ 1.75 K) in bulk-type measurements such as specific heat.
2. Single T_c samples had systematically lower RRR ratios than samples with a double superconducting transition implying their inferior quality.
3. As opposed to the accepted model, the suppression of superconductivity at T_{c1} is via the reduction of the size of the superconducting anomalies, e.g. in specific heat, and not by the reduction of T_{c1} itself.
4. The imaginary part of ac-susceptibility showed two peaks for materials with two superconducting transitions, implying inhomogeneous coexistence of two superconducting transitions.
5. We have concluded that both superconducting phases are intrinsic to $\text{PrOs}_4\text{Sb}_{12}$ and most likely are due to electronic inhomogeneities associated with near degeneracy of lowest crystal field levels.
6. Crystals with a single superconducting transition had linear $H_{c2}(T)$ variation near T_c , when measured by bulk (specific heat) method. This is contrary to the accepted believe derived from resistive measurements.

Experimental Studies of Correlations and Topology in Two Dimensional Hybrid Structures

Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)

Funding: \$160,000 (2014)

PROGRAM SCOPE

Electrons moving through the transistor channels that empower today's semiconductor-based electronic devices do not move in straight lines. This is because they are perpetually being scattered by a host of imperfections and vibrations, which put a strict limit on the electron speed and dissipate their energy by generating heat. It was recently realized that this does not have to be so. Electrons moving through graphene – one atom-thick crystals of carbon – or on the surface of the so called topological insulators, are immune to such collisions. In these materials the electrons behave like massless particles, also known as Dirac fermions, and can move along at a constant high speed in straight lines, just like photons do, over large distances corresponding to tens of thousands times the inter-atomic spacing. This is a proposal to explore electronic properties and possible device applications that arise in graphene and topological insulators due to their unusual electronic properties and topology. We will focus on phenomena that rise when these materials are combined in sandwich structures or brought in proximity with other types of electronic systems. Such heterostructures are expected to host novel phenomena that have no parallel in traditional electron systems. The research topics that will be addressed in this work include: i) effect of screening on the electronic properties of magnetically induced one dimensional chiral edge states in the quantum integer and fractional quantum Hall regime will be studied in sandwiches of graphene with boron-nitride and conducting electrodes; ii) stacking-induced modification of the electronic density of states including twist-induced van Hove singularities, correlated phases and twist-induced slowdown of the Fermi velocity; iii) electron light-like propagation and diffraction effects at boundaries; iv) induced superconductivity in graphene and topological insulators.

FY 2014 HIGHLIGHTS

This project addresses open questions on the emergence of novel electronic properties that arise in low dimensional materials due to the interplay between reduced dimensionality, incomplete screening, boundaries and proximity between different electronic states of matter. Our current focus is thin layers and interfaces including graphene, MoS₂ and stacked hybrid structures. We developed sample preparation and fabrication techniques and characterization tools that allowed us to probe the electronic properties of two-dimensional electron systems and to follow their evolution with distance from an edge, with magnetic field, doping and gating. The characterization techniques include scanning tunneling microscopy, scanning tunneling spectroscopy, Landau level spectroscopy, atomic force microscopy, Raman spectroscopy.

“Screening Charged Impurities and Lifting the Orbital Degeneracy in Graphene by Populating Landau Levels.” *Physical Review Letters*, 112, 036804 (2014). Editor's Choice It is well known that impurities leave their mark on the thermodynamic, transport and optical properties of 2D electron systems often preventing the formation of many-body quantum phases such as fractional quantum Hall states. But experimentally, the connection between the microscopic characteristics of the impurity, screening by the environment and the electronic properties of the system is still largely unexplored. In this work we studied an isolated charged impurity in graphene and obtained direct evidence of the close connection between the screening properties of a 2D electron system and the influence of the impurity on its electronic environment. Using scanning tunneling microscopy and Landau level spectroscopy we demonstrated that in the presence of a magnetic field the strength of the impurity can be tuned and controlled by a gate voltage.

Novel Temperature Limited Tunneling Spectroscopy of Quantum Hall Systems

Institution: Massachusetts Institute of Technology
Point of Contact: Raymond Ashoori

Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$525,000 (2014-2017)

PROGRAM SCOPE

The “single particle” spectrum obtained from techniques such as photoemission or tunneling spectroscopy is among the most fundamental quantities in theories of highly interacting systems, answering the question, “at which energies can electrons be added to (or removed from) the system?” In a number of scientifically exciting and technologically important electronic systems, it has proven very difficult to achieve accurate quantitative determination of this single-particle spectrum. Among these is the two-dimensional (2D) electron system in semiconductors and in graphene. A means of spectroscopy that injects single electrons can reveal how a newly added electron is incorporated in the quantum states that produce novel electronic properties in these systems. This work studies the behavior of 2D electrons in high magnetic fields using of a unique spectroscopic technique, time domain capacitance spectroscopy (TDCS). TDCS injects or ejects electrons from the 2D system by inducing electron tunneling from hundreds of thousands of small electrical pulses. It measures the single-particle spectrum of the 2D electron system with negligible electron heating, even when the in-plane conductivity of the system vanishes. The work applies TDCS to a number of quantum Hall systems and develops a new charge detection scheme for TDCS using single electron transistors. This new method can provide high-resolution spectra of small graphene samples in the quantum Hall regime and in the recently observed “Hofstadter Butterfly”. TDCS will also be used to study the very low temperature behavior of the semiconductor two-dimensional electron systems in high magnetic fields in the regime of the fractional quantum Hall effect. TDCS can grow to be applied to technologically important systems such as high- T_c superconductors, single molecules, topological insulators, and spintronics systems to provide fundamental data on the electronic properties of these materials.

FY 2014 HIGHLIGHTS

Our work in this year has moved forward primarily in two areas: (1) development and measurements of graphene structures with the ultimate goal of performing TDCS experiments on them and (2) measurement of quantum Hall systems in GaAs quantum wells. Our graphene work resulted in a remarkable observation. In transport and capacitance measurements performed on ultra-clean graphene samples with a large in-plane magnetic field, we observed a novel quantum spin Hall (QSH) state. The QSH state is a fascinating state of matter in which the electronic transport is quantized and current is carried by two pairs of counter-propagating, spin-polarized edge modes. Its theoretical prediction and subsequent experimental discovery in an uncommon type of semiconductor quantum well developed from an early prediction of its existence in graphene arising as a consequence of spin-orbit coupling. In an alternative proposal, an exact analog of the QSH state had been proposed to exist in graphene, but unambiguous demonstration of this state has been hindered by lattice-scale Coulomb interactions, which favor valley rather than spin polarization. Our application of a large in-plane magnetic field sufficiently enhanced the Zeeman energy sufficiently to overcome Coulomb interactions, allowing direct observation of the novel QSH state and along with interesting new behaviors of the

conductivity at the sample edges. In our work in GaAs semiconductors, we have performed TDCS measurements of quantum wells containing 2D holes down to 20mK, a temperature significantly colder than our prior studies. At the lowest temperatures, we observe a sharp feature in the spectrum that is anti-symmetric in energy and density about filling factor 1. Analysis of the quasiparticles dynamics is consistent with a picture in which holes are dressed by interactions with bosonic degree of freedom that we attribute to the Goldstone mode emergent from crystalline order of the charged quasiparticles.

High Magnetic Fields as a Probe to Unveil the Physical Properties of the Newly Discovered Fe Oxypnictide Superconductors and Related Compounds

Institution: Florida State University
Point of Contact: Luis Balicas
Email: lbalicas@fsu.edu
Principal Investigator: Luis Balicas
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$162,000 (2014)

PROGRAM SCOPE

The Fe based superconductors are generally accepted to display a superconducting pairing mechanism mediated by antiferromagnetic spin-fluctuations which in these multi-band systems is predicted to lead to a gap of s-wave symmetry and whose wave function changes its sign when going from hole-like to the electron-like cylindrical Fermi surfaces. Our current work revealed evidence for i) additional phases within the superconducting state of some of these compounds and possibly ii) time reversal symmetry superconducting states. Objectives i) To expose evidence for an additional superconducting state at high fields in the $\text{Fe}_{1+y}\text{Te}_{1-x}\text{Se}_x$ series through thermodynamic measurements and map its phase diagram. ii) Similarly, given our magnetic torque data which indicates the presence of a sharp phase transition preceding H_{c2} in extreme high quality samples of URu_2Si_2 , map its entire phase diagram as a function of field orientation and temperature by exposing its magnetic and thermodynamic properties. iii) Given the anomalous magnetic like irreversibility observed in the superconducting state of LiFeAs at high fields, which corresponds to potential evidence for broken time reversal symmetry in a superconducting state, to collect additional evidence for its existence through an array of experimental techniques. We also propose to clarify if this state is induced by the external field. v) To fully map the geometry of the Fermi surface of this compound in an attempt to elucidate what seemingly are strong discrepancies with band structure calculations. This would allow the development of theoretical models explaining its pairing symmetry which might clarify the origin of the anomalous irreversibility. vi) Given the extremely high upper critical fields observed by us in $\text{Ta}_2\text{Pd}_{0.85}\text{S}_5$, we propose to explore the possibility of observing superconductivity in other members of this family but in samples synthesized by us.

FY 2014 HIGHLIGHTS

1) Published a detailed de Haas van Alphen study in LiFeAs unveiling additional, small and nearly isotropic Fermi surface sheets in LiFeAs single crystals, which ought to correspond to hole-like orbits, as previously observed by ARPES. Our results conciliate the apparent discrepancy between ARPES and the previous dHvA results. The small size of these Fermi surface pockets suggests a prominent role for the electronic correlations in LiFeAs . The absence of gap nodes, in combination with the coexistence of quasi-two-dimensional and three-dimensional Fermi surfaces, favors a s-wave pairing symmetry for LiFeAs . 2) Reported a Shubnikov-de Haas (SdH) effect study on the pnictide parent compounds EuFe_2As_2

(Eu122) and BaFe₂As₂ (Ba122) grown by In-flux. 3) Published evidence for a field-induced quantum phase transition associated with the suppression of the spin-density wave in CeCu₂Ge₂. This transition leads to a remarkable effective mass renormalization for fields along the a-axis and to a cascade of field-induced transitions of unknown origin 4) Submitted experimental evidence for a field-induced quantum phase transition associated with the quadrupolar order degrees of freedom in PrV₂Al₂O. 5) Observed the realization of the axial anomaly in quasi-two-dimensional metal. The axial anomaly leads to the violation of separate number conservation laws for left- and right-handed massless chiral (or Weyl-) fermions. To date, there is no concrete experimental realization of a Weyl semi-metal or unambiguous evidence for this field-induced phenomenon. We observed a very large negative magnetoresistance in the extremely clean quasi-two-dimensional metal PdCoO₂. Our experimental study provides strong support for a scenario where this unconventional response results from the axial anomaly of field-induced quasi-one-dimensional conduction channels. The observation of this effect would demonstrate that the axial anomaly is a general feature of clean metals.

Electromagnetic Response of Correlated Electron Systems

Institution: California-San Diego, University of
Point of Contact: Dmitri Basov
Email: dbasov@physics.ucsd.edu
Principal Investigator: Dmitri Basov
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The proposed program was focused on two classes of novel electronic systems: nickelates and graphene. Both classes of materials feature a wealth of new physical phenomena that are yet to be understood. Both classes of materials also hold great promise for technological applications. Therefore the proposed program allowed the PI to explore and exploit novel effects arising in these systems from complex many-body effects. The IR nanoscopy studies were aimed at the systematic investigation of role of electronic phase separation in the insulator-to-metal transition region in nickelates. Specifically, near-field IR experiments will be performed for a series of ultrathin films of NdNiO₃ and superlattices based on LaNiO₃. The electronic properties of these compounds can be controlled through strain and epitaxy. The proposed work on nickelates provided the most complete experimental picture of emergence of the metallic state in this prototypical family of correlated oxides. The graphene component of the program will focus on the methodical examination of the electronic and plasmonic response using in-house nanoscopy instrumentation as well as IR microscopy facility at the Advanced Light Source (ALS). The role of electronic correlations and many-body effects in graphene is an important unresolved problem. The PI investigated a new generation of graphene samples including specimens on BN substrates and also free-standing, suspended graphene. This work will help to ascertain the roles played by disorder and many-body effects in the intrinsic properties of graphene.

FY 2014 HIGHLIGHTS

The PI investigated hexagonal boron nitride (hBN): a common substrate material for high quality graphene. This work has resulted in the discovery of phonon polariton waves in hBN (Science 2014). Phonon polaritons are collective modes that originate from coupling of photons with optical phonons in polar crystals. Phonon polaritons in hBN reveal strong confinement quantified by the ratio of the IR

wavelength λ_{IR} to the polariton wavelength λ_p : $C=\lambda_{IR}/\lambda_p=40$. Prior to work of the PI on hBN, intriguing and potentially technologically significant nano-photonics effects in this prototypical atomic crystal had not been anticipated. These first data of propagating phonon polaritons in hBN call for the systematic studies of these enigmatic waves that are of high interest for fundamental physics as well as for applications in sub-diffractive optics/photonics.

Probing Nanocrystal Electronic Structure and Dynamics in the Limit of Single Nanocrystals

Institution: Massachusetts Institute of Technology
Point of Contact: Mounji Bawendi
Email: mgb@MIT.edu
Principal Investigator: Mounji Bawendi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$235,000 (2014)

PROGRAM SCOPE

Semiconductor nanocrystals (NCs) have been incorporated into a broad array of optoelectronic devices, including solar photovoltaics, LEDs, and downshifters. Given the potential impact of devices that use NCs as a functional material in the energy field, it is crucial to understand at a very basic level the optical physics of NCs. Without such understanding, designing novel structures, novel device architectures, and understanding the potential and limitations of present materials and devices is haphazard at best. This project consists of a set of critical and ambitious studies of nanocrystal electronic structure and dynamics, largely at the single-NC level, including: (1) utilizing a novel single molecule characterization technique that we have developed, Photon-Correlation Fourier Spectroscopy (PCFS), to reveal the intrinsic single-NC spectrum and its dynamics at time scales ranging from 30 nanoseconds to hundreds of seconds, as a function of temperature, directly in solution or fixed on a substrate, and using this to characterize interactions between single nanocrystals and their environment; (2) probing the dynamical and spectral properties of multiexcitons, as a function of temperature and through the development of solution and n^{th} -order Photon Correlation Spectroscopy (nPCS) for higher order multiexcitons ($n>2$); (3) applying PCFS and single-NC photon correlation methods to shortwave infrared (SWIR) emitting NCs that have a band gap matched to the solar spectrum (e.g. PbS, PbSe, and InAs NCs) to extract fundamental intrinsic NC spectral and dynamical properties; and (4) probing the dynamics of fluorescence intermittency to elucidate the effect of NC structure on fluorescence “blinking” and to understand mechanistically the connection between ensemble and single-NC emission properties.

FY 2014 HIGHLIGHTS

In FY 2014, we focused on four projects that advance our understanding of the fundamental photophysics of semiconductor nanocrystals (NCs). First, we leveraged our expertise in solution-phase photon correlation Fourier spectroscopy (S-PCFS) to study the average intrinsic fluorescence lineshape of single NCs. The single-NC lineshape is an important observable because it reports on the vibrational coupling between NCs and their environment. S-PCFS reveals this lineshape with high spectral resolution and signal-to-noise, and without the confounding effects of photo-charging and spectral diffusion. Our efforts, the subject of a manuscript in preparation, have shown that NC exciton-vibrational coupling is highly affected by surface effects and is less affected by NC size. Second, we constructed a new PCFS setup to study infrared-emitting materials. Infrared-emitting NCs are promising optical materials well-matched to the solar spectrum. However, their basic optical physics are not well-understood because of

the lack of sensitive infrared detectors. The recent development of superconducting nanowire single photon detectors has provided an opportunity to access the shortwave infrared optical regime. Third, we developed a new technique to measure the average biexciton quantum yield of a sample of NCs. Although previously difficult to measure experimentally, the biexciton quantum yield is an important parameter for NC fluorescence performance under high excitation flux. Our new method, recently published in Nano Letters, provides a convenient, reliable, and precise method for characterizing the effect of synthesis on the biexciton quantum yield. And finally, we contributed a review paper in Chemical Society Reviews that exhaustively documents the broad array of single-molecule techniques available to study the optical properties of NCs. This review serves as a pedagogical resource for newcomers to the field.

EARLY CAREER: Interface-Driven Chiral Magnetism in Ultrathin Metallic Ferromagnets: Towards Skyrmion Spintronics

Institution: Massachusetts Institute of Technology
Point of Contact: Geoff Beach
Email: gbeach@mit.edu
Principal Investigator: Geoff Beach
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

Magnetic skyrmions are localized chiral magnetic textures in the form of nanoscale vortices or bubbles that are topologically protected from being 'unwound'. Their topological nature gives rise to rich behaviors including ordered lattice formation, emergent electrodynamics and robust current-driven displacement at remarkably low current densities. However, magnetic skyrmions have so far been restricted to just a few materials and observed only at low temperatures, limiting the experimental accessibility and technological application of these unique topological objects. This project aims to realize magnetic skyrmions at room temperature in a new class of engineered chiral ferromagnets that exploit broken mirror symmetry at interfaces to generate helical magnetic order. Ultrathin magnetic heterostructures will be engineered and patterned into laterally-confined nanostructures in which skyrmions can be stabilized, manipulated, and detected for the first time under ambient conditions. Static and dynamic properties will be examined using advanced x-ray imaging and nanoscale electrical probes to provide a fundamental understanding of topological magnetic phases. The interactions between magnetic skyrmions and electron charge and spin currents will be studied to identify fundamental new physics and enable device applications. These experimental studies, supported by detailed modeling, will help launch a new subfield of skyrmion-based spintronics in which individual skyrmions can be used to encode, store, and transport information in high-performance, low power memory and logic devices.

FY 2014 HIGHLIGHTS

Since the project start date of 8/15/2014, we have successfully fabricated and characterized multilayers of Pt/Co/Ta with strong Dzyaloshinskii-Moriya interaction, and performed magnetic transmission x-ray microscopy imaging that provides the first observation of a skyrmion lattice at room temperature in an ultrathin film. In very recent work, we examined the domain structure in films and micro/nanostructures, to confirm a strong antisymmetric (Dzyaloshinskii-Moriya) interaction in these

films, showing that this strong interaction is responsible for the observed behavior. Finally, we have successfully created trains of skyrmions in a magnetic nanostrip and imaged their displacement by current, driven by the spin Hall effect. These results are currently being written up for journal submission.

Nonlinear Transport in Mesoscopic Structures in the Presence of Strong Many-Body Phenomena

Institution: New York-Buffalo, State University of
Point of Contact: Jonathan Bird
Email: jbird@buffalo.edu
Principal Investigator: Jonathan Bird
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$149,968 (2014)

PROGRAM SCOPE

On approaching the microscopic realm from the classical world one enters an intermediate, “mesoscopic”, regime, in which rich quantum-mechanical behavior may be manifested by systems with large numbers of interacting particles. The study of physics on this mesoscopic scale has a long history of informing the development of condensed-matter physics. At the same time, this field remains fertile for fundamental discovery, most notably by addressing issues at the nexus of two distinct fields – nonequilibrium quantum transport and many-body physics. It is the exploration of novel phenomena in these regimes that provides the overarching motivation for this project. More specifically, we address important fundamental questions, such as: how are the many-body interactions of carriers modified when their motion is strongly confined on the nanoscale; how are the quantum states of isolated mesoscopic structures affected when they are coupled to an external environment; can such an environment mediate a coherent coupling between different structures, and; what is the nature of carrier transport in such systems under strongly-nonequilibrium conditions? To address these questions, we study mesoscopic transport in a variety of semiconductor nanostructures, which are implemented in high-quality gallium arsenide heterostructures, or by using an emergent material, graphene, as the carrier host. We bring novel approaches to the study of this problem, most notably by implementing transient electrical measurements that probe transport in mesoscopic systems in real-time. While the primary focus of our studies is on achieving a fundamental understanding of the complex quantum-transport phenomena that emerge at the mesoscopic scale, this project also has potential implications for attempts to develop future nanoelectronic technologies.

FY 2014 HIGHLIGHTS

We have two major accomplishments to report from 2014: (1) 'Formation of a protected sub-band for conduction in quantum point contacts under extreme biasing', *Nature Nanotechnology* vol. 9, 101 (2014). Managing energy dissipation is critical to the scaling of nanoelectronics and to the development of novel devices that use quantum coherence to achieve enhanced functionality. To this end, strategies are needed to tailor the electron-phonon interaction, which is the dominant mechanism for cooling non-equilibrium ('hot') carriers. Here, we showed a surprising behavior, in which strong electron-phonon scattering can instead be used to generate a robust mode for electrical conduction in quantum point contacts, driven into extreme non-equilibrium by nanosecond voltage pulses. When the amplitude of these pulses is much larger than all other relevant energy scales, strong electron-phonon scattering results in the spontaneous formation of a narrow current filament that conducts current with little

backscattering. This collective non-equilibrium mode may provide an effective means to manage heating in nanoscale devices. (2) 'Tuning the Fano resonance with an intruder continuum', Nano Lett. vol. 14, 788 (2014). In this work, we established the possibility of achieving strong tuning of Fano resonances, by allowing their usual two-path geometry to interfere with an additional, "intruder", continuum. As the coupling strength to this intruder is varied, we predicted strong modulations of the resonance line shape that, in principle at least, may exceed the amplitude of the original and Resonance (FR) itself. For a proof-of-concept demonstration of this phenomenon, we constructed a nanoscale interferometer from nonlocally coupled quantum point contacts and utilized the unique features of their density of states to realize the intruder. This general scheme for resonant control should be broadly applicable to a variety of wave-based systems.

Novel Behavior of Ferromagnet/Superconductor Hybrid Systems

Institution: Michigan State University
Point of Contact: Norman Birge
Email: birge@pa.msu.edu
Principal Investigator: Norman Birge
Sr. Investigator(s): William Pratt (retired); Michigan State University
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$165,000 (2014)

PROGRAM SCOPE

The interplay between superconductivity and ferromagnetism gives rise to a number of new physical phenomena. This project focuses on the unusual proximity effects that occur when conventional superconducting (S) materials are placed in contact with ferromagnetic (F) materials. Because of the strong exchange field, the electron pair correlations in F oscillate and decay rapidly with increasing distance from the S/F interface. A decade ago it was predicted that a new type of pair correlations, with spin-triplet symmetry, could be induced in S/F systems in the presence of certain kinds of magnetic inhomogeneity. Those pair correlations penetrate deeply into ferromagnetic materials; hence they are sometimes called "long-range triplet correlations," or LRTC. Our group was among the first to obtain convincing experimental evidence for the LRTC in S/F systems, in 2010. We fabricated Josephson junctions containing three ferromagnetic layers, and observed that the supercurrent persisted as we increased the thickness of the middle F layer well beyond what a conventional spin-singlet supercurrent could penetrate. Since then we have been working to understand better the signatures of the LRTC in a variety of experimental situations, as well as how to optimize and control generation of the LRTC.

FY 2014 HIGHLIGHTS

Since 2010, several groups around the world have been trying to observe long-range spin-triplet superconducting correlations in a variety of systems. Surprisingly, nobody has successfully demonstrated what would be the most dramatic confirmation of the theory, namely, control of the supercurrent in a Josephson junction by changing the relative orientations of the various ferromagnetic layers inside the junction. Such control could occur in one of two ways in a junction containing three ferromagnetic layers: 1) by rotating the magnetization of one of the layers by 90 degrees, one should be able to turn the spin-triplet supercurrent on and off; 2) by rotating the magnetization of the one of the layers by 180 degrees, one should be able to change the junction from a "0" junction to a "pi" junction. (In a "pi" junction, the ground state phase different across the junction is pi, and the current-phase relation has a negative sign relative to the standard relation observed in a "0" junction.) Some progress

toward these goals was achieved by us in 2012, and another step was taken recently by the group of Mark Blamire at Cambridge. We are current working toward both of these goals. To observe the change from 0 to π , we fabricate SQUID samples (SQUID = Superconducting Quantum Interference Device) containing two junctions. We have observed evidence for 0- π switching in such devices, but the magnetic behavior we have observed so far has not been sufficiently reproducible to allow us to make a strong claim. Hence we have not yet published these results. We are putting much effort into characterizing both strong and weak ferromagnetic materials, to help us better control the magnetic states inside our junctions.

Raman Spectroscopy of Iron Oxypnictide Superconductors

Institution: New Jersey-Rutgers, State University of
Point of Contact: Girsh Blumberg
Email: girsh@physics.rutgers.edu
Principal Investigator: Girsh Blumberg
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The objectives of project are to investigate the manner in which charge, spin and lattice coupling and dynamics evolve through various phases of iron oxypnictide superconductor families of materials by employing electronic, magnetic, and phononic Raman (i.e., inelastic light scattering) spectroscopy, and to clarify the microscopic origin of unconventional superconductivity and magnetism in these compounds.

FY 2014 HIGHLIGHTS

(1) The understanding of the phase diagram of iron based superconductors (FeSC) [2-5]; (2) The discovery of novel collective modes in FeSC [2,4]; (3) The elucidation of the superconducting “glue” in FeSC [2-5]; (4) Determination of the SC gap in $K_{0.75}Fe_{1.75}Se_2$, $BaFe_{1.9}Pt_{0.1}As_2$ and $NaFe_{1-x}Co_xAs$ superconductors [2-4]; (5) The establishment of the “Hidden Order” parameter in URu_2Si_2 heavy fermion superconductor [1]. EARLY CAREER: Spin Wave Interactions in Metallic Ferromagnets

Institution: Colorado State University
Point of Contact: Kristen Buchanan
Email: Kristen.Buchanan@ColoState.edu
Principal Investigator: Kristen Buchanan
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Spin waves in ferromagnetic materials play a key role in a range of intriguing phenomena. Recent work shows that spin dynamics measurements can provide a means to quantify spin Hall effects and, conversely, that spin accumulation effects can be used to influence propagating spin waves. At the same time, the macroscopic length scales associated with thermally-driven spin phenomena in magnetic materials have raised new questions regarding the coupling between magnons, phonons, and spin accumulation effects. The goal of this project is to investigate two main directions related to spin dynamics in ferromagnets, namely the interactions between spin currents and propagating spin waves and the role of magnons and phonons in thermally-driven spin effects. Brillouin light scattering, a technique that is sensitive to both spin wave excitations or magnons and phonons, will be used to explore the fundamental nature of these effects.

FY 2014 HIGHLIGHTS

Highlights from FY 2014 include the observation of directly-excited backward volume (BV) spin waves in patterned ferromagnetic nanowires over a range of magnetic fields, including zero field, and investigations of the effect of thermal gradient on spin waves propagation using Brillouin light scattering (BLS). Previous experimental work on spin wave propagation in ferromagnetic nanowires has mainly been performed in the magnetostatic surface wave or Damon-Eshbach (DE) configuration where a static magnetic field is applied in-plane, perpendicular to the wire since spin waves can be excited relatively easily in this configuration. The less studied BV configuration where the magnetization is along the wire is, however, also of interest because spin waves can propagate even in the absence of an external magnetic field in this geometry, which is attractive for applications. Micro-BLS measurements show that although the intensities of the spin waves in the BV geometry were an order of magnitude lower than those observed in the DE configuration, BV spin waves were detectable at a range of magnetic fields including zero. The results agree well with dispersion calculations for propagating BV spin waves that include quantization effects due to the finite dimensions of the nanowire. Although many experiments have been done in the BV geometry in low-loss yttrium iron garnet (YIG), few have been done in nanowires hence these results are an important step towards nanoscale spin wave devices. BLS was also used to study how spin waves are affected by the presence of a thermal gradient, this time in a YIG thin film so that the effects could be studied over longer length scales (millimeters). The BLS data reveal subtle changes in the spectra at low frequencies that become more substantial at higher frequencies. Furthermore, significant changes in the amplitude were detected for a spin wave pulse that travels towards a heated area, an effect that may be useful for applications.

Cold Exciton Gases in Semiconductor Heterostructures

Institution: California-San Diego, University of
Point of Contact: Leonid Butov
Email: lvbutov@physics.ucsd.edu
Principal Investigator: Leonid Butov
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

An indirect exciton is a bound pair of an electron and a hole confined in spatially separated layers. Long lifetimes of indirect excitons allow them to cool down to low temperatures below the temperature of quantum degeneracy. This gives an opportunity to realize cold excitons. Due to their long lifetimes, indirect excitons can travel over large distances before recombination. The spatial separation between an electron and a hole and the suppression of exciton scattering in a coherent exciton gas result to the suppression of spin relaxation facilitating long-range spin currents. Indirect excitons are dipoles, and their energy can be controlled by voltage. This gives an opportunity to create potential landscapes for indirect excitons. The goal of this project is to explore these properties of indirect excitons to study cold excitons in periodic potential landscapes and to study spin-related phenomena in cold exciton gases. We will study exciton transport in periodic potential landscapes. We will also develop stirring potentials for excitons based on the recently developed moving lattices for excitons. We will also study spin transport of excitons. Exciton transport, spin transport, and coherence will be measured by imaging, polarization-resolved imaging, and shift-interferometry imaging.

FY 2014 HIGHLIGHTS

We demonstrated experimental proof of principle for a stirring potential for indirect excitons. The azimuthal wavelength of this stirring potential is set by the electrode periodicity, the amplitude is controlled by the applied AC voltage, and the angular velocity is controlled by the AC frequency. We proposed the application of nonlinear optics for studies of spatially indirect excitons, demonstrated that despite their vanishing oscillator strength, indirect excitons can strongly contribute to the photoinduced reflectivity and Kerr rotation, and found in pump-probe measurements that the spin relaxation time of indirect excitons exceeds one of direct excitons by two orders of magnitude. We observed spin currents and polarization patterns in optically created indirect excitons.

Quantum Materials at the Nanoscale

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Lance Cooper
Email: slcooper@illinois.edu
Principal Investigator: Lance Cooper
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$60,000 (2014)

PROGRAM SCOPE

One of the overarching goals of this program is to study collective effects and emergent phenomena in strongly correlated bulk crystals and films by quantum mechanically 'tuning' these systems with pressure, magnetic field, doping, and epitaxial strain. Among the specific goals of this project are to clarify the origins of, and ultimately control, collective phenomena (e.g., exotic phases, multiferroic behavior, etc.) in crystals and films such as magnetically frustrated spinels, orbital-ordering compounds (e.g., KCuF_3 , Ca_2RuO_4), charge density wave materials (e.g., ZrTe_3 , TiSe_2 , and TaS_2), and the superconducting cuprate $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$. A key tool for achieving these goals rests in our unique capability to perform inelastic light (Raman) scattering spectroscopy of spin and lattice excitations while tuning the sample environment as simultaneous functions of temperature-, magnetic-field-, and pressure. With this unique combination of environmental tuning capabilities, we have the opportunity to create and study novel states of matter in as-yet-unexplored phase regimes. The potential transformative impact of this approach is that it can provide new microscopic details regarding the evolution of exotic phase behavior and phenomena through pressure- and field-tuned transitions in extreme phase regimes of strongly coupled materials that are not accessible with other spectroscopic techniques. The current project supported 2 graduate students (1/2 year each) during fiscal year 2014.

FY 2014 HIGHLIGHTS

Superconductivity evolves as functions of pressure or doping from charge-ordered phases in a variety of strongly correlated systems, suggesting that there may be universal characteristics associated with the competition between superconductivity and charge order in these materials. A particularly interesting group of materials in which phase competition between charge and superconducting order appears to be important is charge-density-wave (CDW) materials that can be tuned to superconductor phases with either pressure or intercalation. These systems offer the opportunity to explore the competition between charge-order and superconductivity, and particularly the structural changes that enable the emergence of superconductivity as the CDW state collapses with increasing pressure or intercalation. During this past fiscal year, we have used variable-temperature and variable-pressure inelastic light (Raman) scattering to investigate the microscopic details underlying the pressure induced phases of the CDW system, ZrTe_3 . In this research, we showed that certain phonon bands of ZrTe_3 undergo dramatic linewidth reductions near T_{CDW} , indicating that these phonons couple strongly to the electronic degrees of freedom associated with the CDW. The same phonon bands, which represent internal vibrations of the ZrTe_3 prismatic chains, are suppressed at pressures above 10 kbar. This indicates a pressure-induced loss of long-range order within the chains, specifically amongst the intra-chain Zr-Te bonds. We also find structural evidence for pressure-induced dimensional crossover in ZrTe_3 . These results suggest a distinct structural mechanism for the observed suppression of CDW formation above 20 kbar and provide insights into the origin of pressure-induced superconductivity in ZrTe_3 .

Novel Sample Structures and Probing Techniques of Exotic States in the 2nd Landau Level

Institution:	Purdue University
Point of Contact:	Gabor Csathy
Email:	gcsathy@purdue.edu
Principal Investigator:	Gabor Csathy
Sr. Investigator(s):	Michael Manfra; Purdue University
Students:	1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$408,000 (2014-2016)

PROGRAM SCOPE

The two-dimensional electron gas is home to a wealth of unusual phases arising from the interplay of reduced dimensionality and strong electron-electron interactions. Recently it was suggested that this system may support unusual ground states which harbor exotic particles which special topological properties. Several of these unusual states develop in high purity AlGaAs/GaAs heterostructures in the region of the phase space called the second Landau level. Examples are the fractional quantum Hall states at the quantum numbers $5/2$ and $12/5$. We pursue a synergistic combination of growth and measurement techniques in order to gain new insight into the nature of the unusual fractional quantum Hall states of the second Landau level. Since the unusual fractional quantum Hall states are fragile, they are most often studied in a narrow range of samples parameters which maximize their strength. The goal of our project is to gain information on these states over an extended range of sample parameters. For this purpose we grow specially tailored AlGaAs/GaAs heterostructures with varying quantum well thickness, density, and disorder level and we employ ultra-low temperature transport and high pressure investigative tools.

FY 2014 HIGHLIGHTS

(1) We have upgraded our MBE system with a new auxiliary source cleaning chamber. As a result we have recently achieved $30 \text{ million cm}^2/\text{Vs}$ mobility. (2) We completed the growth and characterization of a sequence of samples with varying alloy disorder in the channel. We found that the fractional state at $5/2$ survives to much lower electron mobilities than previously thought. Conclusion: Alloy disorder is not particularly detrimental to the formation of the fractional quantum Hall states. These measurements suggest ways of improving the quality of these samples by eliminating impurities with long range scattering potential which are most likely to have the strongest deleterious impact on these states. (3) We have successfully fabricated low-leakage in-situ backgated 2DEGs for density dependent study of the fractional quantum Hall effect (FQHE) in the 2^{nd} Landau level. Ongoing work includes incorporation of nanostructures on to these density-tunable structures. (4) We explored the growth of samples with added charge disorder. Ongoing energy gap measurements have provided feedback on the amount of charge disorder to be added in future growth campaigns. (5) We explored the fractional quantum Hall states of the second Landau level at hydrostatic pressures of the order of 10 kbar. We have observed a novel phase transition in the state at quantum number $5/2$ that we currently study in detail. (6) We have collaborated with the PIs Rokhinson and Lyanda-Geller on strain measurements of the reentrant insulating states believed to be exotic electronic solids. Results: We found evidence of novel topological excitations which do not exist in other types of electron solids.

Spin Dependent Transport in Metallic Nanoparticles

Institution: Georgia Institute of Technology
Point of Contact: Dragomir Davidovic
Email: dragomir.davidovic@physics.gatech.edu
Principal Investigator: Dragomir Davidovic
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

The directional instability of magnetization in nanometer-scale ferromagnets arises due to the irreversible coupling of a magnetic sample to its environment, which induces spin randomization. This effectively quenches the ferromagnetic state and its key signature of magnetic hysteresis. The crossover from stable hysteresis to spin randomization is particularly pertinent as the length scale is reduced, and is well understood in the case of thermal equilibrium. However, in the case of a perturbed, non-equilibrium ferromagnet, this crossover is more difficult to address. All of the prior works reinforce the notion that magnetism on the length scales of about 1-3nm is significantly influenced by the local environment. In this project we investigate the mechanism of coupling between a nanomagnet and its environment out of equilibrium, which leads to magnetization randomization. We find that a single Ni particle $\approx 2.7\text{nm}$ in diameter, embedded within a double-barrier tunneling device, will only exhibit magnetic hysteresis under narrowly defined circumstances at low temperatures. In particular, the degree of magnetic stability depends on the value of the source bias. Over a finite energy bandwidth, magnetic hysteresis is only weakly dependent on voltage. Toward the edge of this bandwidth, however, magnetic hysteresis quickly diminishes.

FY 2014 HIGHLIGHTS

Magnetic properties of single Ni, Co, and Fe particles 2-3nm in diameter are studied by single electron tunneling spectroscopy at temperature of 15mK and higher. It is found that the Ni particles lie at the threshold of stable ferromagnetic order, in a sense that a fraction of the Ni nanoparticles exhibits no magnetic hysteresis at all, while the remaining fraction has magnetic hysteresis that quickly vanishes as the temperature increases above 2K. In comparison, all Fe and Co nanoparticles are found to exhibit magnetic hysteresis at 4.2K, while single magnetic molecules studied by different groups, do not display any magnetic hysteresis under condition of electron tunneling at low temperatures. Thus, Ni nanoparticles fall into the critical range where magnetism is extinguished by electron transport. This regime permits investigation of the physical mechanism for the destruction of stable ferromagnetic order in magnetic nanostructures under condition of electron transport. That mechanism is revealed by our experiments and theoretical simulations. We find that the bias voltage serves as an effective energy limiter to the magnetic excitation energy of the particle. The spin-orbit scattering rate emerges as the characteristic frequency that governs the stability of magnetization as a function of voltage bias.

Disorder and Topological Defects in Magnetically Frustrated Single Crystals and Thin-Film Metamaterials

Institution: Kentucky, University of
Point of Contact: Lance DeLong
Email: delong@pa.uky.edu
Principal Investigator: Lance DeLong
Sr. Investigator(s): Jeffrey Todd Hastings; Kentucky, University of
Sung Seok Seo; Kentucky, University of
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$73,960 (2014)

PROGRAM SCOPE

A fundamental investigation of the effects of controlled disorder and reduced symmetry on patterned thin-film metamaterials is focused on a new class of artificial magnetic quasicrystals that exhibit geometric frustration and complex spin ice behavior. The signature long-range order without periodic

translational symmetry of quasicrystal tilings places them in a unique niche between periodic crystals and amorphous materials. Bulk magnetic quasicrystals exhibit striking physical properties and frustration, but they are difficult to grow and characterize, and are known to adopt spin-glass, rather than long-range magnetic order. The program therefore takes advantage of recent advances permitting nanofabrication of ferromagnetic (FM) thin films into “artificial quasicrystals” whose spin wave excitations and reversal can be systematically controlled via tiling design. The program will pursue spin wave localization due to controlled lattice disorder, and finite-size scaling behavior of static and dynamic physical observables in patterned films having variable topology, size and order. In-house ferromagnetic resonance, static magnetization and numerical simulations characterize spin wave excitations, frustration and possible phase transitions among spin ice phases. The unique temporal coherence and phase sensitivity of X-ray photon coherent scattering (XPCS) has enabled the first studies of magnetic relaxation and nonequilibrium dynamics of spin ices as a function of temperature and magnetic field over a broad interval of time scales (10^{-3} to 10^3 s). Direct nanoscale imaging techniques (coherent X-ray scattering, magnetic force microscopy (MFM) and scanning electron microscopy with polarization analysis (SEMPA)) characterize equilibrium magnetic textures and defects of spin ices of various topologies for comparison to dynamical data and numerical simulations.

FY 2014 HIGHLIGHTS

We have extended a first study of the effects of quasicrystal symmetry on cooperative interactions, frustrated dynamics and equilibrium ground state of Penrose P2 tilings, whose asymmetric pattern vertices strongly affect magnetic reversal and spin wave (SW) spectra [1]. We have observed first evidence of long-range magnetic order and “complex spin ice behavior” in direct SEMPA imaging of artificial P2 tilings [2]. Our first fabrication of aperiodic, long-range-ordered lattices based on Fibonacci distortions of periodic Bravais lattices allow us to investigate the effects of continuously variable aperiodicity on magnetic reversal, dynamics and spin ice behavior [3]. Recent XPCS experiments [4] have shown modest applied magnetic fields can control transfer of orbital angular momentum to a soft X-ray vortex beam resonantly scattered from suitably designed artificial spin ices, which promises to enable novel photonic technologies. Dynamics of Electronic Interaction in Superconductors and Related Materials

Institution: Colorado, University of
Point of Contact: Dan Dessau
Email: Dessau@Colorado.edu
Principal Investigator: Dan Dessau
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 1 Undergraduate(s)
Funding: \$340,000 (2014-2015)

PROGRAM SCOPE

We will perform experimental ARPES studies of the dynamics of electronic interactions in high temperature cuprate superconductors and related materials, especially electron and hole-doped $J=1/2$ Mott insulating iridates. For the ARPES studies on the cuprates we will utilize the new TDoS (Tomographic Density of States) method that we introduced previously, which integrates out most of the unknowns of the ARPES lineshape and for the first time allows quantitative extractions of superconducting gaps Δ and pair-breaking interactions Γ . In contrast to the case of BCS superconductivity, our TDoS results show that the pair-breaking Γ is large and strongly temperature dependent, and appears to play a critical role in cuprates – for example conspiring with the gap to set the T_c . We will extend our TDoS efforts here, among other things working to understand the details and origin of the unusually rapid growth of the pair-breaking scattering rate with temperature. We will study other strongly correlated electronic oxides, especially the new electron and hole-doped $J=1/2$ Mott insulating iridates, which show many similar phenomena as the cuprates. These include Fermi arcs and pseudogaps, with the combination of data giving new insights into these phenomena.

FY 2014 HIGHLIGHTS

We have accomplishments in the advancement of the technique of ARPES as well as in its application to a few different materials. Here we focus on the work that was published in this year. A) We published a paper in Review of Scientific Instruments on the nonlinearity of counting rates present in all modern commercial multichannel analog electron detectors. We show the effects that this commonly-ignored effect has on the spectra, as well as a new highly-efficient method to remove its effect from the data. This greatly increases the quantitative accuracy of modern ARPES data. B) We published a paper on the metallic pyrochlore iridate $\text{Bi}_2\text{Ir}_2\text{O}_7$, which was the first experimental electronic structure measurement of a pyrochlore iridate. Our work showed decent agreement with our companion density functional calculations, setting the stage for measurements and comparisons with other pyrochlore iridates, especially non-metallic ones that have stronger correlation effects and more exotic physics. C) We published a joint theory/experiment paper on a tight-binding model of bilayered manganese oxides. A key aspect of this work is that it allows a simple and accurate way to obtain the electronic structure as a function of the relative canting angle of the spins between the sheets in a manganese-oxide bilayer – something that has so far not been possible by any standard technique.

Infrared Hall Effect in Correlated Electronic Materials

Institution: Maryland, University of
Point of Contact: Dennis Drew
Email: hdrew@umd.edu
Principal Investigator: Dennis Drew
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$145,093 (2014)

PROGRAM SCOPE

The research program has two thrusts: IR Hall Effect in cuprate superconductors and the THz magneto-optics of topological semiconductors. These two classes of materials have had a profound impact on the condensed matter community. The sensitive infrared Hall spectroscopy techniques developed by the PI

at the University of Maryland are being used to investigate materials in these two classes. In the cuprates, the extent to which Fermi liquid theory provides an adequate description of transport and infrared properties is being critically examined across the pseudogap range of the doping phase diagram of p-type cuprate superconductors. The data from our spectroscopic infrared magneto-transport measurements are being compared with the data acquired from Angular Resolved Photoemission Spectroscopy and other experiments such as DC transport and neutron scattering in order to critically test theories. The goal of this effort is an elucidation of the physics of the pseudogap phase of cuprate superconductors. In the topological insulators our magneto-optical techniques provide a powerful means to characterize the Dirac dispersion relation through cyclotron resonance and Faraday rotation. Also while much of the initial work on topological insulators and 3D Dirac semimetals involved surface sensitive probes like ARPES and STM, such techniques are not appropriate for probing bulk properties or buried interface states that are necessary in applications. Novel THz magneto-optical effects have been predicted. In particular, broken time reversal ground states can be detected and effectively probed using Kerr rotation. We are searching for this effect in InSb/GaSb quantum wells which is predicted to have excitonic insulator ground states with broken time reversal. In addition novel surface states exhibiting Fermi arcs have been predicted to exist in 3D Weyl semimetals but have not yet confirmed. Our experiments are designed to investigate these novel predictions.

FY 2014 HIGHLIGHTS

During the 2014 funding year of this award the main effort has been focused on the installation of a Helium recovery and liquefaction system and the renovation of our magneto-optical measurement system for improved stability and to allow higher data throughput. We have also worked on the acquisition and preparation of samples for our magneto-optical measurements on cuprate superconductors and topological insulators and their preliminary optical characterization. The new samples include Bi(2201) single crystal samples provided by Andrea Damescelli, UBC, Canada. We have cleaved Bi(2201) to 100 nm thickness and approximately 100 microns diameter. In order to measure the Faraday rotation with greater precision we are also obtaining large area Bi(2201) films from Dr. Helene Raffy of Laboratoire de Physique des Solides, Universite & Paris Sud, Orsay, France. The second thrust of our fundamental research is on topological insulators with a focus on measuring the magneto-optical response of several candidate materials predicted to have 3D Weyl states. We have made zero field IR optical measurements on of $\text{Eu}_2\text{Ir}_2\text{O}_7$. These data have shown a linear frequency dependence of the optical conductivity in the IR as has been predicted for a 3D Weyl state system. This work is being prepared for publication. The samples for these experiments were provided by Satoru Nakatsuji of University of Tokyo. Our study of 3D Weyl state systems has also been expanded to include several newly discovered systems. They include Cd_2As_3 and Na_3Bi which have been observed to have a Dirac spectrum by ARPES. These materials are being provided by Robert Cava of Princeton University. We have observed the Pauli blocking interband edge for the Weyl bands in Cd_2As_3 . We have also begun work on InSb/GaSb quantum wells, a promising new topological insulator. These samples have been provided by Rui-Rui Du of Rice University.

Microwave Spectroscopy of Electron Solids: Fractional Quantum Hall Effect and Controlled Disorder

Institution: Florida State University
Point of Contact: Lloyd Engel
Email: engel@magnet.fsu.edu
Principal Investigator: Lloyd Engel
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Electron solids related to the Wigner crystal figure importantly in the proposed work. Such solids are present in GaAs at the low Landau filling (ν) termination of the fractional quantum Hall (FQH) series, and within integer quantum Hall effect plateaus, though not exactly at integer ν . These solids are insulators due to pinning by disorder, and exhibit a striking resonance in their microwave or rf spectrum. The resonance is understood as a pinning mode, in which pieces of the solid oscillate within the disorder potential. Due to these resonances, broadband microwave spectroscopy is a natural way to study these phases, and is the tool used in this project. The current scope of the project involves both samples with controlled alloy disorder, and ultralow disorder wide quantum wells.

FY 2014 HIGHLIGHTS

We have published one paper and submitted one more on pinning modes of 2DES residing in $\text{Al}_x\text{Ga}_{1-x}\text{As}$, with $x < 1\%$, in which the Al provides controlled short range random disorder. We found the pinning mode of Wigner solid to be remarkably robust in the presence of this disorder. Near $\nu=1$, the pinning modes of disordered samples which are likely due to composite fermion Fermi surface effects. In addition, we have begun to pursue work on low disorder wide quantum wells, publishing one paper on a phase transition (likely involving spin and composite fermion vortex number) in the vicinity of $\nu=1$. We have submitted a paper on phase transitions found in the insulator that terminates the fractional quantum Hall series, in a regime where the 2DES is expected to form a bilayer solid. The work indicates that the bilayer 2DES produces phases that may have domains of liquid and bilayer solid, or of two bilayer solids of different crystal structure. Finally we have studied low magnetic field nonlinear response of 2DES to the combination large dc current and large microwave power, using a coaxially driven coplanar waveguide set up that is unique for studies of this type, and published a paper on that work.

Atomic Layer Controlled Growth of Artificially Engineered Pnictide Superlattices By Design

Institution: Wisconsin-Madison, University of
Point of Contact: Chang-Beom Eom
Email: eom@enr.wisc.edu
Principal Investigator: Chang-Beom Eom
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$110,000 (2014)

Jointly funded by "Experimental Condensed Matter Physics" and "Synthesis and Processing Science"

PROGRAM SCOPE

Since the discovery of superconductivity in iron-based materials significant progress has been made in the fabrication of high quality bulk and epitaxial thin film materials to explore their intrinsic properties and evaluate novel device applications. The superconducting mechanism, structural transitions, magnetic behavior above and below T_c , interfacial phenomena, and critical current and flux-pinning behavior have all been recognized as critical to progress toward understanding the pnictides. Artificial layered pnictide superlattices with atomically sharp heterointerfaces offer unique opportunity towards tailoring superconducting properties and understanding the mechanisms of superconductivity by

creating model structures which do not exist in nature. Our main tasks are to create and control pnictide superlattices and heterointerfaces at the atomic level, to understand the relation between structure, magnetism and superconducting properties, and to design and grow novel pnictide superlattices tuned to take advantage of the superconducting structure/property relationships possible in this unique new superconductor. The thrusts of our proposed work are: (1) Atomic-layer-controlled growth of artificially engineered superlattices. (2) Designing interfacial superconductivity at pnictide and FeSe interfaces. (3) Investigation of interaction between superconductivity and magnetism by proximity effect (4) Understanding and control of flux-pinning mechanisms (5) Study of growth mechanisms of heteroepitaxial superlattices and artificial pinning centers. The proposed work investigates the basic physical processes of novel superconductivity, primarily by looking at its interaction with magnetism on a microscopic scale, and the role these play in the flux pinning process. We also extend these fundamental investigations to explore routes to interfacial superconductivity in these systems.

FY 2014 HIGHLIGHTS

We investigated the superconducting properties of single- and multilayer Co-doped BaFe₂As₂ (Co-Ba122) thin films grown on CaF₂ and (LaAlO₃)_{0.3}(Sr₂AlTaO₃)_{0.7} (LSAT) substrates. We confirmed the significant improvement of the critical temperature in the film on CaF₂ and we demonstrated that the multilayer deposition has no detrimental effect on T_c. We found that deposition on CaF₂ produces much cleaner films compared to films on LSAT, since on CaF₂ the substrate absorb oxygen preventing the formation of the high density of defects present in the LSAT case. The result of this oxygen reaction is that in the single layer on CaF₂ (CaF-S) the only visible defects are dislocations. Moreover, the different trend of angular dependence of critical current density in CaF-S at intermediate temperature suggests an increasing contribution of point defects with decreasing temperature. The multilayer film on CaF₂ (CaF-M), grown with insertion layers enriched in BaO, does have defects including short nanorods, round particles and flat particles similar in size but with a lower density to those in films on LSAT. Despite the different pinning mechanisms that affect the shape of the angular dependence of J_c, the single layers on both substrates roughly have similar J_c at the same reduced temperature. In contrast the multilayer deposition on CaF₂ is 2-3 times more effective in increasing J_c with respect to the corresponding single layer than in the LSAT case. This results in a record high pinning force (F_p) of 84 and 70 GN/m³ in Ba122 phases (H//ab and H//c, respectively), significantly larger than reported previous values in the Co-Ba122 phase and higher-T_c P-Ba122 phase. Applications interest is strengthened by their notably better in-field performance than in Nb₃Sn.

High-Bandwidth Scanning Hall Probe Imaging of Driven Vortices in Periodic Potentials

Institution: Colorado State University
Point of Contact: Stuart Field
Email: field@lamar.colostate.edu
Principal Investigator: Stuart Field
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$49,247 (2014)

PROGRAM SCOPE

This project will use a novel technique, high-bandwidth scanning Hall probe microscopy, to study the local, real-time dynamical states of current-driven vortices in artificially structured periodic potentials. This technique extends the frequency response of Hall probe microscopy from the usual 10-100 Hz used

for imaging into the MHz range. Using this new technique, the dynamics of driven vortices can be probed with an unprecedented combination of temporal and spatial resolutions, allowing a wealth of new physics, inaccessible to other measurements, to be uncovered. A number of specific experimental systems will be explored. Vortices moving in periodic potentials have unique depinning signatures that can best be addressed by real-space imaging. Once vortices are moving, a variety of dynamical states are predicted, including simple channeled flow and several more complex disordered flows. There are also remarkable effects observed when vortices are driven, in addition to a dc current, a high-frequency ac current. Here, striking steps are found in the dc voltage as the dc driving current is increased. Another exciting recent discovery is the 'vortex ratchet,' in which vortices are driven by a symmetrical ac current in an asymmetrical background potential. This leads to an overall dc motion of the vortices, that is, the vortex motion is rectified. The real-space, dynamical nature of all of these systems are best explored by a high-bandwidth imaging technique. The proposed work will open entirely new avenues for exploration in vortex physics. Questions to be addressed include: How do vortices depin from a periodic potential? Once the vortices are in motion, what is the detailed nature of the moving states? How do the vortices respond to high-frequency driving forces? And how does vortex transport proceed when the potential has a built-in directional bias? And, most importantly, how do all these process depend on the degree of commensurability?

FY 2014 HIGHLIGHTS

During fiscal year 2014, we have completed development of the complex instrumentation and specialized samples required for the project. Specific instrumentation projects completed include the fabrication of a temperature-stabilized, low-vibration cryocooler, a scanning Hall probe microscope with its associated probes, and a combined evaporation/sputtering chamber used for growth of superconducting samples and Hall probe contacts. We have developed a novel technique for fabricating the specialized samples needed for the project. By sputtering superconducting films onto a substrate that has a periodic modulation in its thickness, we can create films with tailored periodic vortex potentials. These films can be grown to be highly symmetric, so that vortices move equally in either direction, or asymmetric, so that there are 'hard' and 'easy' directions for vortex motion. The results of transport measurements on these films will be reported soon, and imaging experiments are currently underway.

Symmetries, Interactions and Correlation Effects in Carbon Nanotubes

Institution: Duke University
Point of Contact: Gleb Finkelstein
Email: gleb@phy.duke.edu
Principal Investigator: Gleb Finkelstein
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The PI's group has recently developed a unique platform for studying the effects of dissipation and interactions on quantum impurity systems, which is based on a carbon nanotube quantum dot with dissipative leads. Tunneling in the Ohmic dissipative environment is known to emulate tunneling in the Luttinger liquid – an archetypical example of an interacting one-dimensional electron system. We have first studied resonant tunneling (i.e. tunneling through an intermediate resonance) in this system, and

observed unitary resonances with vanishing width, predicted for the Luttinger liquid back in 1992 (Nature 2012). We have interpreted the observations in terms of a quantum critical behavior enabled by dissipation. One of the main topics of this project is to further develop the analogy between dissipative environment and the Luttinger liquid, and experimentally realize many “quantum impurity” models with Luttinger leads, for which a rich body of theoretical knowledge has been accumulated, but experimental results are scarce or nonexistent. Our work aims to enhance understanding of electronic interactions and dissipative phenomena in low-dimensional confined nanostructures, which naturally possess high degree of symmetry. Interactions and symmetries in confined systems are one of the fundamental topics in the modern condensed matter physics.

FY 2014 HIGHLIGHTS

We have investigated the exotic state of electronic matter obtained by fine-tuning the system exactly to the quantum critical point (QCP) that we observed earlier. We have reported on several transport scaling laws both near and far from equilibrium, including a non-Fermi-liquid quasi-linear scattering rate at the QCP, interpreted in terms of a Majorana mode localized at the resonant level (Nature Physics 2013). We have further investigated the QCP in collaboration with theoreticians. Specifically, we considered the non-equilibrium effects (PRB 2013) and the role of dissipative gate in tuning the properties of the QCP (PRB 2014). We have also conducted two additional experimental projects. We observed a “bottleneck” in thermal transport between electrons and the substrate in graphene at mK temperatures, allowing for the electrons to be significantly hotter relative to the phonons. This effect may have important applications in ultra-sensitive cryogenic graphene-based detectors (PRL 2013). In collaboration with chemistry colleagues, we developed an alternative catalyst for growing carbon nanotubes that results in tighter control of the nanotube diameter (ACS Nano 2014).

Tunneling and Transport in Nanowires

Institution:	Minnesota, University of
Point of Contact:	Allen Goldman
Email:	goldman@physics.umn.edu
Principal Investigator:	Allen Goldman
Sr. Investigator(s):	
Students:	0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$225,000 (2014-2015)

PROGRAM SCOPE

The goal of this program is to obtain a fundamental understanding of phenomena that might be relevant to the performance of devices and circuits at the limit of the smallest realizable feature sizes. The approach is to study nanowires prepared using top-down physical, rather than bottom-up chemical or biological techniques. When the transverse dimensions are smaller than the inelastic scattering, phase coherence, or superconducting coherence lengths, the wires are quasi-1D. Truly 1D wires are those for which the transverse dimensions are smaller than the Fermi wavelength. For such wires Landau Fermi liquid theory should be replaced by Tomonaga-Luttinger Liquid (TLL) theory. We propose to carry out two classes of experiments on nanowires prepared using electron beam lithography (EBL). The first involves studies of quasi-1D superconductors. We are investigating the mechanism for the restoration of superconductivity by small magnetic fields of nanowires driven resistive by current. This is a phenomenon that we discovered, and have found an explanation involving the counterintuitive idea that superconductivity and dissipation can coexist in certain out-of-equilibrium situations. We are also

studying superconductor-insulator transitions controlled by dissipation. Understanding these transitions will advance our knowledge of quantum phase transitions in reduced dimensions. The level of dissipation will be controlled by changing the conductivity of a two-dimensional electron gas in close proximity to the nanowire. The second class of experiments is directed at exploring the TLL regime of a 1D wire prepared from a low carrier density material, electrostatically doped strontium titanate (STO). We will employ EBL to form a surface mask, and will use an ionic liquid to induce charge in an exposed line of STO. If the lines can be made sufficiently narrow, then when lightly doped, they may exhibit TLL behavior.

FY 2014 HIGHLIGHTS

There has been major progress in the investigations of the properties of superconducting nanowires and of ionic-liquid-gated nanometer scale channels of strontium titanate (STO). As to superconducting nanowires, a paper was published in Nature Physics entitled, "Dissipative superconducting state of non-equilibrium nanowires." It is generally thought that superconducting order is incompatible with dissipation. The one exception is vortex flow, which takes place in sufficiently high magnetic fields. We have observed dissipative superconductivity in far more basic configurations: superconducting nanowires with superconducting leads. We have found that dissipative normal current may flow in the presence of superconducting order throughout the wire. We attribute the phenomenon to the formation of a non-equilibrium state, where superconductivity coexists with dissipation, mediated by Andreev quasiparticles. The effect is an example of a controllable non-equilibrium state of a quantum liquid. These findings suggest that nanowires can serve as a platform to investigate conceptual problems of out-of-equilibrium quantum systems. The I-V characteristics of ionic-liquid-gated nanometer scale channels of STO have been found to exhibit a voltage threshold for conduction and a power law behavior. The temperature dependence of the threshold voltage appears to be related to the inverse of the temperature dependent dielectric constant of STO in qualitative agreement with a model of charge density wave depinning. These observations, when taken together, are evidence that a charge density wave, which can be de-pinned by strong electric fields, has been induced. This work has been written up and a manuscript entitled, "Charge Density Wave Behavior of Ionic Liquid Gated Strontium Titanate Nanowires," is under review by Physical Review Letters. Whether these findings preclude the study of Tomonaga-Luttinger liquid behavior of these channels is an open question.

Colloidal Quantum Dot Films, Transport and Magneto-Transport

Institution: Chicago, University of
Point of Contact: Philip Guyot-Sionnest
Email: pgs@uchicago.edu
Principal Investigator: Philip Guyot-Sionnest
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$95,862 (2014)

PROGRAM SCOPE

The program is to investigate the conductivity and magnetism in solids of colloidal quantum dots. In the foreseeable future, 3D nanostructured materials are a likely source of novel properties, and the colloidal quantum dots provide an initial step in that direction. Starting with colloidal quantum dots of targeted materials, synthesized by chemical means, the program aims to achieve strong enough coupling between these quantum dots, without losing their quantized level structure, in order to obtain useful

conductivity. The applications already explored include photodetection, photovoltaics and light emitting devices. The basic research program investigates the conductivity as a function of the coupling between the particles, the temperature, the bias and the carrier density. The program distinguishes itself from others by carefully identifying the Fermi level position in relation to the quantum dot states, such that transport is taking place through the quantum dots rather than through an unknown density of states in the surrounding matrix or interfaces. Transport measurements are jointly carried out with optical measurements. The magnetic properties of the quantum dots are primarily addressed by considering unpaired electrons and magnetic impurities. In quantum dots, such unpaired electrons are expected to also lead to magnetic effects which could be switchable by changing the carrier density. In the regime of weak coupling between colloidal quantum dots, there is a spin blockade effect which can give positive or negative magnetoresistance (MR). In the presence of magnetic impurities inserted in the quantum dots and unpaired delocalized electron, there is the possibility of forming magnetic polarons with a large paramagnetic moment. This grant investigates the magneto resistance of a number of colloidal quantum dot systems with and without magnetic impurities with the aim to discover a new approach to materials with coupled electric, magnetic and optical properties.

FY 2014 HIGHLIGHTS

We reported the first detailed study of 1/f noise in nanocrystal solids. We initially expected that 1/f noise could be reduced by film processing, by the choice of the materials comprising the nanocrystals, and by the choice of the matrix. We did find that cracks in films increased the 1/f noise. However, for good films of all the different materials studied, we found a “universal” 1/f noise floor, with a noise scaling as the number of nanocrystals in the system, i.e. extensive as for bulk systems, and approximately proportional to the interdot conductance, irrespective of the materials. We qualitatively concluded that the noise is an intrinsic effect of the granularity in conduction, where charges moving in weakly connected part of the network modify the transport in the higher conductivity regions.

Linear and Nonlinear Optical Properties of Metal Nanocomposite Materials

Institution: Vanderbilt University
Point of Contact: Richard Haglund
Email: richard.haglund@vanderbilt.edu
Principal Investigator: Richard Haglund
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$350,826 (2014-2015)

PROGRAM SCOPE

The central theme of this project is nonlinear and ultrafast optics in metal nanoparticle composites, including metamaterials, exciton-plasmon coupling and plasmonic effects in metal-insulator transitions. For FY 2014, we focused on (1) ultrafast electron dynamics in metamaterials, including ultrafast THz microscopy of the insulator-to-metal transition in vanadium dioxide nanoparticles, plasmon-driven electron injection to promote phase transitions in vanadium dioxide and second-harmonic generation in nanostructures without inversion symmetry; and (2) dimensional and structural effects in plasmonic coupling, including exciton-plasmon coupling in zinc-oxide nanowires, in structures that incorporate two-dimensional atomic crystals and tunable plasmon-induced transparency heterostructures incorporating phase-changing vanadium dioxide. Aided by finite-difference time-domain and finite-element calculations, we design and fabricate heterostructures in which we can excite electrons and

quasiparticles (e.g., excitons, phonons, plasmons) and map the material response at femtosecond time and nanometer length scales. We employ nanofabrication tools (dual-layer electron-beam lithography, exfoliation of metal dichalcogenides, focused ion-beam nanomachining) and materials synthesis techniques (e-beam evaporation, vapor-solid nanowire/nanocrystal synthesis) developed during this project period to create novel heterostructures designed to elicit specific kinetic and dynamical responses. The complex phenomenology of these structures is studied using coherent, time-resolved second- and third-order optical spectroscopies, along with confocal and scanning-probe microscopies. We expect the proposed research projects to have significant impact on (1) optical physics in active and nonlinear metamaterials; and (2) ultrafast dynamics in heterostructures designed to elucidate the interactions of plasmons with material degrees of freedom.

FY 2014 HIGHLIGHTS

We measured the second-harmonic generation (SHG) efficiency of Archimedean nanospirals and used ultrafast, two-photon photoelectron microscopy to show that the region of strong excitation was at the focus of the nanospiral as seen in finite-difference, time-domain simulations. Arrays of 4π nanospirals were fabricated in square arrays by electron-beam lithography. Mode-locked pulses from a Ti:sapphire oscillator were passed through a spatial light modulator to create transform-limited pulses of 15 fs duration, at a pulse-repetition rate of 90 MHz. The efficiency of second-harmonic generation in this experiment is much larger than that reported for single gold nanocups or multiresonant antennas. Zinc oxide nanowires are a versatile workbench for studying optical emission and exciton dynamics in the near UV and visible. By depositing a variable thickness MgO shell on the ZnO nanowires and decorating the core-shell nanowires with Ag nanoparticles, the ZnO band-edge emission was strongly enhanced at specific thicknesses of the MgO shell, due to resonant optical-cavity effects. Moreover, the emission rate was further enhanced by the Ag nanoparticles, especially at higher spatial modes corresponding to thicker MgO shells; the larger spatial extent of the higher-order cavity modes results in an enhanced radiative emission rate. To better understand exciton-plasmon interactions we employed scanning transmission electron microscopy (STEM), cathodoluminescence (CL) and electron energy-loss spectroscopy (EELS), to achieve high resolution imaging with EELS while simultaneously detecting optical excitations and radiative decays. We used CL imaging to visualize ZnO emission in the presence of Ag nanoparticles. The locations in the ZnO with the highest emission correspond to strong plasmonic emission in the nanoparticles. Further, we can use the complementary nature of EELS and CL to discern the strength, localization and nature of plasmon modes on a single nano particle.

Antiferromagnetism and Superconductivity

Institution: Northwestern University
Point of Contact: William Halperin
Email: w-halperin@northwestern.edu
Principal Investigator: William Halperin
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$495,000 (2014-2016)

PROGRAM SCOPE

There is a growing impact of technological benefits to our society from basic research on superconductivity. Achieving high electrical current density in a magnetic field is a critical component of this progress. Our research program on Antiferromagnetism and Superconductivity exploits the power

of nuclear magnetic resonance (NMR) to investigate the magnetic and electric fields in superconductors on an atomic scale. Limitations in current density can be related to the dynamics of these vortices and the electronic structure in the vortex core for which NMR is an ideal probe. Using high magnetic fields at the National High Magnetic Field Laboratory and at Northwestern University we explore the electronic structure in the normal and vortex superconducting states of superconductors including Bi2212, Hg1201, and NaFeAs. For the heavy fermion compound UPt₃ we use national neutron scattering facilities to measure the vortex structure and magnetic spin susceptibility. With our collaborators we perform inelastic neutron scattering, tunneling spectroscopy, electrical transport, and optical Kerr rotation experiments. We grow and characterize the highest quality of UPt₃ single crystals and use these materials to define the order parameter symmetry and nodal gap structures in UPt₃, and the coupling of its magnetism to superconductivity. This is an unconventional superconductor that can be grown in our laboratory to unique levels of purity in single crystal form. It may be one of the best choices for understanding spontaneously broken symmetry in superconductors in the presence of competing interactions, such as is the case for magnetism.

Spin-Coherent Transport Under Strong Spin-Orbit Interaction

Institution: Virginia Polytechnic Inst. and State U.
Point of Contact: Jean Heremans
Email: heremans@vt.edu
Principal Investigator: Jean Heremans
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$330,000 (2014-2016)

PROGRAM SCOPE

The project acquires fundamental insight in spin-dependent quantum coherent phenomena arising from spin-orbit interaction, via experiments on semiconductor heterostructures and thin film semimetals patterned into mesoscopic and nanoscale geometries. The experiments are conducted by low-temperature electronic magnetotransport in nanoscale structures of length scales similar to the quantum phase- and spin-coherence lengths and the carrier mean free path of the materials used. Understanding of coherent spin-dependent electronic processes is obtained by the emphasis on quantum and spin coherence. Spin-orbit interaction in the solid-state can provide an avenue for spin operations in quantum information processing and for the creation of new quantum states of matter. The subject is of fundamental interest but also of long-term applied interest in magnetoelectronic and spintronics devices. In two-dimensional electron systems in quantum wells of the narrow-bandgap

semiconductors InAs and InGaAs the objectives include the measurement and characterization of quantum states arising from the Aharonov-Casher quantum-mechanical phase and its associated effective gauge field. The Aharonov-Casher phase is the electromagnetic dual of the Aharonov-Bohm phase, obtained by exchanging the magnetic fields and electric charges in the Aharonov-Bohm phase by electric fields and magnetic moments (spin). The objectives comprise studying an effective dual to the integer quantum Hall effect arising from the Aharonov-Casher effective gauge field. Objectives also include quantum electronic transport at the mesoscopic scale on the semimetal bismuth in thin film form, and particularly on its strongly spin-orbit coupled surface states. Using bismuth structures on the scale of the quantum phase- and spin-coherence lengths, the effects of the strong spin-orbit interaction on electronic properties and quantum states are elucidated.

FY 2014 HIGHLIGHTS

In InGaAs/InAlAs heterostructures, the dependence of quantum phase coherence on excitation current and temperature was studied using mesoscopic single-ring interferometers, using low-temperature Aharonov-Bohm oscillations in the magnetoresistance of individual rings. The Thouless energy was observed to be the relevant measure of excitation energies. An amplitude modulation was concluded to have its origin in the effect of the local magnetic flux through the interferometer arms (J. Phys.: Cond. Mat. 25, 435301 (2013)). Measurements of ring-array interferometers in Sagnac mode, where time reversal symmetry is broken by the local magnetic flux, show that the local magnetic flux in this case acts to limit quantum phase coherence. The spin coherence length was measured in InAs mesoscopic wires, where it was found that diffusive boundary scattering affects this length via the diffusion coefficient (Phys. Rev. B 88, 205407 (2013)). The spin coherence length is otherwise increased in narrow wires, interpreted as resulting from the duality between Aharonov-Casher and Aharonov-Bohm quantum phases. The observations about spin coherence lengths were extended to InSb and bismuth wires and an interpretation of results proposed (Proc. SPIE 9167, 91670-D1 (2014)). On InAs electron accumulation layers, the effect of rare-earth ions on the surface was measured using antilocalization (Chin. Sci. Bull. 59(2), 133 (2014)). The results show that antilocalization measurements can be used to study the interactions between surface species and local magnetic moments. Spin-flip rates were found to be affected by transitions between closely spaced energy levels of the surface species, and spin-orbit interaction to be modifiable by surface species. In InGaAs/InAlAs heterostructures, the effects on spin-flip rate and spin-orbit interaction due to nanolithographic ferromagnetic CoFe pillars was measured (Sol. State Comm. 177, 36 (2014)).

Charge and Energy Transfer in Molecular Superconductors and Molecular Machines

Institution: Ohio University
Point of Contact: Saw Hla
Email: hla@ohio.edu
Principal Investigator: Saw Hla
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$137,886 (2014)

PROGRAM SCOPE

This project is to investigate charge and energy transfer processes at the ultimate atomic scale as well as novel physical phenomena associated with two nascent molecular systems; nanoscale molecular superconductors, and molecular motors on metallic surfaces. The experiments will be performed by

using scanning tunneling microscopy, tunneling spectroscopy, and atomic and molecular manipulation at low temperatures in an ultrahigh vacuum environment. This project includes both conventional and innovative experimental components, and the achievements of this project will not only enhance our understanding of charge and energy transfer processes at the atomic/molecular regime but also will impact a large area of science and engineering disciplines in general.

FY 2014 HIGHLIGHTS

(1) Adding Communication to Molecular Rotors: One of the goals of nanotechnology is to assemble billions of nanomachines packed in a tiny area that can be operated in a synchronized manner and information can be coherently transferred to multiple destinations. Here we show that synchronized and coordinated rotational switching of an entire nanomotor network can be realized by using the electric field of a scanning tunneling microscope tip. Strikingly, over 500 nanomotors can be simultaneously rotated on Cu(111) surface using the biases above 1 V at 80 K. This phenomenon is observed only in the hexagonal network due to the degeneracy of the ground state dipole rotational energy. (Submitted to Nature Nanotechnology). (2) Charge Transfer and Proximity Effects of a Nanoscale Molecular Superconductor: We investigate charge transfer and proximity effects of a (BETS)₂-GaCl₄ nanoscale molecular superconductor on a Ag(111) surface at the atomic limit. Although there is a charge injection from Ag(111) surface to the BETS molecules, the BETS still lose a net charge to GaCl₄ generating a partially filled outermost molecular orbital. Interestingly, tunneling spectroscopy data reveal quenching of the surface state electrons near the superconducting region. A gap state on the Ag(111) surface is observed, which then evolves into a superconducting gap on the molecules. (Submitted to Nano Letters). (3) Mechanical Flexure and Vibrational Maps of Sexiphenyl on Ag(111): We investigate the mechanical flexure and vibrational properties of para-sexiphenyl at single molecule level on a Ag(111) surface using scanning tunneling microscopy, and tunneling spectroscopy. Experiments reveal two low vibrational modes, which are quenched in the case of the self-assembled molecular layer. Lateral manipulations of the molecules show that the molecule can easily conform across the step and it recovers original configuration after the manipulation. (Submitted to Appl. Phys. Lett.).

Search for Novel Topological Phases in Superconductors Using Laser-Based Spectroscopy

Institution: California Institute of Technology

PROGRAM SCOPE

The discovery of topological band insulators has stimulated a wide search for topological phases of superconductors, which are predicted to host Majorana zero modes at their boundaries. Recent advances have been made in engineering one- and two-dimensional topological superconductors through a proximity coupling of ordinary s-wave superconductors to semiconducting nanowires, ferromagnetic atomic chains or topological insulators. In contrast, the existence in nature of three-dimensional topological superconducting phases, which are predicted to host surface Majorana modes as well as more exotic surface topological orders, remains an open question. Unlike the case in lower dimensions, they cannot be engineered from a combination of existing known materials. The objective

of this project is to develop novel laser-based spectroscopic techniques that can be used to directly identify topological phases in intrinsically superconducting three-dimensional compounds.

FY 2014 HIGHLIGHTS

Our research to date has focused on the development of experimental techniques. (1) We completed the design and initial assembly of a laser-based angle-resolved photoemission spectroscopy (ARPES) setup for performing ultra low-temperature and high energy-resolution electronic structure mapping. This capability is important because of the low critical temperature scale (~ 1 K) and low superconducting gap energy scale (~ 1 meV) of three-dimensional topological superconducting candidates. We have achieved a sample temperature below 1 K using a custom designed He-3 ARPES cryostat and are in the process of testing our overall energy resolution, which is targeted for below 1 meV. Initial searches for three-dimensional topological superconductors will focus on layered metal chalcogenides. (2) Upon completion of the ARPES setup, we will be introducing two optical spectroscopic techniques into the same experimental chamber to probe complementary properties of the three-dimensional topological superconductor candidates: i) Nonlinear optical microscopy to perform spatially-resolved mapping of possible time-reversal symmetry broken domains; ii) Time-resolved optical reflectivity for probing superconducting gap symmetry. Preliminary tests of these two optical techniques have so far been successfully conducted on test samples mounted in our commercial He-4 optical cryostat down to a temperature of 4 K. Their integration with our He-3 cryostat will be performed next.

PROGRAM SCOPE

This proposal describes a research program designed to play a leading role in the field of nanoscale quantum electronic transport. The research addresses a current central theme in condensed matter physics: the conceptually new behavior of electrons in solids whose effective Hamiltonian is described by the Dirac equation and whose electronic properties are protected by fundamental symmetries of the materials band structure. In particular, the research objective of this proposal is to investigate novel quantum transport phenomena in topological insulators. Topological insulators (TIs) are materials with a bulk band gap but which have a conducting surface state. This surface state has two special properties: it exhibits a relativistic-like linear energy-momentum dispersion, analogous to graphene and, in addition, its conducting character is protected by time reversal symmetry. The latter confers the surface state its topological protection, i.e., the surface state remains gapless even in the presence of moderate disorder. The unique geometry, band structure and topological characteristics of the TIs have generated an extraordinary interest in the physics community and have led, together with graphene, to the emergence of a new paradigm of “relativistic” condensed matter physics. This research proposes to measure fundamental quantum phenomena, such as superconductivity, the quantum Hall effect and excitonic condensation in new regimes made possible by the TI’s 2D surface state geometry, topological characteristics and relativistic-like band structure. A crucial element of the proposal is the fabrication

and characterization of high quality thin TI devices, by using both exfoliation from single crystals and by growing TIs epitaxially by MBE. Electronic transport measurements as a function of temperature and magnetic field will reveal insights into a wealth of phenomena predicted by theory, including weak antilocalization, exotic types of quantum Hall effect.

FY 2014 HIGHLIGHTS

Our work this year focused on continuing the development on surface-sensitive probes which include tunneling and dual-gated transport spectroscopy. These are implemented in exfoliated devices of Bi_2Se_3 and $\text{Bi}_{0.5}\text{Sb}_{1.5}\text{Te}_{1.7}\text{Se}_{1.3}$ (BSTS), respectively. In both cases, we use our development of an advanced fabrication technique based on exfoliated thin film transfer, which allows us to integrate TI layers into heterostructures including hexagonal Boron-Nitride (h-BN) and graphene. Projects we have pursued include: (i) dual-gated transport in h-BN–TI heterostructures, (ii) TI-graphene junctions, and (iii) STM measurements at the TI-graphene interface. The key accomplishment this year has been on project (i), and it resulted in a paper published in PRL. In this paper, we reported on electronic transport measurements of exfoliated $\text{Bi}_{1.5}\text{Sb}_{0.5}\text{Te}_{1.7}\text{Se}_{1.3}$ (BSTS) nanodevices with top and bottom gate electrodes. We showed for the first time that the chemical potential of the upper and lower surface states can be controlled independently, resulting in different resistance peaks when either surface chemical potential crosses the Dirac point. For thin devices, we found signatures of finite capacitive coupling between the surface states, consistent with fully depleted bulk states. We explained the data through a charging model which incorporates the finite density of states of the surface bands. Using angle-resolved photoemission spectroscopy (ARPES) as a control measurement of the surface state, this model allowed us to measure the chemical potential μ and charge density n of a topological surface state as well as the inter-surface capacitance. At high magnetic fields, increased field penetration through the surface states is observed, strongly suggestive of the opening of a surface state band gap.

Correlated Electrons in Graphene at the Quantum Limit

PROGRAM SCOPE

Strong Coulomb interactions in low dimensions often lead to rich emergent correlated phenomena which can manifest as spontaneous breaking of the symmetry of internal quantum degrees of freedom. In graphene, the combination of real spin and pseudo (valley) spin can be described by a four-component spinor obeying $\text{SU}(4)$ symmetry. In strong quantizing magnetic fields this multi-component internal quantum degree of freedom, coupled with strong electron interactions, often results in a many-body correlated state. Examples of such correlated phases include quantum Hall ferromagnetism (QHF) and fractional quantum Hall (FQH) states, both of which present a novel hierarchy of broken symmetry states. This proposal is largely concerned with understanding the fundamental physics of electron-interaction-driven spontaneous symmetry breaking in bilayer graphene (BLG) at the quantum limit. We focus particularly on BLG, because its multi-component $\text{SU}(4)$ spin is fully experimentally controllable through electric and magnetic fields. For this purpose we investigate: (i) engineering BLG

heterostructures for high mobility and high functionality; (ii) investigating phase transitions of BLG's multi-component spin in integer and FQH states; (iii) exploring the nature of spin/valley-polarized quantum Hall edge states employing quantum point contacts and quantum Hall interferometry; (iv) studying competition between strongly correlated QHF and FQH effects in engineered and adjustable graphene superlattices; (v) realization of symmetry-protected 1-dimensional topological propagation modes in bilayer graphene; (vi) injection of cooper pairs in graphene quantum Hall edge states and investigation of the competition between proximity-induced superconducting states and Landau gap formation.

FY 2014 HIGHLIGHTS

Spontaneous symmetry breaking occurring in an interacting many body system is one of the cornerstones of modern physics. The Coulomb interaction drives spontaneous breaking of the symmetry in the internal degrees of freedom of many electron systems, leading to exotic correlated electronic states, such as the fractional quantum Hall effect (FQHE). In this period of time, we demonstrate that bilayer graphene provides a rich material platform for studying electronic interactions, hosting a variety of interacting ground states for the FQHE. Moreover, we demonstrate the capability to tune phase transitions between different ground state orderings within the FQHE states by application of a transverse electric field. To enable this, we have made innovations in graphene device preparation yielding samples of unprecedented quality, and explored correlated electronic states in these phase spaces in the quantum limit. We also report fractional QHE states in BLG that show phase transitions that can be tuned by a transverse electric field. This result provides a model platform with which to study the role of symmetry-breaking in emergent states with topological order. We believe our result to be particularly significant for 2 reasons: i) while the capability to tune phase transitions within the FQHE in graphene systems has been theoretically identified as one of the fundamentally unique interests of this material platform, this effect has not previously been experimentally accessible. ii) The capability to set the ground state order within the FQHE in bilayer graphene is predicted to have several fundamental consequences such as providing a platform to more carefully study interplay between competing phases with different topological order, and perhaps more exciting the possibility of stabilizing new exotic quantum states. The work is published in Science 345, 61-64 (2014).

Spectroscopy of Degenerate One-Dimensional Electrons in Carbon Nanotubes

Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$176,311 (2014)

PROGRAM SCOPE

We study the fundamental properties of degenerate one-dimensional (1-D) electrons in single-wall carbon nanotubes (SWCNTs) using dynamical methods to probe and understand electronic correlations and many-body phenomena. SWCNTs are an ideal 1-D system for studying novel quantum effects in nanostructures. There have been transport and optical studies on SWCNTs by a number of groups during the past decade, revealing some characteristic features of 1-D systems. However, most of the predicted exotic properties of interacting 1-D electrons have yet to be observed, and some of the

reported experimental evidence remains controversial. Here, using spectroscopic methods from the terahertz (THz) to the optical ranges, we aim to achieve a fundamental understanding of correlations and many-body effects in this prototypical 1-D nanostructure. These studies can provide a wealth of new insight into the nature of strongly correlated carriers in the ultimate 1-D limit and lead to novel nanodevice concepts and implementations.

FY 2014 HIGHLIGHTS

During FY 2014, we have made progress in three aspects of 1-D dynamic phenomena in SWCNTs: (1) Spin dynamics. We measured temperature- and power-dependent electron spin resonance in SWCNTs to determine both the spin-lattice and the spin-spin relaxation times, T_1 and T_2 . We observed that the former decreases linearly with the temperature, whereas the latter increases by over a factor of two when the temperature is increased from 3 K to 300 K. We interpreted the former as spin-lattice relaxation via interaction with conduction electrons and the latter as motional narrowing. By analyzing the latter, we found the spin hopping frequency to be 285 GHz. (2) Plasmon resonance. Plasmon resonance is expected to occur in metallic and doped semiconducting SWCNTs in the THz frequency range, but its convincing identification has so far been elusive. We performed optical, THz, and DC transport measurements on highly enriched metallic and semiconducting nanotube films. A broad and strong THz conductivity peak appeared in both types of films, whose behaviors were consistent with the plasmon resonance explanation, firmly ruling out other alternative explanations such as absorption due to curvature-induced gaps. (3) Coherent phonons. Using a macroscopic ensemble of highly enriched (6,5) SWCNTs, combined with high signal-to-noise ratio and time-dependent differential transmission spectroscopy, we generated vibrational modes in an ultrawide spectral range. A total of 14 modes were clearly resolved, we were able to identify all the observed peaks and determine the frequencies of the individual and combined modes. We provided a full summary of phonon frequencies for (6,5) nanotubes that can serve as a basic reference with which to refine our understanding of nanotube phonon spectra as well as a testbed for new theoretical models.

Dissipative and Fast-Timescale Phenomena in Superconductors

Institution: South Carolina, University of

Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$337,689 (2014-2016)

PROGRAM SCOPE

This project investigates rapid temporal events and transport phenomena at extreme power densities and vortex velocities, using advanced pulsed techniques developed by the PI. The PI developed a sub-nanosecond correlated time-domain current-voltage measurement, which resulted in the first real-time demonstration of ballistic supercurrent acceleration. The PI's investigations have led to the discovery/confirmation of new effects/regimes such as the hot-electron instability, flux fragmentation, quenched vortex dynamics, vortex-core explosion, current-induced depairing, etc. Besides their own novelty, these effects shed light on many key parameters and properties of the superconducting state such as gap anisotropy, electron-phonon coupling, normal-state resistivity below T_c , thermodynamic critical magnetic field, etc. Because of the uniqueness of the PI's techniques for exploring these regimes,

some of these effects have been observed only in a few materials. Finally, this research is directly relevant for practical applications since its very essence is to investigate how dissipation arises when the superconducting state is pushed to its limits.

FY 2014 HIGHLIGHTS

Two refereed publications from completed work resulted in 2014: 'Pinning mechanism in electron-doped HTS $\text{Nd}_{1.85}\text{Ce}_{0.15}\text{CuO}_4$ epitaxial films', A. Guarino, A. Leo, G. Grimaldi, N. Martucciello, C. Dean, M. N. Kunchur, S. Pace and A. Nigro, *Supercond. Sci. Technol.* 27, 124011 (2014); and 'The mixed state of thin films in parallel fields', M. N. Kunchur, M. Liang, C. Dean and A. Gurevich, refereed book chapter in "Nanotechnology in the Security Systems (NATO Science for Peace and Security)", Chapter 2 page 15 under "Part I: Nanomaterials", Springer, ISBN-10: 9401790523, ISBN-13: 978-9401790529 (September 14, 2014). In addition, the PI gave 2 invited talks at international conferences (in Italy and Korea) and won the Donald S. Russell Award for Research in Science, Mathematics, and Engineering (the university's highest research award). Ongoing research in the past year led to the observation of two new effects in the superconductivity that occurs at the interface between the Bi_2Te_3 topological insulator and the FeTe iron chalcogenide, neither of which is itself superconducting. We have observed a transition in the current-induced depairing response as the temperature is swept through the Berezinsky-Kosterlitz-Thouless (BKT) transition, to our knowledge the first observation of its kind in such a system. The second novel result is the observation of an anomalous current-voltage response that shows a double plateau. The lower plateau exists only in the limit of very low magnetic fields and temperatures. While we are working on the detailed theory of these new effects, we were able to show that the lower plateau is associated with the Likharev explosion effect. This is the first time to see this effect in an interface superconductor, and the second time in history to confirm it at all.

Spontaneous and Field-Induced Symmetry Breaking in Low Dimensional Nanostructures

Students: 0 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$208,210 (2014)

PROGRAM SCOPE

Electron-electron interactions can strongly modify the qualitative properties of low-dimensional materials. This program aims at investigating and understanding strongly correlated electron behavior using carbon nanotubes and graphene, which has emerged as archetypal 1D and 2D nanostructures, via low temperature transport experiments and nanoelectromechanical measurements. The research program consists of 3 key projects: (1). symmetry-broken phases and quantum phase transitions in ultra-clean bilayer graphene (BLG); (2). symmetry-breaking, phase diagrams and stacking-order dependent transport of trilayer graphene (TLG); and (3). momentum-conserved tunneling between 2D graphene and 1D carbon nanotubes. These projects are motivated by the instability of few-layer graphene to the formation of a correlated electron ground state. A variety of states with different properties have been theoretically proposed, though the exact nature of the ground state is under intense experimental and theoretical debate. We plan to investigate and establish the nature of the ground state in BLG and TLG, using dual-gated suspended devices with mobility as high as 300,000

cm^2/Vs . We will measure the devices' electrical properties as functions of electric field, perpendicular and parallel magnetic fields, charge density and temperature, and explore possible quantum transitions among the phases. A related direction is to search for fractional quantum Hall effect and Wigner crystal states in these atomic membranes. We also plan to measure the layer polarization directly in BLG and TLG using the graphene layers as nanomechanical elements, via a technique akin to Kelvin probe microscopy, thus realizing a which-layer probe. Taken together, these proposed experiments will provide an in-depth investigation of how electron-electron interactions affect the properties of these exciting materials.

FY 2014 HIGHLIGHTS

(1) Landau level Gaps in Bilayer Graphene Landau level gaps are important parameters for quantum Hall effect in 2D materials. Using bias spectroscopy, we show that at filling factor $\nu=-2$, the gap $\Delta \sim 1.1 \text{ meV/T}$ for singly-gated geometry, and 0.17 meV/T for dual-gated geometry at zero out-of-plane electric field E_{\perp} , thus suggesting that the $\nu=-2$ state strongly depends on E_{\perp} . Our studies, published by Nano Letters, provide the first measurements of the gaps of the broken symmetry QH states in BLG with controlled layer polarization. (2) Competing $\nu=2$ States in Bilayer Graphene Quantum Hall (QH) effect, which normally appears in strong magnetic fields B , may also appear spontaneously at $B=0$ in devices with strong interactions. An example is charge-neutral bilayer graphene that is unstable to a variety of gapped spontaneous QH states, which can be explored via their adiabatic connection to QH states with the same Hall conductivity. We find two distinct phases at filling factor $\nu=2$, stabilized by large magnetic and electric fields, respectively. The majority spins of both phases form a quantum anomalous Hall state; the minority spins form a Kekulé state with spontaneous valley coherence for phase I, and a quantum valley Hall state for phase II. Our results, published by Nature Communications, shed light on the rich set of competing ordered states in BLG. (3) Graphene Nanoelectromechanical Stochastic-Frequency Oscillators To date the physical origin of the quality factor Q in nanoelectromechanical systems remains unresolved. We explore this issue by using graphene drumhead resonators, whose Q is found to scale inversely with temperature. This is understood by a model of thermally fluctuating high frequency modes that broaden the spectral response of the fundamental mode through nonlinear coupling. Our results provide a general framework for understanding dissipation and spectral line broadening in atomically thin membrane resonators. This work is published by Nano Letters.

Institution: Colorado, University of
Point of Contact: Minhyea Lee
Email: Minhyea.Lee@Colorado.edu
Principal Investigator: Minhyea Lee
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$153,310 (2014)

PROGRAM SCOPE

Controlling the electrical properties of materials by manipulating their spin structure is a key feature in the field of magnetism research and applications. The unusual spin textures found in inversion symmetry broken magnets, e.g. Skyrmions and the Chiral Soliton lattice are of particular interest due to their stability granted by their topology. Our work focuses on the magnetotransport properties of two systems with such non-trivial spin textures in inversion symmetry broken crystalline structure. In the

isotropic cubic helimagnets MnSi and Fe-doped MnSi, a pronounced topological Hall effect emerges, and is a direct result of the gauge field generated by the Skyrmin lattice. On the other hand, in the highly anisotropic helimagnet $\text{Cr}_1/3\text{NbS}_2$, a Heisenberg spin model with Dyzaloshinkii-Moriya interactions and magnetocrystalline anisotropy successfully captures the complex spin structure and shows excellent agreement with magnetization measurements. An unusual dependence of magnetoresistance on spin orientation (i.e. parallel or perpendicular to the helix direction) is attributed to a change of the electronic structure caused by spin-orbit coupling, rather than to a purely spin-related mechanism.

FY 2014 HIGHLIGHTS

First, we perform the topological Hall effect (THE) study in Fe-doped MnSi and compare it with results from pure MnSi under pressure. We find that Fe doping increases the size of THE, indicating an enhancement of the magnitude of the emergent gauge field generated by the Skyrmin lattice (SKL). This is consistent with the concurrent reduction in the length scale of the SKL. For both pressurized and doped samples, we calculate the emergent magnetic field based on the size of the measured THE and compare it with a theoretical upper bound. The ratio of these two is found constant with pressure or Fe doping, despite their quite distinct trends in suppressing magnetic ordering. This result appeared on PRB.88.214406. In a highly anisotropic helimagnet $\text{Cr}_1/3\text{NbS}_2$ (CNS), we found understanding the role of spin-orbit coupling (SOC) is crucial to controlling magnetic anisotropy, rather than the spin texture itself. We find a larger enhancement of in-plane electrical conductivity when spins are polarized perpendicular to plane rather than parallel in CNS. This is consistent with the density of states variation near the Fermi energy, from our first principles calculations. The result shows spin-orientation dependent electronic structure modification mediated by SOC leads to the changes in in-plane conductivity. We observe unusual H dependence of the Hall signal in the same temperature range. This is likely to further indicate strong dependence of electronic structure on spin orientation relative to the plane. The result is currently under review at PRX. In order to have a better understanding of the spin structure of CNS, we study a Heisenberg spin model with Dyzaloshinkii-Moriya interactions and magnetocrystalline anisotropy, which allows the ground state spin structure to be calculated for magnetic fields of arbitrary strength and direction. The magnetization measurements show excellent agreement with the predicted spin structure. This result is published in APL.105.072405.

Experimental Study of Superconductivity in Reduced Dimensions and in Novel Materials

Institution: Ohio State University
Point of Contact: Tom Lemberger
Email: trl@mps.ohio-state.edu
Principal Investigator: Tom Lemberger
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

The overall goal is to expand our experimental understanding of quantum fluctuations in the vicinity of continuous quantum phase transitions through an exploration of ultrathin, effectively two-dimensional films of cuprate superconductors and other superconductors. Theoretically, the understanding of quantum fluctuations is under development. In superconductors quantum fluctuations take the form of zero-point motion of quantum vortex-antivortex pairs, and perhaps other objects, especially in cuprates where the underlying physics of normal state is complicated (enriched?) by the pseudogap in the

electron excitation spectrum. Experimentally, we grow ultrathin films of YBCO and BSCCO by pulsed-laser-deposition (PLD) and pursue a suite of electron transport measurements including superfluid density, resistivity, and most recently, critical cooper pair momentum. Quantum fluctuation effects are expected in the magnitude and temperature dependence of the superfluid density and the critical cooper pair momentum.

FY 2014 HIGHLIGHTS

(1) We benchmarked our novel technique for determining the superconducting coherence length, ξ , in superconducting films from measurement of the critical cooper-pair momentum. The technique involves inducing a supercurrent density comparable to the theoretical maximum, where vortices necessarily appear, by applying a large current to a small superconducting coil adjacent the film. That is, we operate our two-coil apparatus way beyond the linear-response regime. Benchmarking was done on thin Nb and amorphous MoGe films, both being conventional superconductors. It was published in Physical Review B. We had published the theoretical underpinning for the technique in PRB the previous year. (2) We measured the critical cooper-pair momentum, p_c , in a number of strongly-underdoped, very thin films of the cuprate superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$. We found that p_c is linearly proportional to the superconducting transition temperature, T_c , thereby establishing that the important energy scale for superconducting cooper pairs is $k_B T_c$. In retrospect this seems obvious to some, but spectroscopy identifies two other important energy scales, so this result is significant. A paper on this work is available on ArXiv, but is not yet published. (3) In very thin cuprate superconducting films, we consistently observe a significant temperature range between where resistivity seems to go to zero and the lower temperature where superfluid density appears. The effect is absent from thicker films. The physics of this state is at present unknown.

EARLY CAREER: Probing High Temperature Superconductors with Magnetometry in Ultrahigh Magnetic Fields

Institution: Michigan, University of
Point of Contact: Lu Li
Email: luli@umich.edu
Principal Investigator: Lu Li
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

The goal of the program is to investigate the high-field magnetic properties of high temperature superconductors, materials that conduct electricity without loss. High temperature superconductivity discovered in Fe-based and Cu-based materials has been a treasure trove for condensed matter physicists. The relatively high transition temperature T_c , critical field, and critical currents indicate many possible applications in energy transfer and conservation. More importantly, the investigation of the origin of the superconductivity leads to various breakthroughs in fundamental physics. Moreover, in both cuprates and Fe-based materials, superconductivity arises by doping an antiferromagnetic state. Precise measurement of the magnetization M in ultrahigh magnetic fields will shed light on the magnetic ground state, the superconducting property, and the interaction between them. To achieve the goal, torque magnetometry will be adapted to ultrahigh magnetic field up to 100 T in the pulsed magnetic field facilities in Los Alamos National Laboratory (LANL). Major challenges for research in the pulsed field

facilities are 1) the vibrational and electrical noise, 2) difficulty stabilizing temperatures in elevated temperature ranges, and 3) short magnetic field pulses as narrow as milli-seconds. These conditions exclude some common approaches based on resonating oscillators or piezo resistors. We propose several technical innovations to advance the high frequency capacitance bridge technique to precisely measure the magnetic torque in pulsed magnetic fields. The major innovations include, 1) home-built capacitance bridge working the best from 10 kHz to 10 MHz measurement frequencies, and 2) cold amplifier near the sample to eliminate the large shunt capacitance and to greatly enhance the bridge balancing signal.

FY 2014 HIGHLIGHTS

Samarium hexaboride SmB_6 is a paradigm of strongly correlated mixed valence leading to an insulating ground state. Using torque magnetometry my group observed quantum oscillations from the conductive surface states. Results reveal that the quantum oscillation frequency is proportional to the inverse of the sinusoidal function of the magnetic field tilt angle. This confirms that the electronic state is two-dimensional, as expected for a surface state. High field measurements further reveal that the Landau Level index in the infinite field limit is $-1/2$, a Berry phase contribution in Dirac systems just like that of graphene. One big achievement is the development of a tool that directly measured the magnetization of the surface states. Traditional experimental tools to study surface states are photoemission, tunneling, and electrical transport properties. Using our advanced magnetometry technique, we determined the surface state magnetization. The results provide a novel experimental method to detect the surface electronic state of quantum materials.

Studies of Multiband and Topological Superconductors

Institution: Pennsylvania State University
Point of Contact: Qi Li
Email: qil1@psu.edu
Principal Investigator: Qi Li
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014-2015)

PROGRAM SCOPE

This project has two goals. One is to investigate the effect of scattering on the superconducting energy gap features and the proposed interband mode of multiband superconductors through electron tunneling. The other is to investigate the topological superconducting state in proximity induced superconductivity in topological insulators. For the multiband superconductivity, we have mainly focused on MgB_2 , which is the first well established multiband superconductor with clearly distinguishable two gaps. For the topological superconducting state, we have mainly focused on Bi_2Se_3 and Bi_2Te_3 nanowire and nanotubes in contact with conventional superconductor leads. Owing to the discovery of superconductivity in MgB_2 and iron pnictides, multiband superconductivity has gained tremendous attention recently. Many new physical phenomena, such as the “Leggett mode”, interband interference, soliton, and Andreev bound state, have been proposed. They are collective modes due to phase relationship or fluctuations between bands. It is also known that the scattering will smear out the energy gaps and other physical signatures in a multiband system. Due to the advance in MgB_2 thin film deposition using hybrid physical chemical vapor deposition (HPCVD) developed at Penn State, very clean thin films have been achieved with a long electron mean free path and very low scattering rate. In this

project, we have showed that MgB_2 does not just have two gaps as previously thought. Each band has a distribution of gap values associated with different parts of the Fermi surface, depending on the momentum directions. We will study how the scattering affects the distribution of energy gaps. We will use focused ion beam and electron beam lithography to create nanometer sized superconducting contacts on the topological insulator nanowire and nanotubes to study the characteristic features of the induced superconducting state.

FY 2014 HIGHLIGHTS

(1) Proximity-effect induced superconductivity in $\text{NbSe}_2/\text{Bi}_2\text{Se}_3$ heterostructures has been studied using a point contact Andreev reflection (PCAR) spectroscopy technique at low temperatures down to 40 mK. In samples with high contact interface transmission, Andreev reflection is observed with the differential conductance (dI/dV) increases at the NbSe_2 energy gap when the temperature is below its $T_c \sim 7.2$ K and a proximity induced gap in Bi_2Se_3 below ~ 5 K. In samples with intermediate contact transmission, the spectra is close to tunneling and the superconducting gaps near the surface of Bi_2Se_3 within the proximity coherence length are obtained as a function of Bi_2Se_3 thickness. In addition, at very low temperatures below 100 mK, the spectrum cannot be fitted with the standard BTK model and we speculate that this may be due to the induced topological superconducting surface states. (2) We have successfully synthesized topological insulator Bi_2Te_3 nanotubes by a solution phase method through the mechanism of Kerkendall Effect. Nanotube geometry can optimize the surface to bulk volume ratio of topological insulators and minimize the bulk conduction in the transport properties. Single crystal Tellurium nanowires were first obtained by reducing TeO_2 and then bismuth compound, as a precursor, was added into the solution. The nanotubes with inner hollow structure are formed due to the large difference of the diffusion constant between the elements. Transmission electron microscopy (TEM) and scanning electron microscopy (SEM) studies confirm the nanotube structure with typical outer diameter ranging from 90 nm to 200 nm and wall thickness around 10 to 15 nm. The typical length is about 5 – 15 μm . The temperature dependence of conductance of a single nanotube shows very insulating behavior. This is very different from the typical Bi_2Se_3 thin films and nanowires, which are often metallic due to Se vacancies.

Engineering of Mixed Pairing and Non-Abelian Majorana States of Matter in Chiral p-wave Superconductor Sr_2RuO_4 and Other Materials

Institution: Pennsylvania State University
Point of Contact: Ying Liu
Email: liu@phys.psu.edu
Principal Investigator: Ying Liu
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

This project deals with unconventional superconductivity, the consequences of and the mechanism for such unconventional superconductivity, and other novel phenomena in Sr_2RuO_4 and related ruthenates, and monolayer FeSe grown on SrTiO_3 . While few people doubt the spin-triplet nature of superconductivity in Sr_2RuO_4 , the precise pairing symmetry, namely, how the superconducting order parameter is varied on the entire Fermi surface, is yet to be determined. The first goal of this project is to establish the precise pairing symmetry in pure Sr_2RuO_4 and that in the related system of the Ru-

Sr_2RuO_4 eutectic phase (the 3-K phase); Our second goal is to explore the consequences of exotic pairing symmetries in these two material systems and establish the presence of some novel topological objects, including gapless chiral surface states, domains and domain walls, half-flux-quantum vortices that support the Majorana mode; Our third goal is to gain insight into the mechanism of superconductivity in Sr_2RuO_4 and $\text{Ru-Sr}_2\text{RuO}_4$ - How are unconventional pairings including mixed pairing states are realized in a real material? To accomplish these goals, we propose to: 1) perform phase-sensitive measurements on k_z -dependence of the order parameter for Sr_2RuO_4 ; 2) detect the presence of chiral edge states in Sr_2RuO_4 ; 3) search for a mixed pairing state in the $\text{Ru-Sr}_2\text{RuO}_4$ eutectic phase; and finally, 4) perform Little-Parks resistance oscillations and scanning SQUID measurements to search for half-flux-quantum flux states in mesoscopic samples of Sr_2RuO_4 . In addition, we will also investigate compounds closely related to Sr_2RuO_4 , such as $\text{Sr}_3\text{Ru}_2\text{O}_7$, and single crystalline films of FeSe grown on $\text{SrTiO}_3(001)$ that features a very high transition temperature.

FY 2014 HIGHLIGHTS

In 2014 we focused on the search of half-flux-quantum Little-Parks (L-P) oscillation in mesoscopic rings of Sr_2RuO_4 and the study of band-dependent electronic and magnetic properties of single crystals of $\text{Sr}_3\text{Ru}_2\text{O}_7$. Recent cantilever magnetometry measurements on micron-sized, doubly connected crystals of Sr_2RuO_4 have indicated that a half-flux-quantum state may be present in this material. To provide independent evidence for the presence of this new topological object by electrical transport measurements and examine its stability we carried out the L-T measurements which should trace out the phase boundary of the mesoscopic rings of Sr_2RuO_4 fabricated using a combination of mechanical exfoliation of Sr_2RuO_4 crystals, photolithography, and focused ion beam techniques. Without an in-plane magnetic field, large-amplitude resistance oscillations of a full-flux quantum were found as ramping the out-of-plane field. When the in-plane field and the measurement current were sufficiently large, a pronounced second set of resistance peaks consistent with the existence of half-flux-quantum states was observed in one sample. Measurements on additional samples suggest that the half-flux-quantum states, if indeed present, are likely to be metastable. In addition, we have studied the bilayer member of the Roddlesden-Popper(R-P) series, $\text{Sr}_3\text{Ru}_2\text{O}_7$, closely related to the single-layer member, Sr_2RuO_4 but non-superconducting. A band-dependent metamagnetic transition and heavily renormalized quasiparticle properties may be relevant to superconductivity in Sr_2RuO_4 . We carried out angle-dependent magnetoresistance and magneto thermoelectric measurements on crystals of $\text{Sr}_3\text{Ru}_2\text{O}_7$ cut along two specific crystalline directions and a magnetic field rotating in the ab plane. We found evidence supporting the presence of spin-momentum locking and the emergence of a coherent state with unconventional magnetism phase formed in a two-dimensional band in $\text{Sr}_3\text{Ru}_2\text{O}_7$.

Time-Resolved Spectroscopy of Insulator-Metal Transitions: Exploring Low-Energy Dynamics in Strongly Correlated Systems

PROGRAM SCOPE

Our research program focuses on the study of the large interfacial magneto-electric coupling effect and coherent spin dynamics in complex multiferroic oxide heterostructures using interface-specific and time-resolved nonlinear-optical techniques. The goal of these studies is to elucidate the static and dynamic magnetic interactions and their correlations with the electronic structure and strain states at the valence and lattice mismatched interfaces, which can be artificially engineered. Building on key advances of the previous award period, our program concentrates on two major themes: (i) to determine the interfacial magneto-electric coupling mechanism and its correlation with charge transfer, orbital states and strain states induced by the substrate or film thickness using the interface-specific magnetization-induced second-harmonic generation (MSHG) technique, and (ii) to investigate its effect on the coherent spin precession in these strongly correlated systems as a new path for fast magnetic switching utilizing the time-resolved magneto-optical Kerr effect (MOKE) technique. The science addresses issues of energy dissipation and the coupling between electronic and magnetic order in such advanced materials, of fundamental importance to our understanding of solid-state properties and has numerous applications.

FY 2014 HIGHLIGHTS

The sensitivity of the electronic and spin state of strongly correlated oxides to charge provides enhanced coupling between magnetic and ferroelectric order parameters; it often relies on charge doping of a colossal magneto-resistance manganite to modulate between high and low spin state, which compete for the ground state of the system. However, the microscopic origin of this effect is still not fully understood. The optical MSHG technique is particularly effective for probing the magnetic state at buried interfaces, and thus turns out to be suitable for investigating the interfacial magneto-electric coupling mechanism. We have investigated the interfacial spin state of the multiferroic heterostructure $\text{PbZr}_{0.52}\text{Ti}_{0.48}\text{O}_3 / \text{La}_{0.67}\text{Sr}_{0.33}\text{MnO}_3$ (PZT/LSMO) and its dependence on ferroelectric polarization with MSHG at 78 K. The magnetization in the first unit cell layer at the interface can be widely tuned over an order of magnitude by varying the applied electric field by 180 kV/cm. The cross-coupling between ferroelectric and ferromagnetic behavior at the heterointerface is mainly electronic, due to charge injection. The ferroelectric polarization of PZT can tune the spin alignment of Mn ions at the heterointerface from ferromagnetic to antiferromagnetic exchange coupled. In contrast, the bulk magnetization probed with MOKE remains unchanged. Multiple domains of ferromagnetic to antiferromagnetic phase coexist as the ferroelectric polarization of PZT is switched. We believe our results provide new insights into the interfacial spin-charge coupling.

Establishing the Consequences of Intertwined Order Parameters in Spatially Modulated Superconductors

Funding: \$431,666 (2014)

PROGRAM SCOPE

Over a surprisingly diverse set of materials, unconventional superconductivity (SC) resides near the boundary of some other ordered phase exhibiting broken translational symmetry, such as antiferromagnetism, charge or orbital order. It is commonly thought that these order parameters compete with SC, however there is widespread evidence that some optimal degree of inhomogeneity may, in fact, be favorable for SC in some cases. Moreover, recent transport and magnetization experiments on the classic, stripe-ordered superconductor $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ indicate that the interaction between charge order and SC is coherent, implying that the interaction between SC and alternate orders is more nuanced than previously thought. Subsequent work has shown, on pure symmetry grounds, that if the interaction between SC and charge order is coherent, several other highly novel phenomena should also exist, which can be readily explored with a combination of existing experimental techniques. The purpose of this project is to establish the generality and full implications of the presence of coherent, phase-dependent coupling between charge and SC order in unconventional superconductors. This will be accomplished with a set of experiments designed to detect several predicted phenomena, including neutron scattering and growth of single crystals, scanning SQUID microscopy and Josephson interferometry, Raman scattering, and x-ray scattering. These experiments will comprise an exhaustive test for coherent interference phenomena in several distinct material systems. If successful, this project will establish for the first time the physical origin of the sometimes perplexing relationship between SC and other forms of order in unconventional superconductors. It will also lead to the discovery of several new phenomena not previously observed in any condensed matter (CM) system. If not observed, the negative results will set strong constraints on the types of interactions that take place in unconventional SC.

FY 2014 HIGHLIGHTS

Recent months have seen headway in materials development, experimental and theoretical aspects of this program. PI MacDougall has begun preparations for the production of single crystals across the doping series of stripe-ordered $\text{La}_{2-x-y}\text{Eu}_y\text{Sr}_x\text{CuO}_4$ via the float zone technique and Cu-intercalated TiSe_2 using chemical vapor transport, and has performed proof-of-principle growths of both. PI Van Harlingen has grown nanowires of stripe material, $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ (LBCO), and begun studying fluctuations in the resistance to explore the dynamics of charge stripes associated closely with the sharp drop in the SC T_c near $x=1/8$. He observes a sharp increase in the noise at a temperatures of 40-50K, near the where the onset of charge ordering has been previously reported by Abbamonte, and signatures in the spectral density suggestive of an origin in pinned dynamical stripes. PI Abbamonte has been studying the effect of Ti-doping on the CDW-state of TaS_2 . Using temperature dependent transport and x-ray measurements, his group has uncovered new information about the evolution of the CDW wavevector, and put forward an alternate explanation for the known resistivity anomaly at 8% doping, in terms of a commensurability effect with the lattice. A paper on this work, co-authored by all PIs, is currently under review at Physical Review B (PRB). PI Fradkin has worked on the theory of intertwined orders in high temperature superconductors. He has coauthored a review article on this subject, to appear in Reviews of Modern Physics, and a recent Physical Review Letter, in which his group showed that simple one-dimensional models that have pair density wave (PDW) ground states are actually topological SC and exhibit protected Majorana bound states at interfaces with uniform SC. On a different tack, Fradkin recently co-authored a paper in PRB on a theory of time-reversal breaking spin liquid states in the magnetization plateaus of anisotropic frustrated quantum Heisenberg antiferromagnets on the kagome lattice.

Magnetotransport Studies of Low-Dimensional Electron Systems Based on GaAs/AlGaAs Heterostructures and Graphene

Institution: Georgia State University
Point of Contact: Ramesh Mani
Email: rmani@gsu.edu
Principal Investigator: Ramesh Mani
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 6 Graduate(s), 2 Undergraduate(s)
Funding: \$146,289 (2014)

PROGRAM SCOPE

Emergence is the process of complex behaviors arising out of a multiplicity of basic interactions. Emergent phenomena often exhibit remarkable, useful, and collective aspects - features which have helped to make emergent behavior a topic of current research. A high quality GaAs/AlGaAs two-dimensional electron system subjected to modest microwave/terahertz photo-excitation at low temperature exhibits radiation-induced zero-resistance states at small magnetic fields, and this phenomenon has been cited as evidence for emergence in a driven, steady state non-equilibrium context. Since the initial observations, photo-excited electronic systems have become a popular arena to search for new physical phenomena. The prime objectives of this research are to (a) uncover novel emergent phenomena in the photoexcited GaAs/AlGaAs electronic system and (b) elucidate the electronic properties of graphene and other 2D materials using photo-excited transport in the near-to-equilibrium context. The study of high mobility GaAs/AlGaAs heterostructures will help to provide a better understanding of the physics of zero-resistance states and associated magnetoresistance oscillations. The microwave photo-excited transport studies of graphene will serve to characterize spin properties through the resistive detection of spin resonance. Such a study will expand our empirical knowledge of steady state non-equilibrium electronic transport, provide a better understanding of basic interactions that leads to the emergence of the microwave-induced zero-resistance states in the two-dimensional electron system, and provide new insight into the response of the novel 2D materials to microwave and terahertz radiation while illuminating upon, for example, the spin characteristics of massless Dirac fermions.

FY 2014 HIGHLIGHTS

Some highlights: (a) Transport characteristics of a negative magneto-conductivity state - Negative diagonal magneto-conductivity/resistivity is a spectacular property of driven, far-from-equilibrium, low dimensional electronic systems. Yet, the physical response of this exotic electronic state is not yet fully understood since it is rarely encountered in experiment. Here, we examined numerically the magneto-transport characteristics of a negative conductivity/ resistivity state. Obtained results suggest, surprisingly, that a bare negative diagonal conductivity/resistivity state in the 2DES in a magnetic field under photo-excitation should yield a positive diagonal resistance, with a concomitant sign reversal in the Hall voltage.[R. Mani and A. Kriisa, Scientific Reports, 3, 3478 (2013)] (b) Size dependent giant magnetoresistance in mm-scale GaAs/AlGaAs devices – Observations of large changes in the electrical resistance induced by the application of a small magnetic field provide new understanding into the physical phenomena involved in the associated electronic transport. This study examined a “bell-shape” negative giant magnetoresistance (GMR) that grows in enormously in magnitude with decreasing temperatures in mm-wide high mobility 2D GaAs/AlGaAs devices. Experiments showed, remarkably,

that the span of this magnetoresistance on the magnetic-field-axis increases with decreasing device width, W , without producing a concurrent Hall resistance correction. These results were successfully reproduced in a multi-conduction model. The results suggested that a size effect in the mm-wide 2DES with mm-scale electron mean-free-paths is responsible for the observed effects. [R. Mani *et al.*, Scientific Reports 3, 2747 (2013)]

Superconductivity and Magnetism in d- and f-Electron Materials

Institution: California-San Diego, University of
Point of Contact: Brian Maple
Email: mbmaple@ucsd.edu
Principal Investigator: Brian Maple
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$300,000 (2014)

PROGRAM SCOPE

This research program focuses on superconductivity, magnetism, and their mutual interaction in d- and f-electron materials. An overarching goal of superconductivity research is the discovery of materials which are superconducting at high temperature (ideally, near or above room temperature). While a theoretical approach is useful for understanding the properties of superconductors, it has not yet proven to be successful in predicting practical superconducting materials and, to date, virtually all known superconductors have been discovered through systematic experimental research. The emphasis of our research program is on the physics of superconducting, magnetic, heavy fermion, non-Fermi liquid and other types of strongly correlated electron phenomena in novel transition metal, rare-earth, and actinide based oxides and intermetallic compounds with a particular focus on the growth of high quality single crystals. The research will involve the search for new superconducting materials and the preparation of high quality single crystal, thin film, and polycrystalline specimens of high- T_c and novel f-electron superconductors. The anisotropic normal and superconducting state properties of these materials will be studied as a function of chemical composition, temperature, pressure, and magnetic field in order to obtain information about the underlying electronic, lattice, and magnetic excitations involved in the superconductivity, the symmetry of the superconducting order parameter, and the electron pairing mechanism. Phenomena associated with the interplay between superconductivity and magnetic order and vortex flux-line dynamics and pinning in the mixed state will be investigated. Neutron scattering, photoemission, infrared spectroscopy and other specialized measurements will be carried out with collaborators. This research program will contribute to furthering the understanding of the optimal conditions for the occurrence of superconductivity.

FY 2014 HIGHLIGHTS

(1) Electrical resistivity measurements under pressure to ~ 2.8 GPa on the compounds $\text{LnO}_{0.5}\text{F}_{0.5}\text{BiS}_2$ (Ln = La, Ce, Pr, Nd) revealed a transition from a low-pressure superconducting phase to a high-pressure superconducting phase with a higher T_c (highest $T_c = 10$ K for La) at a critical pressure P_c that increased with Ln atomic number. (2) Electrical resistivity measurements on single crystals of LaFeAsO under pressure revealed a decrease of the spin density wave (SDW) transition temperature with pressure towards 0 K at $P \approx 10$ GPa, but no evidence for superconductivity above 1 K up to $P \approx 37$ GPa. (3) Penetration depth measurements on single crystals of $\text{Ce}_{1-x}\text{Yb}_x\text{CoIn}_5$ revealed a crossover from nodal to nodeless superconductivity near $x \approx 0.2$, the concentration where an Yb valence transition, suppression

of the quantum critical field, and a Fermi surface reconstruction occur (the actual composition is 1/3 of the nominal concentration x up to $x \sim 0.5$). (4) NMR measurements on URu_2Si_2 yielded evidence for the formation of a pseudogap between the hidden order (HO) transition temperature of 17.5 K and 30 K. Experiments on $URu_{2-x}Os_xSi_2$ suggest a phase transition at $x \approx 0.2$ from the HO to the antiferromagnetic phase. (5) Kondo disorder in the filled-skutterudite system $CePt_4Ge_{12-x}Sb_x$ that governs the physical properties and emergence of non-Fermi liquid behavior and antiferromagnetic order was studied by means of thermoelectric power measurements. (6) Eleven new Cd-based compounds with chemical formulas RNi_2Cd_{20} ($R = Y, La, Nd, Sm, Gd, Tb$) and RPd_2Cd_{20} ($R = Ce, Pr, and Sm$) were synthesized in single crystalline form. (7) Electrical resistivity measurements under pressure revealed that pressures of 55 GPa were insufficient to close the energy gap of Sr_2IrO_4 , while pressures up to 60 GPa reduced the electrical resistivity of $Sr_3Ir_2O_7$ at 10 K by five orders of magnitude. Further increases in pressure up to 100 GPa were unable to completely close the Mott energy gap and induce a metallic state in $Sr_3Ir_2O_7$.

Controlling Superconductivity via Tunable Nanostructure Arrays

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Nadya Mason
Email: nadya@illinois.edu
Principal Investigator: Nadya Mason
Sr. Investigator(s): Raffi Budakian; Illinois-Urbana Champaign, University of
Taylor Hughes; Illinois-Urbana Champaign, University of
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$733,333 (2014-2015)

PROGRAM SCOPE

The goal of this proposal is to understand and control how collective behavior emerges in exotic superconducting systems. To achieve this, we precisely control the configuration and coupling of islands of superconductors patterned on conducting substrates, to develop tunable, proximity-coupled nanostructure arrays that emulate quantum phases observed or predicted in bulk materials. Array parameters that are tuned include disorder, lattice configuration, geometric frustration, and dimension. These studies aim to clarify the factors that diminish or enhance superconductors' critical properties. Further, the studies focus on controlling these parameters to induce novel phase regimes, such as pseudogap-like phases, 2D metallic states and Fulde-Ferrell-Larkin-Ovchinnikov (FFLO) phases. The research combines temperature- and field-dependent transport measurements with magnetic resonance force microscopy measurements of local vortex spatial structure and surface currents. This combination of probes, along with accurate phenomenological modeling, can provide complete characterization of the phase behavior (e.g., superconducting, strange metal, strange insulator, etc.) of the samples, and allows the determination of how different island interactions lead to different collective phenomena.

FY 2014 HIGHLIGHTS

We have made progress on multiple fronts, including understanding the superconducting behavior of single mesoscopic islands, determining the vortex dynamics of island arrays, and developing a new method of imaging surface currents. In studying single, mesoscopic, granular superconducting islands, we found that the onset of superconductivity is determined by the size of the largest grain within each island, rather than by charging effects or just bulk transition temperature. The results explain how superconductivity can be suppressed in surprisingly large systems, and clarify the behavior of disordered

or granular superconductors. We also studied the behavior of vortices in island array systems having an applied perpendicular magnetic field. By combining experiment with phenomenological modeling we could understand an unusually wide range of vortex-dominated transport behavior. Additionally, we noticed a particular vortex transport regime that was not accurately described by our model, which may have an unconventional origin, and which will be further examined via transport and imaging. Finally, we have developed a high sensitivity magnetic force microscopy (MFM) method to image surface currents with a sensitivity in the nano-Tesla range and sub-micron spatial resolution. We have demonstrated this technique by imaging the current flow in micron-scale patterned metal wires. Our immediate goal is to use this technique to study the spatial distribution of surface currents in the superconducting island arrays in the mixed superconducting-normal state.

Spectroscopic Investigation of Novel Electronic and Magnetic Materials

Institution: Tennessee, University of
Point of Contact: Janice Musfeldt
Email: musfeldt@utk.edu
Principal Investigator: Janice Musfeldt
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$147,845 (2014)

PROGRAM SCOPE

The goal of our research program is to develop a fundamental understanding of the mechanisms underlying the interplay between charge, structure, and magnetism in complex materials. This insight facilitates the development of tunable multifunctional solids and nanomaterials, which are scientifically and technologically important. Our main strategy involves investigating the dynamic response of functional materials like multiferroics, quantum magnets, frustrated systems, and compounds containing domain walls or 4- and 5d centers, and we perform these measurements under external stimuli (like high magnetic fields and pressures) and at very small sizes where quantum confinement becomes apparent. By so doing, we learn about the relationships between different ordered and emergent states, explore the dynamic aspects of coupling, and gain insight into the generality of these phenomena and their underlying mechanisms. In addition to broadening the understanding of novel solids under extreme conditions, multifunctional materials and their assemblies are of interest for light harvesting, spintronic, and solid state lubrication applications.

FY 2014 HIGHLIGHTS

Several exciting discoveries were made under the auspices of our Department of Energy-supported program during the past year. Briefly, they include (i) revealing the magnetic field-induced shift of the optical band gap in $\text{Ni}_3\text{V}_2\text{O}_8$, (ii) testing the role of combined frustration and spin-orbit interactions on field-induced color change mechanisms in $\text{R}(\text{In},\text{Mn})\text{O}_3$, (iii) uncovering the dynamic signatures of domain walls in multiferroic ErMnO_3 , (iv) analyzing the electronic structure of a series of spinel ferrites, (v) unraveling size-dependent vibronic coupling in nanoscale $\alpha\text{-Fe}_2\text{O}_3$, and (vi) investigating the Burstein-Moss effect in Re-substituted MoS_2 nanoparticles. What brings these findings together is the interplay between charge, structure, and magnetism and the spectroscopic techniques with which we investigate these phenomena. A broad range of educational, outreach, and service activities also took place under the auspices of this Department of Energy grant. The majority were in the area of conference organization (2013 Telluride workshop on spin-orbit coupling in 4- and 5d materials and the 2014

Gordon Research Conference on multiferroic and magnetoelectric materials) and service to the National High Magnetic Field Laboratory and the National Synchrotron Light Source.

Nanostructure Studies of Strongly Correlated Materials

Institution: Rice University, William Marsh
Point of Contact: Douglas Natelson
Email: natelson@rice.edu
Principal Investigator: Douglas Natelson
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

Over the last two decades nanofabrication techniques have advanced significantly, and nanostructure-based methods have enabled great advances in our fundamental understanding of the physics of electrons in conventional metals and semiconductors such as Si and GaAs. In this program, we apply these nanostructure-based approaches to strongly correlated electronic materials, systems in which the electron-electron interactions can dominate the electronic, magnetic, and thermodynamic properties of the material. Specific materials of interest are those that exhibit metal-insulator transitions, when the conductivity of the material changes dramatically as the temperature is shifted through a transition that may include a structural component. Specific materials under examination include: vanadium dioxide (VO_2), layered dichalcogenides (TiSe_2), and rare earth nickelates (e.g., NdNiO_3). All three of these materials have high temperature conducting states and low temperature insulating states. We are using nanostructure techniques (very closely spaced electrodes to observe the electric-field-driven stability of the insulating phase; studies of contact resistance to gain insight into the injection and removal of charge from correlated materials above and below the transition; ionic liquids and hydrogen intercalation to tune charge density and hence the state of the material) to gain insights into the underlying physics behind the transitions and the relevant ordered states. We are also using nanostructure methods to examine emergent magnetism in related correlated materials (e.g., Fe-intercalated TaS_2), and mesoscopic electronic transport in materials where the Fermi liquid theory, the conventional model of metals, seems to fail (e.g., the hydrogen-doped “bad” metal H_xVO_2).

FY 2014 HIGHLIGHTS

In the past year (ending 9/30/14) we have had several successes in this program. Through collaborative investigations with a synchrotron/neutron scattering group, we have determined the phase diagram and precise structures of hydrogen-intercalated H_xVO_2 . We find that hydrogen intercalations as large as $x=0.6$ are possible, and that the stabilization of a “bad” metal phase (and the complete elimination of the metal-insulator transition of VO_2) takes place through doping of the vanadium 3d band (Mott physics) rather than changes in lattice stability (Peierls physics). This work has been published in the Journal of the American Chemical Society. We also investigated the kinetics of hydrogen diffusion in single-crystal VO_2 nanowires. We found that H diffusion along the (rutile) c-axis is far faster than transverse to that axis; moreover, we found that H diffusion is significantly more rapid in the rutile (metallic) structure than in the monoclinic (insulating) structure, even when accounting for temperature effects. This work has been published in Nano Letters. We have examined electronic transport from the micron to the nanoscale in NdNiO_3 films. At low temperatures we find a crossover from conventional Ohmic response to nonlinear conduction that appears consistent with the correlated equivalent of

Landau-Zener breakdown. This work has been published in Phys. Rev. B. We have also examined the remarkable magnetism and associated magnetoresistance in Fe_xTaS_2 , through a collaboration with Prof. Emilia Morosan. We have found a magnetization-switching magnetoresistance approaching 100% (!) at low temperatures, and it appears that the mechanism is spin-disorder scattering in the presence of strong spin-orbit coupling; this is a previously unreported mechanism that may provide a path toward technologically useful magnetoresistive materials. This work has been submitted for publication.

EARLY CAREER: Exploring Superconductivity at the Edge of Magnetic or Structural Instabilities

Institution: California-Los Angeles, University of
Point of Contact: Ni Ni
Email: nini@physics.ucla.edu
Principal Investigator: Ni Ni
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

This project aims at understanding the interplay among structural, magnetic and electronic degrees of freedom in unconventional superconductors, a class of materials in one of the most challenging and interesting areas of condensed matter physics. Compared with conventional superconductors, unconventional superconductors have not been explained by current theories and typically exhibit high critical temperatures (T_c 's), meaning they can conduct electricity with low losses, some of which can do this at or above liquid nitrogen temperatures. This property makes them of particular use for applications in energy generation and electrical energy transmission. These materials are also of fundamental scientific interest because the existence of structural, magnetic, orbital/charge and superconducting orders provides a platform in understanding and ultimately manipulating these interactions. Therefore the objective of this research project is to design, fabricate and characterize new superconducting materials, including the iron-based superconductors that lie at the edge of structural/magnetic instability using solid state reaction, crystal-growth methods, electrical transport and thermodynamic measurements with/without magnetic field. The goal of this research project is to help understand the relationship among different orders in these materials, to examine the structure-property relationship, and to shed light on the electron-electron interactions responsible for the superconducting phase transition.

FY 2014 HIGHLIGHTS

We have three major projects going on: (1) We have successfully grown and characterized two new series of Fe-based superconductors, the Co and Ni doped 10-3-8 superconducting family. The structural/magnetic phase transitions in the parent compound were suppressed to lower temperature and superconductivity up to 15 K occurs. The comparison between the two families shows rigid band approximation is applicable here. T_c is relatively lower in Ni doped 10-3-8, may be due to the strong impurity scattering from Ni atoms comparing to Co dopants. No coexistence between superconductivity and magnetism is observed. Considering the fact that coexistence occurs for more isotropic 122 and no coexistence for anisotropic 1111 Fe pnictide families, this may suggest the importance of interlayer coupling in the interplay of magnetism and SC. (2) We have successfully grown high quality single crystals of $\text{Ca}_{0.73}\text{La}_{0.27}\text{FeAs}_2$, the 'parent'/overunderdoped compound of the 112 superconducting family. We found there is a monoclinic to triclinic structural phase transition at 58 K and a paramagnetic to

stripe AFM phase transition at 54 K. Unlike other parent compounds of cuprates and Fe-based superconductors, without external stress/magnetic field, this material naturally remains a single structural domain with fixed crystallographic a and b directions below 58 K. In this single structural domain, S-type magnetic domain walls form with spin direction rotating 90° across the domain wall. The fact that the spin orientation is 45° from the stripe direction, instead of 90° as in other Fe pnictides, may indicate this material has weaker spin-orbital coupling. (3) New 112 superconductors with T_c up to 20 K are discovered. This is a new route to lead to SC in the 112 family. This discovery made the systematic study of nematic fluctuation without external pressure possible for Fe pnictide.

Mapping the Electron Response of Nanomaterials

Institution: Columbia University
Point of Contact: Richard Osgood
Email: osgood@columbia.edu
Principal Investigator: Richard Osgood
Sr. Investigator(s): Andrew Millis; Columbia University
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$211,000 (2014)

PROGRAM SCOPE

This program has the goal of understanding the physics of emergent properties in artificially nanostructured low-dimensional systems. To accomplish this goal, we are focused on (1) preparing large surface arrays of 1D and 2D systems, such as monatomic wires synthesized by self-assembly and freestanding monolayer films formed via exfoliation techniques or epitaxial CVD, and (2) examining their physics using advanced photoemission techniques, i.e., small-spot, time-resolved, or high-resolution, and atomic resolution low- and variable-temperature STM probes. Finally, a major component of this effort involves a simultaneous theoretical effort using the concepts and tools of many body physics as well as DFT computations. Examples of some of the important questions our work is trying to answer include: Are there new electronic phases near surfaces in one-atom-wide wires or in nanoparticles, and can theoretical constructs be developed to examine such systems? What are the emergent dynamic properties arising from lateral confinement in 1D and 2D confined systems? Can we probe many-body effects in exfoliated freestanding graphene and in other exfoliated materials such as oxides or topological insulators?

FY 2014 HIGHLIGHTS

We have continued our investigations of monolayer and few layer transition-metal dichalcogenides. In the previous year, we had investigated the thickness dependent electronic structure of substrate supported MoS₂. This year, we directly measured the electronic structure of suspended exfoliated monolayer molybdenum disulfide (MoS₂) using micrometer-scale angle-resolved photoemission spectroscopy. Measurements of both suspended and supported monolayer MoS₂ elucidated the effects of interaction with a substrate. A suggested relaxation of the in-plane lattice constant was found for both suspended and supported monolayer MoS₂ crystals. For suspended MoS₂, a careful investigation of the measured uppermost valence band gave an effective mass at Gamma and K of 2.20m₀ and 0.42m₀, respectively, and a fitted band spin-orbit splitting at K of 129 meV. We have also investigated other transition-metal dichalcogenides. Specifically, we performed angle-resolved photoemission spectroscopic measurements of the evolution of the thickness-dependent electronic-band structure of the heavy-atom two-dimensional layered, dichalcogenide, tungsten-diselenide (WSe₂). Our data, taken

on mechanically exfoliated WSe₂ single-crystals, provided direct evidence for shifting of the valence-band maximum from Gamma (multilayer WSe₂), to K, (single-layer WSe₂). Further, our measurements also set a lower bound on the energy of the direct band-gap and provided direct measurement of the hole effective mass. We have initiated other photoemission experiments on correlated electron oxide crystals.

Exploring Photon-Coupled Fundamental Interactions in Colloidal Semiconductor Based Hybrid Nanostructures

Institution: Maryland, University of
Point of Contact: Min Ouyang
Email: mouyang@umd.edu
Principal Investigator: Min Ouyang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$128,194 (2014)

PROGRAM SCOPE

The interplay between photon and matter is the basis of many fundamental processes and various applications. Harnessing light-matter or even more exotic light-matter-spin interactions can allow new underlying physical principles as well as technologies of solid-state quantum information processing. This program is aimed at gaining an improved understanding of emerging fundamental photon-coupled processes at the nanoscale with particular emphasis on photon and spin-related interfacial coupling of semiconductor on the ensemble level. This program involves integration of various far-field time-resolved optical spectroscopies with recent nanoscale materials advance of precisely tailored zero-dimensional colloidal semiconductors based hybrid nanostructures possessing different functionality.

FY 2014 HIGHLIGHTS

(1) We have achieved a new class of colloidal hybrid nanostructures with well-defined intra- synergistic coupling interactions that can offer tunable nanoscale colloidal condensed matter systems for understanding a few photon-coupled fundamental processes on the ensemble level, and performing ultrafast far-field all-optical measurement and spin manipulation in hybrid core-shell nanostructures based on (ac) optical Stark effect (ac-OSE). A hybrid nanostructure is defined as a nanoscale unit that can integrate various functional units (such as semiconducting, metallic and magnetic quantum dots) with internal synergistic coupling. We have particularly focused on controlling fine parameters of hybrid nanostructures including anisotropy, symmetry, composition, and structural order, which are critical for materials characteristics. The progress includes both development of a hierarchical synthetic approach for controlling the structural order of non-centrosymmetric hybrid nanooligomers (Nature Commun. 5, 4792, 2014) and morphology imprinting synthetic strategy for centrosymmetric hybrid core-shell nanostructures, with independent control of anisotropic core and shell (manuscript in preparation). (2) We have made substantial progress towards demonstration of all optical ultrafast coherent manipulation of fundamental physical processes in complex colloidal nanostructures by light-matter interactions. The progress includes all optical manipulation of both phonon and spin dynamics in colloidal nanostructures for the first time. For example, by utilization of multiple femto-second pulses the selective phonon mode can be enhanced or suppressed, which can be critical for understanding various phonon-related nanoscale physical phenomena (manuscript in preparation).

EARLY CAREER: Non-Centrosymmetric Topological Superconductivity

Institution: Maryland, University of
Point of Contact: Johnpierre Paglione
Email: paglione@umd.edu
Principal Investigator: Johnpierre Paglione
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Superconductors without inversion symmetry, or non-centrosymmetric superconductors, promise a much more robust route to realizing topological superconducting states. With inversion symmetry being one of two key symmetries for Cooper pairing (time reversal being the other), its absence has profound implications on the formation of Cooper pairs. With a non-trivial topology of the Bogoliubov quasiparticle wavefunction resulting in protected zero-energy boundary states analogous to those of topological insulator (TI) systems, the promise of topological superconductivity (TSC) in NC superconductors is very strong. With strong band inversion, the RPtBi and RPdBi ternary half-Heusler compounds are candidate TI systems that, as non-centrosymmetric superconductors, also have the potential to harbor mixed-parity states and are therefore unique in that they are simultaneously both TI and TSC candidate systems. We are exploring the family of rare earth-bismuthide (RPtBi and RPdBi) half-Heusler compounds, synthesizing high-quality crystalline specimens and fully characterizing their normal, superconducting and magnetic states in an effort to reveal their potential for realizing the next generation of topological insulators and superconductors. Our most recent developments include synthesis and characterization of the palladium-based RPdBi series, revealing another family of superconducting compounds in the RPdBi (R=La to Lu) series. These include non-metallic transport, low carrier densities, unconventional magnetoresistance, magnetism and superconductivity.

FY 2014 HIGHLIGHTS

Electrical resistivity and magnetic susceptibility measurements of the RPdBi series have been performed down to 20 mK temperatures, revealing an interesting progression of superconducting phase transitions that evolves with rare earth species. Intriguingly, our results on the RPdBi compounds indicate that superconductivity in this series onsets at a higher transition temperature than in the Pt-based series, with maximum superconducting transition above one Kelvin found in the non-magnetic Y- and Lu-based compounds. Furthermore, superconductivity may coexist with long-range magnetic order, as determined by neutron scattering experiments on TbPdBi, DyPdBi and HoPdBi, which all undergo antiferromagnetic ordering transitions before entering a superconducting state at a lower temperature. These results have been confirmed by AC susceptibility measurements and continue to be probed by specific heat measurements, which are challenging owing to extremely low carrier densities ($\sim 10^{18} \text{ cm}^{-3}$). Rare earth magnetism has been characterized in this series, as evidenced by transport, magnetization and specific heat signatures of bulk phase transitions, as well as neutron scattering experiments in collaboration with Dr. Jeffrey Lynn at the NIST Center for Neutron Research. Specific heat measurements have revealed a progression of the bulk magnetic transition that is consistent with order parameter studies of the magnetic phase via neutron scattering. Continuing work is studying the inelastic (crystal electric field) properties of these materials. Penetration depth measurements on the RPtBi series using the tunnel-diode resonator technique in collaboration with Prof. Ruslan Prozorov at Ames National Laboratory are being used to determine the unconventional nature of the superconducting state. In

addition, preliminary point contact spectroscopy measurements at UMD exhibit unusual characteristics of the superconducting state conductance spectrum.

Artificially Structured Semiconductors to Model Novel Quantum Phenomena

Institution: Columbia University
Point of Contact: Aron Pinczuk
Email: aron@physics.columbia.edu
Principal Investigator: Aron Pinczuk
Sr. Investigator(s): Shalom J. Wind; Columbia University
Vittorio Pellegrini; Istituto Italiano di Tecnologia
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

We seek the design and exploration of novel electron states in controllable artificial structures that are realized in semiconductor quantum heterostructures by advanced nanofabrication. We strive to uncover new collective states of strongly interacting electrons in artificial potential energy patterns of tunable geometry. The fabricated devices belong to a class of scalable simulators of quantum states in which the main actors are many electron systems in high quality semiconductor structures. A primary goal is to reveal striking interplays between fundamental electron interactions and geometrical constraints (topology). These interactions should be venues for creation of novel quantum states that could, eventually, lead to new device concepts. To achieve milestones in this research we strive to advance the state-of-the-art of nanofabrication of patterns superimposed on semiconductors. The honeycomb topology, or 'artificial graphene' (AG), is a benchmark of the proposed research. In AG lattices an assembly of quantum dots is in a honeycomb pattern with electron entanglement occurring via inter-dot interactions. The initial studies have focus on AG lattices designed and fabricated with exquisite precision. We seek here to achieve electron systems that display the states with energies that have relativistic-like momentum dispersion that characterize Dirac fermions, and that could have novel topologically protected behaviors. Reaching this milestone leads to research goals that we describe as creation and study of 'novel quantum states in a semiconductor chip of high perfection' At Columbia Dr. Shalom Wind leads on nanofabrication with a new 100keV e-beam nanolithography, and Prof. Aron Pinczuk leads on optical experiments at high magnetic fields and low temperature reaching to below 50mK. High quality modulation doped GaAs/AlGaAs quantum wells are the starting material for the fabrication of artificial lattices.

FY 2014 HIGHLIGHTS

We fabricated very short period (as small as 40 nm) honeycomb lattice patterns in GaAs quantum wells. These structures have a potential modulation for electron states that is described as artificial graphene (AG) because the topology of the potential is similar to that of natural graphene. The fabricated AG lattices consist of an assembly of quantum dots arranged in a honeycomb pattern that are created by e-beam lithography followed by very low damage reactive-ion-etching of GaAs quantum wells. Very small quantum dot diameters below 20nm have been achieved for the first time. The small diameter quantum dots enable the creation of AG lattices with record extremely short periods that are expected to support formation of well-defined Dirac fermion states of electrons with kinetic energy that is linear in momentum (massless). Characterization by photoluminescence (PL) from conduction to valence band optical transitions enables determinations of electron density in the fabricated AG structures. Resonant

inelastic light scattering (RILS) experiments at low temperature (about 4K) probe the ‘miniband’ structure created by the AG potential. Low-lying modes observed by RILS are interpreted as transitions of electrons from populated minibands to empty minibands. The calculated miniband structure for the AG structures with shortest period, 40 and 50nm, indicates formation of well-defined Dirac fermions. Joint density-of states evaluations based on calculated mini-band structures are in excellent agreement with RILS results from the short period AG structures. Further control over parameters such as the Fermi level should permit manipulation of massless fermions. These results demonstrate that high precision patterning of semiconductor quantum wells create a platform for explorations of novel behavior in a semiconductor quantum simulator.

Engineering Topological States of Matter and Search for Majorana Fermions

Institution: Purdue University
Point of Contact: Leonid Rokhinson
Email: leonid@purdue.edu
Principal Investigator: Leonid Rokhinson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

Excitations with non-Abelian statistics are non-local objects and their wavefunctions contains information about the history of topological deformations of the many-particle system. Non-locality makes them resilient against local perturbations and quantum information can be encoded by exchanging (braiding) non-Abelian particles. Development of systems where non-Abelian excitations can be created and manipulated is a step toward development of a topologically-protected fault tolerant quantum computer. Within the scope of this program we are developing and studying systems which can support non-Abelian excitations. The main objective is the development of hybrid one-dimensional wires where superconductivity is induced in the semiconductor material by proximity effects from an ordinary superconductor. In the presence of strong magnetic field in a properly designed system topological superconductivity can be realized, where Majorana modes are formed at the ends of the wire.

FY 2014 HIGHLIGHTS

The major drawback of nanowire-based proposals to realize Majorana fermions is the rigidity of nanowires and inability to perform exchanges to demonstrate non-Abelian properties. Within the last year we designed an entirely new platform where non-Abelian excitations can be created and manipulated within a two-dimensional space. At the heart of the new platform is a 2D magnetic semiconductor where Lande g-factor changes sign at high magnetic fields. The system combines topological protection of edge states of the quantum Hall effect and deterministic localization of non-Abelian excitations at the phase boundary between topologically trivial and non-trivial phases of gate-formed helical 1D wires. It also supports higher order non-Abelian excitations which are required for universal qubit realization. Key feasibility experiments have been performed where we demonstrated gate control of the quantum Hall ferromagnet polarization and extracted important spin-orbit parameters of the system.

Quantum Coherence and Random Fields at Mesoscopic Scales

Institution: Chicago, University of
Point of Contact: Tom Rosenbaum
Email: t-rosenbaum@uchicago.edu
Principal Investigator: Tom Rosenbaum
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$149,998 (2014)

PROGRAM SCOPE

Disorder and fluctuations can combine to produce novel and important electronic, magnetic, and optical effects. Inhomogeneous quantum systems are particularly appealing in this context because they have a proclivity for self-organization on the mesoscale and can exhibit pronounced fluctuations away from equilibrium. With the right choice of materials, there are manifest opportunities for tailoring the macroscopic response and for garnering insights into fundamental quantum properties such as coherence and entanglement. We seek here to explore and exploit model, disordered and geometrically frustrated magnets where spin clusters stably detach themselves from their surroundings, leading to extreme sensitivity to finite frequency excitations and the ability to encode information. Moreover, by tuning the spin concentration and/or the quantum tunneling probability, it should be possible to study the competition between quantum entanglement and random field effects. As one passes from the quantum to the classical limit, clear implications develop for magnetic storage architectures. Finally, extensions from quantum ferromagnets to quantum antiferromagnets promise new physics as well as tests of universality and general applicability. A combination of ac susceptometry, dc magnetometry, noise measurements, hole burning, non-linear Fano experiments, and neutron diffraction as functions of temperature, magnetic field, frequency, excitation amplitude, dipole concentration, and disorder should address issues of stability, overlap, coherence, and control. We are especially interested in probing the evolution of the local order in the progression from spin liquid to spin glass to long-range-ordered magnet.

FY 2014 HIGHLIGHTS

One of the key aspects of optimization is the process by which the computer settles into a solution to questions akin to the traveling salesman problem. The solutions exist in a landscape where the heights and depths of features are the total distance travelled; the best solution corresponds to the deepest valley. To find the deepest valley, the optimizer hops between valleys either by thermally climbing over barriers or quantum tunneling through them. We looked at the valleys found after thermal and quantum annealing in the quantum magnet, $\text{Li}(\text{Ho},\text{Y})\text{F}_4$. At low temperatures the speed and strength of thermal annealing can be controlled by rods of sapphire connecting the sample to a dilution refrigerator. The quantum annealing can be controlled by means of a magnetic field that sets the rate of quantum tunneling. We found that when the system reaches its final valley via thermal annealing alone it was dramatically different from the state reached when thermal annealing was weakened and quantum annealing was turned on. The Random Field Ising Model (RFIM) is a simple and powerful approach to quantifying the effects of disorder. While it has been studied extensively via theory and simulations and by decades of experiments on antiferromagnets, the difficulty of realizing the RFIM in bulk ferromagnets has limited the ability to interrogate fundamental quantities like hysteresis loops and avalanche dynamics. We begin to fill this gap in our experiments. We studied the domain dynamics of the ferromagnet $\text{Nd}_2\text{Fe}_{14}\text{B}$ in transverse field, a room-temperature realization of the RFIM. The power-law

exponents and scaling forms of Barkhausen noise events as a function of temperature and transverse field demonstrate that the system can be placed into two regimes depending on tunable disorder: a regime where random-field-induced pinning dominates and one where thermal fluctuations dominate. The deep free-energy minima allow for domain-wall oscillations for extended periods of time.

Thermalization of Artificial Spin Ice and Related Frustrated Magnetic Arrays

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Peter Schiffer
Email: pschiffe@illinois.edu
Principal Investigator: Peter Schiffer
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$174,149 (2014)

PROGRAM SCOPE

This program encompasses experimental and theoretical studies of lithographically fabricated arrays of nanometer-scale single-domain ferromagnetic islands in which the array geometry results in frustration of the magnetostatic interactions between the islands, known as ‘artificial spin ice’. Such geometrical frustration can lead to multiple energetically equivalent configurations for the magnetic moments of the islands and a variety of associated novel collective behavior. These systems are analogs to a class of magnetic materials in which the lattice geometry frustrates interactions between individual atomic moments, and in which a wide range of novel physical phenomena have been recently observed. The advantage to studying lithographically fabricated samples is that they are both designable and resolvable: i.e., we can control all aspects of the array geometry, and we can also observe how individual elements of the arrays behave. In previous work, we have demonstrated that we can fabricate and probe frustrated magnet arrays, including some geometries that are directly analogous to the “spin ice” materials. We have designed frustrated lattices, controlled the strength of interactions by changing the spacing of the islands, and demonstrated that the island magnetic moment orientation is controlled by the inter-island interactions. Current work is focusing on several different aspects of these systems including thermal annealing of these arrays at temperatures above the Curie point of the ferromagnetic permalloy, a technique that allows better access to the low-energy ground state of these many-body systems. Another set of studies is focusing on electrical transport through connected networks based on artificial spin ice geometries.

FY 2014 HIGHLIGHTS

In FY 2014 we capitalized on our development of an annealing protocol for artificial spin ice and the subsequent observation of magnetic charge ordering. Artificial spin ice was introduced to investigate many-body phenomena related to frustration and disorder in a controllable system that could be locally probed. Because of the large magnetic energy scales associated with the magnetic elements in artificial spin ice, it had previously been impossible to thermally anneal artificial spin ice into desired thermodynamic ensembles. Our group demonstrated a method for thermalizing artificial spin ices with square and kagome lattices by heating them above the Curie temperature of the constituent material, leading to moment ordering and effective magnetic charge ordering respectively. In this FY, we applied this technique to artificial spin ice created on the shakti lattice, a structure that does not directly correspond to any known natural magnetic material. On the shakti lattice, none of the near-neighbor interactions are locally frustrated, but instead the lattice topology frustrates the interactions leading to

a high degree of degeneracy. We demonstrate that the shakti system achieves a physical realization of the classic six-vertex model ground state. Furthermore, we observe that the mixed coordination of the shakti lattice leads to crystallization of effective magnetic charges and the screening of magnetic excitations, underscoring the importance of magnetic charge as the relevant degree of freedom in artificial spin ice and opening new possibilities for studies of its dynamics. This work was published in Nature Physics.

Nanostructured Materials: From Superlattices to Quantum Dots

Institution: California-San Diego, University of
Point of Contact: Ivan Schuller
Email: ischuller@ucsd.edu
Principal Investigator: Ivan Schuller
Sr. Investigator(s):
Students: 5 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$525,000 (2014-2016)

PROGRAM SCOPE

This project is dedicated to the main issues arising when materials, especially magnetic ones, are nanostructured in one, two and three dimensions. The comprehensive approach combines preparation of nanostructures using thin film (Sputtering and MBE) and lithography (electron beam and self assembly) techniques, characterization using surface analytical, scanning probe microscopy, high-resolution scattering (light, X-ray, synchrotron and neutron) and microscopy techniques and measurement of physical properties (magneto-transport, magnetic and magneto-optical) and modeling of the results. All preparation of unique materials and devices and most structural and physical characterization are performed in the PI's laboratory at UCSD. More sophisticated structural and magnetic studies at the nanoscale are performed in collaboration at several major DOE funded facilities. This project aims to investigate general physical phenomena, including exchange bias, effects of confinement on magnetic properties, a variety of proximity effects in magnetic hybrids, and induced phenomena by the application of external driving forces such as time varying electric and magnetic fields, light and other types of radiation. In all cases, a crucial ingredient is the reduction of complex or highly correlated materials to the nanoscale, where fundamental changes may occur in their physical properties. The studies performed included fluorides, oxides, borides and organics in addition to many combinations of transition metal elements. The battery of instrumentation continues expanding the experimental capabilities at UCSD and elsewhere. More recently experiments at fast time scales have been started to investigate the very unusual dynamics present in many hybrid systems.

FY 2014 HIGHLIGHTS

ACCOMPLISHMENT Using specially engineered hybrid nanostructures we have obtained control of one of the key properties of a magnetic material, the coercivity, without using a magnetic field. This was shown to be a very general phenomenon, appearing in a large variety of hybrid combinations. **IMPLICATIONS** Science: This development allows engineering novel functionalities in hybrid materials by transferring properties of one into another material. We have engineered a unique, hybrid, magnetic-oxide bilayer in which there is a giant (factor of 5!) change in the coercivity in a very narrow (smaller than 10 degrees K) range of temperature. This is unlike any magnetic material known until now. The possibility of using a voltage or a current as the controlling parameter is being currently investigated. Technology: This development shows the road towards the development of new transformer materials,

which can provide large energy savings in the transformation of electrical energy. This development also has important energy saving implications for the field of data storage and energy-assisted writing.

Fundamental Studies of High-Anisotropy Nanomagnets

Institution: Nebraska, University of
Point of Contact: David Sellmyer
Email: dsellmye@unlnotes.unl.edu
Principal Investigator: David Sellmyer
Sr. Investigator(s): George Hadjipanayis; Delaware, University of
Ralph Skomski; Nebraska, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

The project is focused on artificially structured nanoscale magnets, a key class of materials important in magnetism and nanoscience. The specific focus is on nanometer-length-scale and real-structure control of new or metastable structures as a means of creating materials with high spin polarization, magnetic anisotropy and ordering temperatures. Innovative aspects of the research include synthesis of new magnetic nanostructures with special fabrication techniques. The proposed research consists of three main parts. The first is aimed at preparation and properties of complex nanoscale clusters and particles where anisotropic structures and surface effects are expected to lead to novel magnetic properties. Both rare-earth-free and rare-earth-containing Co- and Mn-rich systems are explored. The second part is focused on assembly and interfacial interactions in nanoscale composites. Here, the goals are to understand and control the alignment, assembly and coercivity of Co-based two-phase structures where grain size and interfacial exchange interactions are critical. The third part is aimed at exploring new high-anisotropy structures expected to have relatively high Curie temperatures and controllable spin polarizations. The focus is on Mn-based compounds with properties potentially useful for future magnetoelectronic devices. The research is based on a continuing collaboration between groups at the Universities of Nebraska and Delaware. A broad set of experiments is performed over a wide temperature range. These include structural characterization by x-ray diffraction, analytical and high-resolution electron microscopy, Lorentz microscopy and others. Magnetic measurements include dc magnetization to fields of 7 T between 4.2 and 1000 K. The results are correlated with theoretical work on analytical and simulational nanomagnetism to study spin polarization, magnetic nanostructures, anisotropies, magnetic interactions, and magnetization reversal mechanisms.

FY 2014 HIGHLIGHTS

Collaborative experimental and theoretical research has led to two papers highlighting the understanding and control of nanoscale structures to achieve enhanced magnetic properties. In the first, [Adv. Funct. Mater. 23, 3262 (2013)], single-crystal SmCo₅ nanoparticles with an average size of 3.5 nm have been produced by cluster-beam deposition. When closely packed, the nanoparticles showed a super-paramagnetic behavior with a blocking temperature of 145 K. Dispersion of the SmCo₅ nanoparticles in a carbon matrix resulted in increase in both the coercivity and the blocking temperature. Room temperature coercivities as high as 12 kOe have been obtained for the first time in mono-layers of SmCo₅ nanoparticles dispersed in C matrix. δM plots showed that the interactions in the sample with closed packed particles are of exchange type, which could decrease the overall effective anisotropy and coercivity. Coercivity is found to be inversely proportional to the packing density of the

particles. In the second paper [Sci. Reports 4, 6265 (2014)], we have studied magnetic nanomaterials with a view towards new high-performance permanent magnets. The nanostructures are designed from Co- and Fe-rich building blocks without critical rare-earth elements, and often are required to exhibit high coercivity and magnetization at elevated temperatures to 180°C for many important applications. Here we achieve this goal in exchange-coupled hard-soft composite films by effective nanostructuring of high-anisotropy HfCo₇ nanoparticles with a high-magnetization Fe₆₅Co₃₅ phase. An analysis based on a model structure shows that the soft-phase addition improves the performance of the hard-magnetic material by mitigating Brown's paradox in magnetism.

Magneto-Transport in GaAs Two-Dimensional Hole Systems

Institution: Princeton University
Point of Contact: Mansour Shayegan
Email: shayegan@Princeton.edu
Principal Investigator: Mansour Shayegan
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

Two-dimensional (2D) carrier systems confined to modulation-doped semiconductor hetero-structures provide a nearly ideal testing ground for exploring new physical phenomena. At low temperatures and in the presence of a strong magnetic field, these systems exhibit fascinating, often unexpected, many-body states, arising from the strong electron-electron interaction. Examples include the fractional quantum Hall liquid, the Wigner solid, and the newly discovered striped and bubble phases in the higher Landau levels. Much of the work on clean 2D systems has been performed on 2D electrons confined to a remotely-doped GaAs quantum well. The goal of our DOE project is to study the materials science and physics of 2D holes confined to such wells. Compared to the 2D electrons in GaAs, the 2D holes possess a more complex energy band structure which not only depends on the quantum well width and 2D hole density, but it can also be tuned via perpendicular electric field (gate bias), parallel magnetic field, and strain. These characteristics add new twists and allow for insight into fundamental phenomena in confined, low-disorder carrier systems. In our project we study 2D hole samples, grown via state-of-the-art molecular beam epitaxy, and use low-temperature magneto-transport measurements to explore their novel physics. Among the problems we are addressing are the shapes of Fermi contours of 2D holes and of flux-hole composite Fermions in the presence of applied parallel magnetic field and/or strain. Also of interest are the fractional quantum Hall states, including the state at the even-denominator filling $\nu = 1/2$, in 2D hole systems confined to wide GaAs quantum wells. We collaborate closely with Prof. Roland Winkler (Univ. of Northern Illinois), who is an expert in calculating the energy band in 2D hole systems, and Dr. Loren Pfeiffer who is a world expert in molecular beam epitaxy.

FY 2014 HIGHLIGHTS

When electrons at sufficiently high density are confined to a high-quality wide GaAs quantum-well, they occupy two electric subbands and possess a bilayer-like charge distribution. Under appropriate conditions, the additional layer and/or subband degree of freedom stabilizes a special fractional quantum Hall state (FQHS) at the even-denominator Landau level filling factor $\nu = 1/2$. This state is generally believed to be the two-component, Halperin-Laughlin (Ψ_{331}) state, a FQHS with strong inter-layer and intra-layer correlations. Although the $\nu = 1/2$ state was discovered over 20 years ago, its

observation was only reported in high quality GaAs electron systems until now. During the last year, we made the first observation of the $\nu = 1/2$ FQHS in GaAs hole systems. The evolution of this $\nu = 1/2$ FQHS as a function of hole density in the quantum well is quite unexpected and qualitatively different from what is seen in 2D electron systems. In our study, we also observe an unusual crossing of the two, lowest-energy, hole Landau levels as we tune the 2D hole density. The crossing leads to a weakening or disappearance of the commonly seen odd-denominator FQHSs in the filling range $1/3 \leq \nu \leq 2/3$. But, surprisingly, a new FQHS at the even-denominator filling $\nu = 1/2$ comes to life at the crossing. We tentatively interpret this $\nu = 1/2$ FQHS as a two-component Ψ_{331} state. A detailed understanding of its origin and properties await future research.

EARLY CAREER: Dynamics of Emergent Crystallinity in Photonic Quantum Materials

Institution: Chicago, University of
Point of Contact: Jonathan Simon
Email: simonjon@uchicago.edu
Principal Investigator: Jonathan Simon
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of this work is to realize a wholly new platform for studying quantum manybody dynamics, and employ it to investigate physics in the neighborhood of superfluid-crystalline phase transition. This system will be composed of 2D, effectively massive optical-resonator photons, whose interactions are mediated by virtual rydberg excitations. To achieve this, the first ~ 2 years of the effort is being spent to realize the new, strongly interacting, low-decoherence 'photonic material samples,' and the remainder of the effort to employ the unique tools available for manipulating resonator photons to study the behaviours of these samples, focusing in particular on quantum defects in small crystalline systems, and blockade-enhanced approach to driven equilibrium in the system near the phase transition.

FY 2014 HIGHLIGHTS

This year we have succeeded in building the experimental apparatus; we have prepared a laser cooled rubidium gas, loaded it into an optical trap and conveyor belt, and demonstrated transport. We have prepared a medium finesse, degenerate, small-waist optical resonator and installed it in our vacuum system. We have prepared a high-finesse ultrastable resonator, and succeeded in tunably locking our 780nm probe laser and 480nm dressing laser to it. We are now preparing to load the atoms into the optical resonator, and determine the residual electromagnetically induced transparency (EIT) linewidth in the presence of nearby metal surfaces/trapped adsorbed dipoles; as long as this linewidth is well below a MHz, our 'samples' will be ready for analysis, and the target science will begin.

Magneto-optical Study of Correlated Electron Materials in High Magnetic Fields

Institution: Florida State University
Point of Contact: Dmitry Smirnov
Email: smirnov@magnet.fsu.edu
Principal Investigator: Dmitry Smirnov
Sr. Investigator(s): Zhigang Jiang; Georgia Institute of Technology
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)

Funding: \$484,655 (2014-2016)

PROGRAM SCOPE

Probing energy, symmetry and dispersion of low-lying excitations and studying many-body effects in novel electronic materials via magneto-optical spectroscopy is a longstanding goal of this program. The remarkable properties of graphene have generated a great interest in other inorganic, two-dimensional crystalline materials or Dirac-like surface-state materials with potentially unique electronic and optical properties. Among those 'graphene-inspired' materials, two-dimensional topological insulators and transition metal dichalcogenides are of great interest due to their extraordinary range of new properties and new functionalities. Here, we exploit the exceptional sensitivity and selectivity of optical spectroscopy probes in exploring electronic structure of solids subjected to a strong magnetic field. The proposed work is focused on investigating the optical properties of graphene and its nano-structures, two-dimensional topological insulators and atomically-thin transition metal dichalcogenides, using a combination of various optical techniques with very high magnetic fields.

FY 2014 HIGHLIGHTS

(1) Magnetic field tunable Dirac plasmons in topological insulator (Bi_2Se_3) micro-ribbons. Topological insulators represent an exciting new state of quantum matter exhibiting great potential to revolutionize electronics. In this program, we demonstrate that plasmons can be confined in topological insulator micro-ribbons, and in the presence of magnetic field it couples with the cyclotron motion of Dirac electrons, forming the so-called upper hybrid mode. The resonance frequency of this mode is in the terahertz spectral range, and it can be tuned by varying the external magnetic field. We extract the effective mass of Dirac electrons in Bi_2Se_3 that is consistent with direct cyclotron resonance measurement of unpatterned thin films. (2) Infrared magneto-spectroscopy study of two-dimensional topological insulators. Recently, inverted InAs/GaSb quantum well bilayers have been theoretically predicted and experimentally confirmed as a quantum spin Hall insulator (a two-dimensional topological insulator). In this program, by changing the relative thickness of each quantum well layer, we are able to band-engineer the material from the normal region to the inverted region (quantum spin Hall region) through a phase transition (critical region). We show that in the normal and critical region only single cyclotron resonance can be observed, while in the inverted region multiple cyclotron resonances, as well as anti-crossing behavior, occur. Our observations agree with predictions of eight-band k.p calculation.

Spin-Polarized Scanning Tunneling Microscopy Studies of Nanoscale Magnetic and Spintronic Nitride Systems

Institution: Ohio University
Point of Contact: Arthur Smith
Email: smitha2@ohio.edu
Principal Investigator: Arthur Smith
Sr. Investigator(s): Jeongihm Pak; Ohio University
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

Jointly funded by "Electron and Scanning Probe Microscopies" and "Experimental Condensed Matter Physics"

PROGRAM SCOPE

Taking advantage of electron spins in gallium nitride (a Nobel prize-winning technology) is desirable in order to develop its even greater potential as a spintronic material. This project seeks to investigate spin properties in nitride-based material systems down to ultimately small spatial length scales (such as atomic dimensions), using the advanced technique of spin-polarized scanning tunneling microscopy (SP-STM). Using this method, it is possible to obtain information directly about the polarized and unpolarized spin densities of states at surfaces. We have shown through publications the promising spin properties occurring in nitride systems, such as: manganese, manganese gallium, and iron layers deposited onto semiconducting gallium nitride; manganese and chromium doped gallium nitride layers; and layers of pure manganese and chromium nitrides. We synthesize ultra-thin films of these systems using molecular beam epitaxy (MBE), allowing us to tailor the spin properties with atomic layer precision. The magnetic/spintronic systems are then explored using both STM and SP-STM in which a magnetically functionalized needle-sharp probe is brought to within just a few atomic diameters away from, and then scanned across, the sample surface. Structural, electronic, and spin magnetic properties can be directly obtained as topographical, electronic conductance, and spin conductance images (dI/dV maps), respectively. Correlations among these interrelated properties are provided as the images are simultaneously acquired pixel by pixel. By manipulating tip and sample magnetization using an applied magnetic field, it is possible to deduce 3-dimensional spin information for complex material structures. Such information is also combined with results from different complimentary experimental techniques, and with theoretical calculations as well, in order to address a wide range of fascinating phenomena related to the growth and properties of these materials.

FY 2014 HIGHLIGHTS

Highlights related to the stated program scope include first of all, our work on manganese gallium ultra-thin films (1-25 nanometers) grown on Ga-polar GaN, which was recently published in Applied Physics Letters. We have shown that for the case of slightly Mn-rich growth conditions that there are predominantly three surface reconstruction patterns occurring, including 1x2, 2x2, and 2x3. The most commonly seen 2x2 corresponds to a manganese rich surface having a 3:1 Mn:Ga ratio, in agreement with theoretical calculations; whereas, the film is overall stoichiometric (having a 1:1 Mn:Ga ratio), indicating that excess Mn tends to segregate to the surface of the growing film. Ongoing work is extending to the gallium-rich side of growth, which will ultimately allow a comprehensive understanding of these important magnetic alloys. Secondly, we highlight our discovery of a novel 6x6-patterned surface structure induced by sub-monolayer iron deposition on the atomically smooth, Ga-polar GaN surface. These highly periodic 6x6 structures decorate the surface step edges. First principles calculations find a Ga dimer model consisting of 2/9 monolayers of iron embedded within 7/3 monolayers of Ga, resulting in a relaxed but distorted structure. These results have been published in Applied Physics Letters. Further extension of this work to the N-polar GaN case has also been carried out, which results in completely different structures forming. A final highlight of our recent work is our publication in Review of Scientific Instruments demonstrating the design and capabilities of our low-temperature SP-STM/MBE facility which also includes pulsed laser deposition. This system enables the growth of a wide variety of spintronic materials and their investigation down to the atomic scale under variable magnetic fields at low temperatures. Initial results on the N-polar GaN surface reveal novel features not previously observed in any room-temperature STM images.

Understanding and Controlling Conductivity Transitions in Correlated Solids: Spectroscopic Studies of Electronic Structure in Vanadates

Institution: Boston University
Point of Contact: Kevin Smith
Email: ksmith@bu.edu
Principal Investigator: Kevin Smith
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$515,000 (2014-2016)

PROGRAM SCOPE

The scientific and technological interest in solid state conductivity transitions is enormous. The switching of the electrical properties of a material between those of a metal and those of a non-metal is the very basis of the electronics industry. These transitions are also the focus of significant fundamental physical interest. Indeed a substantial fraction of all research in solid state physics is directed at understanding such transitions in some form. Vanadium oxides are a class of solid that displays particularly complex and fascinating properties. Whether as simple binary oxides or as ternary compounds with another metal cation, these oxides are replete with complex conductivity transitions, as well as charge ordering transitions, structural phase transitions, frustrated spin structures, superconductivity, and unusual magnetic properties. Key to understanding the origin of all these phenomena in the vanadates is accurate experimental determination of the underlying electronic structure. This program aims to make definitive spectroscopic measurements of the electronic properties of vanadium oxides, in particular pure and doped VO_2 and V_2O_3 . The primary goal is to use the knowledge gained on the electronic structure of these vanadates to facilitate a deeper understanding of the origins of conductivity transitions in correlated materials. The experimental tools used are soft x-ray emission spectroscopy, soft x-ray absorption spectroscopy, resonant inelastic soft x-ray scattering, x-ray photoemission spectroscopy, angle resolved photoemission spectroscopy, and spectroscopic photoemission low energy electron microscopy (SPELEEM). The use of this suite of techniques enables a wide range of oxides to be studied, since we are able to measure electronic structure in electrical conductors and insulators, and samples in crystal, thin film, or powdered form.

FY 2014 HIGHLIGHTS

During the reporting period we completed a series of new vanadate studies, including direct observation of the separation of the structural and electronic components in the metal-insulator transition of VO_2 , and a study of low-energy orbital excitations in NdVO_3 . Ongoing studies, with manuscripts in preparation, include examination of the effects of rare-earth size on the electronic structure of rare-earth orthovanadates (RVO_3), a study of enhanced electron correlations at the surface of $\text{Sr}_x\text{Ca}_{1-x}\text{VO}_3$, a low energy electron diffraction study of the quantitative surface structure and stability of the VO_2 (110) surface across the metal-insulator transition, and, most excitingly, an ARPES study of the Fermi surface of VO_2 .

Understanding Iron Superconductors/Focus on Nodal Behavior

Institution: Florida, University of
Point of Contact: Greg Stewart
Email: stewart@phys.ufl.edu
Principal Investigator: Greg Stewart
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project characterizes (primarily via specific heat, electrical resistivity, and magnetic susceptibility) single- and poly-crystalline iron-based superconductors between 0.4 and 300 K in fields between 0 and 14 T. Quality of sample, particularly a low level of magnetic impurities, is important particularly in the magnetic field measurements. Single crystal samples are both grown in-house and obtained via collaboration. Measuring the iron based superconductors as a function of magnetic field down to 0.4 K determines whether the superconducting gap is fully open or whether there are 'nodes' on parts of the Fermi surface where the gap goes to zero, i. e. where there is a finite electronic density of states. Knowing the nodal behavior is important for understanding the symmetry of the superconducting electron pairing and indeed the nature of the superconducting mechanism itself. In addition, this project has a focus on understanding the 20 K superconductivity in some (*a priori*) undoped single crystals of BaFe₂As₂, which should be non-superconducting. Investigation into the effect of water vapor has progressed to exposure to fluorine gas as well as other reactant gaseous species.

FY 2014 HIGHLIGHTS

Using a series of small mass (~5 mg) single crystals of overdoped Ba_{1-x}K_xFe₂As₂ obtained via collaboration, scaling of the specific heat with both field and temperature has been used to find strong evidence for nodal behavior around x=0.88 in the larger of the two gaps present. This work demonstrates a new, powerful technique for tracking the presence or absence of nodal behavior vs composition in a phase diagram, as well as specifying which gap possesses the nodes.

Thermodynamics of Strongly Correlated Fermi Gases

Institution: North Carolina State University
Point of Contact: John Thomas
Email: jethoma7@ncsu.edu
Principal Investigator: John Thomas
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$157,828 (2014)

PROGRAM SCOPE

The purpose of the proposed program is the broad study of the thermodynamic properties of a strongly correlated Fermi gas of ⁶Li atoms. The primary goals are (1) to make measurements away from (rather than on) a collisional (Feshbach) resonance, to understand the properties when the gas is no longer scale-invariant and (2) to explore a new 'relativistic' regime of this unique quantum gas, by using optical fields to control the dispersion relation of the trapped interacting atoms. This novel cold atomic Fermi

gas will be a paradigm for relativistic strongly correlated matter, from graphene to quark-gluon plasmas, and will bring trapped ultra-cold unitary gases a step closer to theoretical treatment by conformal field methods, which are difficult to apply to non-relativistic systems.

FY 2014 HIGHLIGHTS

We are currently testing our new bichromatic lattice laser system, which has been described in our previous reports. This comprises an IPG 30 W 1064 nm fiber laser and a Toptica frequency doubler with an output of 4W at 532 nm. The beams are sent into fiber-optic cables from the laser table to the vacuum chamber, where two combined beams will intersect at an adjustable angle to create two standing waves, one with a period in the micron range and one half as long, enabling continuous tuning of the atomic dispersion for atoms in our CO₂ laser trap. As a warm-up experiment, we will use the 1064 nm lattice and our CO₂ laser trap to create continuously tunable, quasi-two-dimensional potentials, providing a new tool for the study of layered materials. Another new breakthrough has emerged in our studies of expanding Fermi gases: We have determined the local shear viscosity of the resonantly interacting gas as a function of the temperature from nearly the ground state to the high temperature limit. We use methods borrowed from image analysis to invert the raw trap-averaged shear viscosity to extract the local shear viscosity for the first time. The results are directly compared to recent predictions. A paper on this result is in preparation. We have made the first study of the thermodynamics of spin-imbalanced mixtures in a two-dimensional Fermi gas. We observe phase separation and find that 2D-polarons play a central role in the thermodynamics. This work nicely connects our ARO program on strongly interacting Fermi gases in two dimensions to our DOE program on thermodynamics. A paper on this result is in preparation. We have made the first measurement of the trap-averaged shear viscosity as a function of the total entropy of the cloud in the BEC-BCS crossover. A paper on this result is in preparation.

EARLY CAREER: Control Graphene Electronic Structure for Energy Technology

Institution: California-Berkeley, University of
Point of Contact: Feng Wang
Email: fengwang76@berkeley.edu
Principal Investigator: Feng Wang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$750,000 (2010-2014)

PROGRAM SCOPE

Graphene, a one-atom thick sheet of carbon, exhibits incredible structural flexibility, electrical transport, and optical responses. And remarkably, the graphene electronic structure can be varied through interlayer coupling, nanoscale patterning, and electrical gating. The objective of this project is to understand and control the electronic structure using a variety approaches and exploit the unique graphene properties for innovative energy technology.

FY 2014 HIGHLIGHTS

(1) Gate-dependent pseudospin mixing in graphene/boron nitride moiré superlattices: In this work, we demonstrate that the unusual moiré superlattice between graphene/BN leads to a spinor potential with unusual hybridization of electron pseudospins, which can be probed directly through infrared

spectroscopy because optical transitions are very sensitive to excited state wavefunctions. This work is published in Nature Physics in 2014. (2) Observation of an intrinsic bandgap and Landau level renormalization in graphene/ boron-nitride heterostructures: In this study we use magneto-optical spectroscopy to determine the Landau level transitions in this system and reveal a bandgap of ~38 meV (440 K). (Nature communications in 2014.) (3) Photoinduced doping in heterostructures of graphene and boron nitride: In this study we demonstrated photoinduced doping in van der Waals heterostructures consisting of graphene and boron nitride layers. (Nature Nanotechnology in 2014.) (4) Giant bandgap renormalization and excitonic effects in a monolayer transition metal dichalcogenide semiconductor: In this work, we observed extraordinarily large exciton binding energy of 0.55 eV for monolayer MoSe₂ on graphene. (Nature Materials in 2014.) (5) Evolution of Interlayer Coupling in Twisted MoS₂ Bilayers: In this work we demonstrated the evolution of interlayer coupling with twist angles in as-grown MoS₂ bilayers. (Nature Communications in 2014.) (6) Ultrafast Charge Transfer in Atomically Thin MoS₂/WS₂ Heterostructures: In this study we reported the first experimental observation of ultrafast charge transfer in photo-excited MoS₂/WS₂ heterostructures using both photoluminescence mapping and femtosecond (fs) pump-probe spectroscopy and observed the hole transfer within 50 fs after optical excitation. (Nature Nanotechnology in 2014.)

Charge Inhomogeneity in Correlated Electronic Systems

Institution: Connecticut, University of
Point of Contact: Barrett Wells
Email: wells@phys.uconn.edu
Principal Investigator: Barrett Wells
Sr. Investigator(s): Joseph Budnick; Connecticut, University of
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$110,000 (2014)

PROGRAM SCOPE

This project explores the basic physics of high temperature superconductivity through the synthesis and measurement of unique materials. High temperature superconductors are produced by making small chemical changes to a simpler parent compound, a process known as doping. A fundamental question we seek to answer is exactly how does doping create a superconductor. Our primary tool is the control of oxygen content as a dopant ion using a variety of techniques. We have been focusing on two systems. The first is an iron-based superconductor. FeTe is a parent compound typically made into a superconductor by the substitution of Se or S for Te. This kind of doping does not change the charge balance as Te, Se and S all have the same valence. We co-discovered that in film form, FeTe can also be made a superconductor through the incorporation of excess oxygen. Oxygen enters as an ion and causes a large change in the charge balance. Thus comparing FeTeO_x with FeTe_{1-y}Se_y should be a good avenue for understanding the role of dopant ions. We are exploring several curious aspects of FeTeO_x, particularly the interplay between the magnetism and superconductivity. These two electronic states robustly coexist in these compounds; a unique feature. The second system is a copper-based high temperature superconductor. La₂CuO₄ is a parent compound typically made superconducting through the substitution of Sr for La. A superconductor can also be made by incorporating excess oxygen, best done with the unusual procedure of using wet electrochemistry. The oxygen ions are highly mobile, leading to several interesting phenomena including electronic phase separation. Magnetic and superconducting states both develop in one material, but spatially separate to exist in different regions. We are exploring the implications of this electronic phase separation and what it implies about a pure superconductor.

FY 2014 HIGHLIGHTS

Our primary activity during FY 2014 was conducting extensive experiments on magnetism in superconducting samples of FeTeO_x . This material is unique in being both strongly magnetic and strongly superconducting. It can only be made in film form, making magnetic studies difficult. We found two avenues for measuring magnetism in these samples. The first is using neutron scattering. Such experiments typically take large samples, while films are by definition small. After several attempts and improvements in the quality of the films, we were able to perform a magnetic neutron scattering study at the NIST neutron center. A second approach was to study magnetism using Mossbauer Spectroscopy in collaboration with David Hinks and Ercan Alp of Argonne National Laboratory. Dr. Hinks provided target materials enriched in the isotope enriched ^{57}Fe which we used to produce appropriate films. We worked with Dr. Alp conduct experiments using both a conventional laboratory source and synchrotron radiation at the Advanced Photon Source. We were able to establish the presence of magnetism in the superconductor and measure basic properties. A combined paper describing magnetism as measured by both techniques is in progress. A second activity was the preparation of a study of potential charge order in superoxygenated $\text{La}_2\text{CuO}_{4+y}$. This superconductor has been shown to exhibit coexistence of magnetism and superconductivity in a single sample, but in spatially separated regions. The magnetic regions have a stripe-like ordering of ion magnetic moments, implying charges should have similar order. That charge order has never been seen, though the proper experiment may never have been performed. We are oxidizing crystals for just such a measurement, a process that takes several months. We also performed an exploratory measurement at the Canadian Light Source and are prepared for a full measurement in FY 2015.

Imaging Electrons in Atomically Layered Materials

Institution: Harvard University
Point of Contact: Robert Westervelt
Email: westervelt@deas.harvard.edu
Principal Investigator: Robert Westervelt
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

Objectives and Significance - Graphene is an exciting new material composed of a single atomic layer of carbon atoms in a hexagonal lattice. Its properties are radically different from traditional semiconductors and open the way for new science and applications. Electrons can travel ballistically over distances $\sim 1 \mu\text{m}$, quantum phenomena are unusually strong, and atomic-scale devices are possible. Goals - Our goal is to address two important questions: How do electrons move through a graphene structure? - how do they pass through barriers and bounce off edges? - what are the effects of disorder? How can one make and study atomic-scale graphene structures? - how stable are different atomic configurations? - what are the electronic states? Approach - Our project will combine the expertise of PI Westervelt in imaging electron motion using custom-made cooled scanning probe microscopes (SPMs) with the skill of collaborator Bell in characterizing materials with transmission electron microscopy using the atomic-resolution Zeiss TEM and JEOL STEM in Harvard's Center for Nanoscale Systems. Research Plan - SPM imaging of Electron Flow in QPC structures - Westervelt's lab will image electron flow in graphene hexagonal boron nitride stacked structures with quantum point contacts (QPCs). The sample size ($\sim 100 \text{ nm}$) should permit ballistic flow. We plan a series of

experiments to image the unusual characteristics of electrons in graphene: cyclotron orbits and magnetic focusing, and electron flow in bilayer graphene. Nanosculpting and Imaging Graphene Structures at the Atomic Scale - Experiments in the high resolution STEM and TEM will move toward the atomic scale by using the electron beam to both cut and image graphene structures. The high resolution of these instruments will permit us to study the materials science of newly cut edges and gaps in a graphene sheet.

FY 2014 HIGHLIGHTS

(1) Scanning capacitance microscopy: We successfully designed and implemented a cooled scanning capacitance probe that operates at liquid He temperatures. The conducting tip of a scanned probe microscope (SPM) is held above the nanoscale structure, and an applied sample-to-tip voltage creates an image charge measured by a cooled charge amplifier next to the tip. We have achieved a low noise level (0.13 e/VHz) and high spatial resolution (100 nm), providing a useful tool to image electron charge density in nanoscale devices. (2) Imaging electrons in BN/Graphene/BN stacks: We have begun a collaboration with Philip Kim to image electron motion in high mobility graphene using a G layer stacked between two insulating hexagonal boron nitride (hBN) sheets. Hall-bar samples with two end contacts and two side contacts on each side were fabricated, showing a mobility $> 30,000 \text{ cm}^2/\text{Vs}$. Using these hall-bars, we plan to image magnetic focusing in graphene, similar to experiments on GaAs/AlGaAs 2DEGs by Kathy Aidala in our lab. A voltage applied between a conductive SPM tip and the graphene layer creates a dip in the electron density directly below that deflects electrons away from their initial trajectories, changing the transmission between two electrodes. By associating the conductance with electron transmission through the Landauer formula, we can map the electron flow. This technique could reveal images of the cyclotron orbits that cause magnetic focusing. In another experiment, we plan to image the coherent flow of electrons in hBN-bilayer graphene-hBN stacks with gate-defined QPCs. Electrons in bilayer graphene have a mass, and backscatter like conventional materials. Extending imaging on GaAs/AlGaAs 2DEG samples by Mark Topinka in our lab, we plan to measure changes in the QPC conductance as the tip is scanned above the surface. This approach should image electron flow, as well as interference fringes generated by paths backscattered by the tip.

Investigation of Spin Physics in Semiconductor Nanowires-Based Heterostructures.

Institution: Ohio State University
Point of Contact: Fengyuan Yang
Email: fyyang@physics.osu.edu
Principal Investigator: Fengyuan Yang
Sr. Investigator(s): Ezekiel Johnston-Halperin; Ohio State University
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$220,000 (2014)

PROGRAM SCOPE

The goal of this DOE project is to study spin dynamics in low-dimensional systems. The original focus of this project was on spin physics in one-dimensional semiconductors. Motivated by the breakthrough in the PI's lab that enabled growth of $\text{Y}_3\text{Fe}_5\text{O}_{12}$ (YIG) epitaxial films of unprecedented quality and the exciting spin pumping results that emerged, in consultation with our DOE program manager, we shifted our focus to dynamically driven pure spin transport in magnetic heterostructures. Spin currents carried by mobile charges in metallic and semiconducting ferromagnetic and nonmagnetic materials have been the central focus of spintronics for the past two decades, while spin transport in insulators is largely

unexplored. Ferromagnetic resonance and thermally driven spin pumping have attracted intense interest in magnon-mediated spin currents, which can propagate in both conducting and insulating ferromagnets and antiferromagnets. Specifically, in this DOE project, we investigate dynamically generated pure spin currents in antiferromagnetic insulators excited by ferromagnetic resonance and thermally driven spin pumping in YIG-based heterostructures by focusing on a series of antiferromagnetic insulators to reveal mechanisms of spin transfer in antiferromagnetic insulators and across interfaces. The results from this effort open a new venue for exploration of spin manipulation in tailored structures composed of ferromagnetic, antiferromagnetic and nonmagnetic materials.

FY 2014 HIGHLIGHTS

In FY 2014, our DOE grant (DE-SC0001304) is a primary support for 2 papers in Physical Review Letters [PRL 113, 097202 (2014); PRL 113, 176601 (2014)], 2 papers in Physical Review B [PRB 90, 140407(R) (2014); PRB 90, 214428 (2014)], 2 invited papers in Journal of Applied Physics [accepted], and 1 paper in Journal of Applied Physics (accepted). In addition, we have one manuscript under review in a high impact journal and 2 manuscripts almost ready for submission under DOE support. These results include: 1) robust spin transport from YIG to Pt across an antiferromagnetic insulator NiO, which strikingly enhances the inverse spin Hall effect (ISHE) signals at thin NiO thicknesses and can transmit spin currents up to 100 nm NiO thickness, demonstrating highly efficient spin transport through an antiferromagnetic insulator; 2) investigation of spin transport by spin pumping measurements on six insulators using YIG/insulator/Pt trilayer structures, including one diamagnet, one paramagnet, and four antiferromagnets, demonstrating the systematic spin transport behavior mediated by magnetic correlations; 3) surprisingly large inverse spin Hall effect in 3d transition metals which reveal systematic variation of spin-orbit coupling with d-orbital filling; 4) study of magnetic damping of confined modes in YIG thin film by ferromagnetic resonance force microscopy, which demonstrates intralayer spin pumping, i.e., angular momentum transfer across a nanoscale field-defined interface; 5) broadly tunable approach to localizing ferromagnetic resonance modes using ferromagnetic resonance force microscopy through experimental and numerical understanding of localized modes in arbitrarily oriented magnetic fields.

Emergent Phenomena in Quantum Hall Systems Far from Equilibrium

Institution: Minnesota, University of
Point of Contact: Michael Zudov
Email: zudov@physics.umn.edu
Principal Investigator: Michael Zudov
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

The main goal of this project is to investigate magnetotransport phenomena in semiconductor nanostructures driven away from equilibrium by microwave and sub-THz radiation. Prominent examples of such phenomena include microwave-induced resistance oscillations and radiation-induced zero-resistance states, as well as Hall field-induced resistance oscillations and dc field-induced zero-differential resistance states. Of particular interest is the previously unexplored regime of separated Landau levels and extending studies of non-equilibrium phenomena to material systems other than 2D electrons in GaAs/AlGaAs quantum wells.

FY 2014 HIGHLIGHTS

(1) We have investigated microwave photoresistance in 2D electron system subject to two radiation fields. We have found that at a certain ratio between microwave frequencies, a new, phase-sensitive photoresistance can appear. This photoresistance oscillates with the magnetic field and can be a good fraction of the total photoresistance under typical experimental conditions. [Phys. Rev. B 88, 245409 (2013)]. (2) Microwave-induced resistance oscillations (MIRO) have been extensively studied for more than a decade but, until recently, have remained unique to GaAs/AlGaAs-based 2D electron gases. Recently, we have observed MIRO in a 2D hole gas hosted in Ge/SiGe quantum wells, confirming that MIRO is a universal phenomenon and demonstrating that microwave photoresistance can be utilized to probe the energy spectrum, disorder, and correlation effects of 2D holes in Ge/SiGe quantum wells. [Phys. Rev. B 89, 125401 (2014)]. (3) We have studied magnetotransport in a high-mobility 2D hole gas hosted in a Ge/SiGe quantum well subject to dc electric fields. We have found that under applied dc bias the differential resistivity exhibits a pronounced maximum at a magnetic field which increases linearly with applied current. This maximum was associated with the fundamental peak of Hall field-induced resistance oscillations, which are known to occur in 2D electron gases in GaAs/AlGaAs [Phys. Rev. B 90, 161301(R) (2014)]. (4) We have observed a colossal negative magnetoresistance (MR) effect in a GaAs/AlGaAs quantum well which is manifested by a drop of the resistivity by more than an order of magnitude at low temperatures and at a magnetic field of only 1 kG. In contrast to MR effects reported earlier, this particular MR is not parabolic and persists to much higher in-plane magnetic fields and temperatures. Remarkably, the temperature dependence of the resistivity at 1 kG is linear up to 30 K and appears to coincide with the high-temperature limit of the zero-field resistivity.

DOE National Laboratories

Complexity from Simplicity: Quantum Criticality and Novel Collective Phases in Itinerant Ferromagnets

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Meigan Aronson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$533,000 (2014)

PROGRAM SCOPE

Correlations among conduction electrons in metals leads to collective instabilities where charge, spin, and orbitals can be fully or partially ordered, separated at $T=0$ by quantum critical points (QCPs), where quantum fluctuations decide the stabilities of competing ground states. Much needed is an overarching phase diagram that would show how different types of correlations lead to novel ordered phases such as superconductivity, magnetic and orbital order, and charge localization, to provide direction for the discovery of new materials with purpose-built functionality, which are the feedstocks for advancing new technologies for sensor and device applications, as well as energy conversion and distribution applications. This FWP focuses on the explication of the quantum critical fluctuations that accompany these QCPs, which lead to the breakdown of conventional metallic behaviors and to the stabilization of novel ordered states, particularly superconductivity. We focus on new transition-metal based systems where correlations among the d-electrons lead to moment formation and charge localization, and we

will explore new classes of layered and chainlike compounds where low dimensionality enhances quantum fluctuations. We combine a vigorous program of materials synthesis integrated with the characterization of structure, thermal, magnetic, and transport properties to identify new compounds that order at low or vanishing temperatures. Electrical transport, photoemission and optical spectroscopy measurements will probe the evolution of the electronic structure and correlations as the system is compositionally driven through the QCP. We will quantify moment localization in the ordered, quantum critical, and normal metal phases using neutron scattering and magnetic measurements.

FY 2014 HIGHLIGHTS

In FY 2014, we concluded a suite of extremely accurate magnetic, transport, and specific heat measurements in $\text{YFe}_2\text{Al}_{10}$ which demonstrate anomalous divergencies at the lowest temperatures. Muon spin resonance (MuSR) experiments carried out by our collaborators L. Shu (Fudan University) and D. MacLaughlin (Riverside) found no order above 0.02 K. $\text{YFe}_2\text{Al}_{10}$ is a rare system that forms without the use of pressure or composition to provide tuning to the QCP itself. With A. Tsvetik (CMPMSD), we carried out a complete scaling analysis of $\text{YFe}_2\text{Al}_{10}$ that showed hyperscaling is obeyed and mean field behavior is absent, confirming that this system is the first bulk system where quantum critical fluctuations dominate. This finding, published in PNAS, has touched off a flurry of new work. With Igor Zaliznyak (CMPMSD), we carried out inelastic neutron scattering measurements on $\text{YFe}_2\text{Al}_{10}$, showing that the critical scattering associated with the QCP is instead wave vector independent. This local criticality is also completely unprecedented, and is strong evidence that an electronic instability, possibly involving moment formation, accompanies the magnetic QCP. Chris Homes (CMPMSD) has obtained optical evidence for increasing electronic mass at the lowest temperatures, in potential support of this local criticality scenario. Electronic structure calculations via DFT and DMFT are in progress by members of the CMPMSD theory group to assess the importance of electronic correlations. It is clear that $\text{YFe}_2\text{Al}_{10}$ is a very special system that can significantly advance our understanding of quantum criticality. We are also developing new systems that may have related QC properties. We discovered a new compound $\text{CaMn}_2\text{Al}_{10}$, which is isostructural to $\text{YFe}_2\text{Al}_{10}$. Although Hund's rule usually makes Mn-based compounds highly magnetic, very small Mn moments were found in $\text{CaMn}_2\text{Al}_{10}$, indicating its itinerant character. Neutron diffraction measurements found antiferromagnetic (AF) order above 300 K, but $\text{CaMn}_2\text{Al}_{10}$ becomes ferromagnetic (FM) at the lowest temperatures.

Digital Synthesis - A Pathway to Create and Control Novel States of Condensed Matter

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Anand Bhattacharya
Sr. Investigator(s): John Pearson; Argonne National Laboratory
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$685,000 (2014)

PROGRAM SCOPE

In our program, we seek to create, characterize and understand novel electronic and magnetic states at interfaces of complex oxides. We synthesize 'digital' heterostructures of perovskite complex oxides in single atomic layer-by-layer manner. This allows us to tailor artificial crystals, superlattices and heterostructures comprising a broad range of complex oxides with great precision. The complex oxides host a diverse range of collective states of condensed matter. The richness of observed phenomena in

these materials, which have also presented some of the greatest challenges to our understanding, is due to their strongly interacting degrees of freedom. Tailoring surfaces and interfaces between complex oxides, and even the layering of atoms within a unit cell provide a unique opportunity for new properties to emerge, that are qualitatively different from their bulk constituents. We seek to explore states that occur as a result of artificially broken inversion symmetry, electronic states that arise as a result charge transfer at interfaces, and interfacial collective states that may be tuned by gating with DC and transient electric fields. These include non-collinear magnetic states, charge ordered states, superconductivity at interfaces, multiferroics and novel two-dimensional electron gases. We work with materials that are known to have interesting phases, such as the manganites, nickelates, ferrites, titanates and cuprates, where the atoms have been 're-arranged' in simple ways – for example by layering the cations in a manner such that the effects of disorder have been engineered away, or where global inversion symmetry is broken – to reveal new properties. We create these materials systems using state-of-the-art, ozone-assisted oxide Molecular Beam Epitaxy (MBE) at Argonne, and characterize them using the major DOE facilities for neutron and photon scattering, and at the DOE Nanoscale Science Research Centers.

FY 2014 HIGHLIGHTS

- (1) We have developed a new way to create artificially polar materials out of materials that are non-polar, but have crystal structures with large unit cells and varied cation valences. This allows us to tailor electrostatic forces within a formula unit to create large distortions in bond lengths and to tailor electronic properties. Our initial demonstration was carried out using Ruddlesden-Popper nickelates, and these results have been published in *Advanced Functional Materials* and in *APL Materials* in 2014.
- (2) We have developed a technique to create and detect thermally generated spin currents in patterned structures of oxide films. A paper regarding was published in *Appl. Phys. Lett.* in 2014 where we able to show that spin currents generated from an epitaxial Fe_3O_4 film could be detected using a CoFeB magnetic film, where the Nernst and inverse spin-Hall effect could be clearly separated.
- (3) We were invited to write a review article in *Annual Reviews of Materials Research* on magnetism in oxide heterostructures that was published in 2014. We reviewed the current status and future opportunities in this field.
- (4) We created superlattices of $\text{SrFeO}_3/\text{LaFeO}_3$, where an electron microscopy study revealed an oxygen vacancy induced polar behavior. These findings were published in *Nano Letters* in 2014.
- (5) We were part of a team that designed and commissioned an oxide MBE system on a grazing incidence x-ray scattering beamline at the Advanced Photon Source. This unique tool allows us to probe the structure of a growing film. Our study on nickelate films was published in *Nature Materials* in 2014.
- (6) We are currently in the final stages of commissioning of a new oxide MBE system that combines sputtering with regular MBE. This will enable the synthesis of oxide heterostructures incorporating refractory 4d and 5d transition metals where spin-orbit coupling plays a central role, leading to novel spin and charge transport properties and new collective states.

Complex States, Emergent Phenomena, and Superconductivity in Intermetallic and Metal-Like Compounds

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov

Students: 4 Postdoctoral Fellow(s), 9 Graduate(s), 0 Undergraduate(s)
Funding: \$2,455,000 (2014)

PROGRAM SCOPE

The goal of this FWP is the design, discovery, characterization, understanding and ultimately control over materials with complex and potentially useful properties. In some cases the systems will be designed to ask, and answer, focused, basic questions (e.g. quantum criticality). In other cases the systems will have direct impact on societal needs (improved superconductors, magnets, thermoelectrics).

FY 2014 HIGHLIGHTS

Over the past year the FWP has made significant impact in the broad fields of Fe-based superconductivity, heavy fermion and quantum criticality, local moment magnetism and the development and discovery of new compounds. Of particular note is the discovery of highly anisotropic, single atom magnetism in Fe substituted Li_3N . Our discovery paper, "Giant magnetic anisotropy and tunneling of the magnetization in $\text{Li}_2(\text{Li}_{1-x}\text{Fe}_x)\text{N}$ " was published in Nature Communications and was based on a systematic development of Li-based solutions, Li-N melts in this case, as summarized in an extensive technical growth paper, "Single crystal growth from light, volatile and reactive materials using lithium and calcium flux" also published this fiscal year. These efforts are the results of BES funding to develop a reactive materials growth and characterization capability in our FWP several years ago. During FY 2014 the lab continued its extensive and fruitful collaborations with other Ames Lab FWPs leading to the discovery and characterization of a new family of R-Cd based quasicrystals, the discovery of the ordering wave vector of the quantum critical heavy fermion YbBiPt , ambient pressure measurements of excitations spectrum in the collapsed tetragonal phase of CaFe_2As_2 , and the ultrafast observation of critical nematic fluctuations and giant magnetoelastic coupling in iron pnictides.

Towards a Universal Description of Vortex Matter in Superconductors

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor
Email: ttaylor@lanl.gov
Principal Investigator: Leonardo Civale
Sr. Investigator(s): Boris Maierov; Los Alamos National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$611,000 (2014)

PROGRAM SCOPE

Complex vortex phenomena in oxide high temperature superconductors (HTS) arise from the strong influence of thermal fluctuations, which is a consequence of the small superconducting coherence length (ξ) and the large crystalline anisotropy (γ). On the other hand these fluctuations are the main obstacle for applications; moreover the problem is general and will also occur in any new-discovered superconductor operating at high temperatures. The control of vortex matter for performance

enhancement requires the design of the pinning landscape by nano-engineering of the material disorder at the scale of ξ , a few nm in HTS. Although the HTS vortex behavior contrasts with the simpler physics in conventional superconductors, according to the present understanding there is no sharp boundary between them. However, modern vortex matter models have been developed to describe the oxide HTS, thus it is important to test them in different systems. Our approach is to perform comparative studies on a variety of materials covering a broad spectrum of properties. The new family of iron-based superconductors provides an opportunity to 'bridge the gap' and check the validity of vortex models in a new family of materials with broad ranges of T_c , ξ and γ . On the other hand, the multi-band superconductivity in the Fe-based compounds introduces a new level of complexity, requiring a re-evaluation of the concept of anisotropy in the vortex behavior. We also obtain valuable information from other compounds such as MgB_2 , a chemically simpler two-band superconductor, and borocarbides that exhibit strong interactions of vortices with their magnetic sublattices. Recently we have expanded the scope of our work to include unconventional superconductors, as well as other areas of condensed matter physics such as quantum criticality, magnetic frustration and metamagnetic transitions.

FY 2014 HIGHLIGHTS

(1) We continued exploring vortex pinning and dynamics in all the main families of superconductors contained in our program, including technologically relevant YBCO-based coated conductors, Fe-based single crystals and MgB_2 epitaxial films. A general theme has been the analysis of how the pinning energy and the dynamic regimes are influenced by the relative size of the vortex core and the defects. In some cases the pinning landscape was engineered by chemical introduction of second phase nanoparticles or irradiation. (2) The new 3He probe allowed us to extend the vortex pinning and dynamics studies to the sub-Kelvin regime. We observed surprisingly large flux creep rates in single crystals of the borocarbide superconductor $ErNi_2B_2C$ ($T_c \sim 11K$). We observed clear anomalies in the creep rate (S) at the antiferromagnetic transition ($T_N \sim 6.3K$), a weak ferromagnetic transition ($T_{WFM} \sim 2.2K$), and another one, whose origin is still unidentified, at $T \sim 0.8K$. To our knowledge, this is the first observation of the effects of magnetic transitions on the vortex dynamics in superconductors. Preliminary results were presented at the 2014 March Meeting of the American Physical Society. (3) Collaborations have been initiated with other BES-MSE projects at LANL, resulting in several nascent research directions. These new research directions include: • "Magnetic ordering in the frustrated J1-J2 Ising chain candidate $BaNd_2O_4$ ". • "Quantum critical exponents in $UCo_{0.77}Fe_{0.23}Ge$ ". • "Double metamagnetic phase transition in $Sr_4Ru_3O_{10}$ ".

Correlated Materials - Synthesis and Physical Properties

Institution: SLAC National Accelerator Laboratory
Point of Contact: Thomas Devereaux

Sr. Investigator(s): Theodore Geballe; Stanford University
Aharon Kapitulnik; Stanford University
Steven Kivelson; Stanford University
Kathryn Moler; Stanford University
Alan Fang; Stanford University
Students: 4 Postdoctoral Fellow(s), 20 Graduate(s), 0 Undergraduate(s)
Funding: \$1,630,000 (2014)

PROGRAM SCOPE

The overarching goal of this FWP is to understand, and ultimately control, emergent behavior in strongly correlated quantum materials. Our research combines synthesis, measurement and theory to coherently address questions at the heart of these issues. Our experiments emphasize novel techniques that reveal important quantities and effects, such as time reversal symmetry breaking, nematic susceptibility, the local density of states, and local variation in the current distribution. During FY 2014 our effort has been largely directed towards theoretical and experimental studies of broken symmetry states in cuprate and ferro-pnictide high-temperature superconductors, in the heavy fermion superconductors UPt_3 and URu_2Si_2 , and imaging of edge currents in topological insulators and quantum Hall systems.

FY 2014 HIGHLIGHTS

(1) Quantum criticality in $BaFe_2(As_{1-x}P_x)_2$, (Nature Physics 10, 194–197 (2014)). Quantum critical behavior was observed near optimal doping in the representative Fe-based superconductor $BaFe_2(As_{1-x}P_x)_2$ via measurement of the power law behavior of the electrical resistivity. These measurements establish that the physics of quantum criticality is likely important in determining the physical properties of the Fe pnictides close to optimal doping, possibly including the occurrence of high-temperature superconductivity. (2) Effect of disorder on the resistivity anisotropy near the electronic nematic phase transition in pure and electron-doped $BaFe_2As_2$, (Phys. Rev. Lett. 112, 227001 (2014)). We show that the strain-induced resistivity anisotropy in the tetragonal state of the representative underdoped Fe-arsenides $BaFe_2As_2$, $Ba(Fe_{1-x}Co_x)_2As_2$ and $Ba(Fe_{1-x}Ni_x)_2As_2$ is independent of disorder over a wide range of defect and impurity concentrations. This result demonstrates that the anisotropy in the in-plane resistivity in the paramagnetic orthorhombic state of this material is not due to elastic scattering from anisotropic defects, and is most easily understood in terms of an intrinsic anisotropy in the electronic structure. (3) Evidence of Chiral Order in the Charge-Ordered Phase of Superconducting $La_{1.875}Ba_{0.125}CuO_4$ Single Crystals Using Polar Kerr-Effect Measurements, (Phys. Rev. Lett. 112, 047003 (2014)). High resolution polar Kerr effect (PKE) measurements were performed on $La_{1.875}Ba_{0.125}CuO_4$ single crystals revealing that a finite Kerr signal is measured below an onset temperature- T_K that coincides with charge ordering transition temperature T_{CO} . We further show that the sign of the Kerr signal cannot be trained with magnetic field, is found to be the same of opposite sides of the same crystal, and is odd with respect to strain in the diagonal direction of the unit cell.

Science of 100 Tesla

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor

Cristian Batista; Los Alamos National Laboratory
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$809,000 (2014)

PROGRAM SCOPE

This project concerns a coordinated research plan at the extremes of non-destructive high magnetic field, tackling pressing questions in condensed matter physics relevant to the BES mission that only magnetic fields around 100 tesla can answer. Our scientific team ensures that the record delivery of non-destructive magnetic fields reaching 100 tesla provided by the National High Magnetic Field Laboratory is matched by an experimental program in the extremes of high magnetic field that is unparalleled by that any other laboratory – routinely publishing scientific results in fields extending to 100 tesla. Our scientific team is continuously in the process of expanding the variety of physical phenomena that can be accessed by 100 tesla fields, which is enabled by our expertise in key areas of condensed matter physics in strong magnetic fields and extensive international collaborations. Magnetic fields manipulate matter either through a tunable nanometer length scales or a tunable magnetic energy scales (or sometimes both), enabling a great variety of different physical effects to be studied. The magnetic length scale is important for pairing and cyclotron motion in unconventional superconducting materials, which constitutes one of our foremost research focus areas in 100 tesla magnetic fields. The magnetic energy scale is most relevant for tuning competing interactions or phase transitions in multifunctional magnetic materials, which is a second focus area. The magnetic length scale can further be used for tuning commensurability phenomena in low dimensional materials, which constitutes a third focus area of this project.

FY 2014 HIGHLIGHTS

(1) Angle-dependent measurements of the quantum oscillation in underdoped $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$, where $x=0.56$, together with fits to a simple Fermi surface model developed by us in previous papers, have enabled a determination of the Fermi surface of the normal state of the underdoped regime. (2) Measurements have also been made to magnetic fields of 92 T of magnetic quantum oscillations in $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$, up to 15% hole doping. Quantum oscillations are now observed over most of the underdoped regime, indicating them to be a universal property of the pseudogap regime. (3) Angle-dependent magnetoresistance measurements have also been performed on $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$ where $x=0.59$, in pulsed magnetic fields of up to 65 T and DC fields of up to 45 T, indicating Fermi surface likely consists of two components. (4) Comprehensive doping-dependent high magnetic field transport measurements on the iron-based superconducting compound $\text{BaFe}_2(\text{As}_{1-x}\text{P}_x)_2$, revealing evidence for a quantum critical point near optimal doping (analogous to that believed to exist in the cuprates). (5) Measurements of several insulating iridate compounds have revealed the existence of an extraordinarily large coercive magnetic field. These systems are typically ferromagnetic and exhibit magnetization avalanche phenomena (i.e. magnetization jumps) in swept magnetic fields. (6) Measurements of CeRhIn_5 in fields extending to 92 T reveal features that suggest a possible connection with field-induced charge-density wave phases. (7) A study has also been made of URu_2Si_2 samples prepared using FIB lithography in magnetic fields extending to 45 T. A significant change in the Fermi surface topology is observed to occur at 40 tesla, indicating a localization of the 5f electrons in high magnetic fields. (8) In $\text{SrCu}_2(\text{BO}_3)_2$, we found evidence of a non-negligible magnetoelastic coupling using pulsed magnetostriction measurements. (9) In semimetallic graphite, we performed angle-resolved measurements of the phase diagram and resistivity at high fields.

Magnetic Thin Films

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov

Principal Investigator: Axel Hoffmann
Sr. Investigator(s): Sam Jiang; Argonne National Laboratory
Valentine Novosad; Argonne National Laboratory
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$1,929,000 (2014)

PROGRAM SCOPE

The Magnetic Films Group creates, explores and derives new insights into novel fundamental physics and new materials related to magnetic phenomena. Towards this end we synthesize a variety of thin film heterostructures and more complex lithographically patterned device concepts with the goal to understand and control their physical, chemical and metallurgical properties. We focus especially on emerging new phenomena associated with the competition between spatial and magnetic length scales, as well as proximity effects. Our vision is to understand the ultimate limits of miniaturization and prepare magnetic materials with specifically designed functionalities. Thus we tailor properties via systematic control of preparation conditions and manipulate dimensionalities and geometric confinement by means of thin film deposition via sputtering and electron-beam evaporation combined with advanced patterning and templating techniques. Additional complexity comes from coupled heterostructures, which integrate ferromagnets, antiferromagnets, superconductors, and insulators. Cutting-edge characterizations include the use of neutron-, synchrotron-, and electron-scattering and microscopy at DOE user facilities, as well as sophisticated in-house magnetotransport measurements, low-temperature high-magnetic-field magnetic force microscopy, broadband ferromagnetic resonance, and spatially resolved Brillouin light scattering microscopy. This infrastructure enables us to comprehensively investigate magnetization dynamics, magneto-transport phenomena, and interfacial coupling effects. These new phenomena push the boundaries of fundamental understanding of nanostructured magnetic materials and underlie novel applications ranging from information technologies to energy conversion.

FY 2014 HIGHLIGHTS

- Demonstrated controlled manipulation of spin wave propagation via local Oersted magnetic fields. This enables new approaches for computation with the spin degree of freedom.
- Validated spin Hall spin pumping experiments through the magnetic field orientation dependence.
- Experimentally and theoretically showed how magnetic proximity effects can give rise to reduced spin Hall effects in Pd and Pt. Furthermore identified additional magnetic damping in yttrium iron garnet/Pt bilayers, indicative of magnetic proximity effects.
- Determined spin Hall effects in metallic antiferromagnets and observed systematic trend of increased spin Hall effects for heavier elements, which is also validated by *ab initio* calculations.
- Observed spin transfer torque ferromagnetic resonance in permalloy/MoS₂ bilayers.
- Detected new magnetization reversal mode in exchange coupled antiferromagnetic/ferromagnetic vortex structures.
- Validated the approach of generating antivortices in elongated magnetic elements via dynamic resonant spin ordering.
- Systematically explored the energy transfer in dynamically coupled vortices. Surprisingly, for anti-parallel vortex polarities, applied field always result in a softening of the dynamics.
- Prepared ferromagnetic/superconducting heterostructures with perpendicular magnetic anisotropy. The interplay between magnetic stripe domains and superconducting vortices, resulted in the formation of spontaneous vortex-antivortex pairs and re-entrant superconductivity.
- Analyzed the magnetization reversal process in different composite magnet morphologies, revealing that soft-cylinders-in-hard-matrix gives rise to a maximum energy product.
- Installed new electron-beam lithography system.

Atomic Engineering Oxide Heterostructures: Materials by Design

Institution: SLAC National Accelerator Laboratory
Point of Contact: Thomas Devereaux
Email: tpd@stanford.edu
Principal Investigator: Harold Hwang
Sr. Investigator(s): Srinivas Raghu; Stanford University
Yasuyuki Hikita; SLAC National Accelerator Laboratory
Jun-Sik Lee; SLAC National Accelerator Laboratory
Students: 5 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$727,000 (2014)

PROGRAM SCOPE

A central aim of modern materials research is the control of materials and their interfaces to atomic dimensions. In the search for emergent phenomena and ever greater functionality in devices, transition metal oxides have enormous potential. They host a vast array of properties, such as orbital ordering, unconventional superconductivity, magnetism, and ferroelectricity, as well as (quantum) phase transitions and couplings between these states. Our broad objective is to develop the science and technology arising at interfaces between these novel materials. Using atomic scale growth techniques we explore the synthesis and properties of novel interface phases. Magnetotransport, x-ray, and scanning probes are used to determine the static and dynamic electronic and magnetic structure. Heterostructures with low-density superconductors are developed to explore new regimes of low-dimensional superconductivity, particularly in the presence of tunable spin-orbit coupling. Surface and interface couplings are used to engineer band alignments and control their physical properties. The experimental efforts are guided and analyzed theoretically, particularly with respect to x-ray scattering, superconductivity, and new states of emergent order. A wide set of tools, from analytic field theory methods to exact computational treatments, are applied towards rational heterostructure design.

FY 2014 HIGHLIGHTS

- Bilayer superconducting heterostructures based on delta-doped SrTiO_3 have been systematically investigated both experimentally and theoretically. In terms of the angular variation of the upper critical field, systematic coupling between the superconductors has been observed, from the decoupled limit at wide separations, to increasing coupling on the length scale of the superconducting coherence length. We investigated the role of multiple subband degrees of freedom and interlayer pair tunneling on the transition temperature. Furthermore, by moving to lower density higher mobility samples, we can observe well-defined quantum oscillations in the magnetoresistance, by which we can extract the coupling of the normal state and directly compare to the superconducting state. This suggests a novel approach to designing multicomponent superconductivity using subband structure in quantum wells.
- We developed new scaling theories of non-Fermi liquid metals. These theories are based on a proper renormalization group theory of interacting fermions near a quantum phase transition. Our theory predicts new patterns of universal properties such as the heat capacity behaving logarithmically in temperature in 3 dimensions. It also suggests that near a nematic quantum critical point, there is a significant tendency towards high temperature superconductivity.
- Several investigations of the unconventional state at the $\text{LaAlO}_3/\text{SrTiO}_3$ interface have been performed. By using top-gating, or surface charge/adsorbate control, a new regime of low-density high-mobility electrons can be achieved. Most notably, we see the development of Hall plateau features in a regime of occupying a single light

and single heavy subband. We also measured the gate-bias dependent band alignment, especially the confining potential profile, at the conducting $\text{LaAlO}_3/\text{SrTiO}_3$ heterointerface using soft and hard x-ray photoemission spectroscopy.

Electron Spectroscopy

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Peter Johnson
Sr. Investigator(s): Chris Homes; Brookhaven National Laboratory
Tonica Valla; Brookhaven National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,817,000 (2014)

PROGRAM SCOPE

The Electron Spectroscopy Group's primary focus is on studies of the electronic structure and associated dynamics of condensed matter systems using High-Resolution Photoemission and Infra-Red Spectroscopy or Optical Conductivity. A new capability, laser based ARPES, is currently under construction. The group carries out studies on a range of materials including strongly correlated systems and nano-structured materials. A special emphasis is placed on studies of High T_c superconductors and topological insulators. The group is also actively engaged in planning new facilities associated with NSLS II.

FY 2014 HIGHLIGHTS

$\text{Pb}_{1-x}\text{Sn}_x\text{Se}$ is a material that can be tuned from a trivial insulator to a Topological Crystalline Insulator (TCI). ARPES studies establish the quantum critical point and show that, on the TCI side, a Lifshitz transition can be induced at the material's surface. This transition can be exploited to manipulate transport in film devices. The shift from Fermi liquid (FL) to non-FL behavior and the removal of superconductivity as a result of increasing cobalt doping has been studied in the optical and transport properties of the Fe-based superconductor $\text{Li}(\text{Fe}_{1-x}\text{Co}_x)\text{As}$. The phase diagram indicates that further cobalt doping recovers the FL behavior but superconductivity remains absent. The collapse of the pseudogap on the electron pocket below the magnetic and structural transition in strongly-correlated FeTe results in an anomalous increase in the low-frequency conductivity and plasma frequency associated with the pocket. Proximity-induced superconductivity in Topological Insulators (TI) represents an avenue for observing the elusive Majorana fermions. Cuprates are considered ideal candidates for inducing superconductivity in TIs, but our ARPES studies show that they are extremely inefficient, due to the short c-axis coherence length. The discovery of a huge Magnetoresistance (MR) in WTe_2 questions the current understanding of transport in a magnetic field. ARPES studies show that the Fermi surface in WTe_2 consists of tiny electron and hole pockets of equal size, implying that the large MR emerges from perfect charge compensation. Using ARPES to measure lifetimes and density of states indicates that optimally doped high temperature cuprates represent a nearly perfect liquid as determined by the viscosity/entropy ratio being close to that determined in the quark gluon plasma.

Superconductivity and Magnetism

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Wai Kwok

Vitalii Vlasko-Vlasov; Argonne National Laboratory
Alexei Koshelev; Argonne National Laboratory
Zhili Xiao; Northern Illinois University
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$2,020,000 (2014)

PROGRAM SCOPE

This program undertakes experimental and theoretical investigations of novel superconducting and magnetic materials that are important for fundamental physics and applications. It explores novel physical phenomena associated with superconductivity and its interplay with magnetism and determines the origins of these phenomena for eventual novel application of superconductivity. We investigate materials from macroscopic to meso and nanoscale crystals and heterostructures under controlled environments using a wide range of sophisticated thermodynamic and dynamic characterization tools. One grand challenge pursuit is devoted to the thermodynamic studies of the new iron based superconductors, which embody a new opportunity to create an intrinsically isotropic high temperature superconductor. Another grand challenge pursuit is to develop novel strategies for controlling vortex dynamics at high temperatures where conventional core pinning is ineffective by creating magnetic, adaptive and smart vortex pinscapes to tailor the electromagnetic behavior of type II superconductors. In addition, we are also pursuing research into the collective behavior underlying high power THz radiation from synchronized Intrinsic Josephson Junctions in high temperature superconducting meso-crystals - an example of the remarkable properties that can emerge from complex correlations between individual constituents in far from equilibrium meso-scale systems. We maintain leading programs in experiment and theory, with each deriving strong benefit from close mutual cooperation.

FY 2014 HIGHLIGHTS

We made progress in all the research areas listed above. (1) We discovered that the thermodynamic superconducting anisotropy in iron-based superconductors can be reduced by incorporating a low-density of columnar-defects induced by heavy-ion irradiation and developed a model based on the variation of the electron scattering lengths due to defects. (Nat. Commun.); (2) Using our micro-calorimeter, we settled a controversy regarding the 'true' phase transition between the tetragonal high-temperature and orthorhombic low-temperature phases of Fe-based superconductors; (3) We discovered novel stripe domains and first-order phase transition in the vortex matter of anisotropic high-temperature superconductors. (Phys. Rev. Lett); (4) We imaged current filamentation in large $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$ mesa structures via luminescent and scanning laser thermal microscopy; (4) Discovered Rayleigh instability of critical superconducting vortex droplets in meso-Pb crystals (Nature Physics). In addition, we developed a low temperature magnetic force microscope (MFM) to operate in a triple-axis vector magnet environment, a Helium-3 Tunnel Diode Magnetometer for penetration depth measurements and a novel low-temperature thermal imaging system for detecting 'hot-spots' in superconductors.

Interfaces in Epitaxial Complex Oxides

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Ho Nyung Lee
Sr. Investigator(s): Gyula Eres; Oak Ridge National Laboratory
T. Zac Ward; Oak Ridge National Laboratory
Hans Christen; Oak Ridge National Laboratory
Chris Rouleau; Oak Ridge National Laboratory
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$1,948,000 (2014)

PROGRAM SCOPE

This project aims at addressing the central challenge of understanding, manipulating, and utilizing hetero-interfaces in epitaxial oxide thin films in order to obtain desired functional properties. In particular, we treat not just the layers of materials as the building blocks in complex-oxide heterostructures but regard the interfaces themselves as fundamental constituents in epitaxial assemblies. Specifically, our objectives are (1) to discover new functional properties in epitaxially stabilized oxides, (2) to explore unprecedented approaches and strategies to control the physical properties that emerge at epitaxial interfaces, and (3) to develop a new paradigm for functional oxides with exceptional control over various energy quanta and order parameters, including electrons, ions, orbitals, spins, phonons, etc. A unique combination of experimental approaches is used to underpin the work. Particular emphasis is given to the growth of perovskite oxides and related materials using pulsed-laser epitaxy utilizing real-time monitoring of interface formation and electronic structure evolution by surface x-ray diffraction and ellipsometry, coupled with detailed *in situ* and *ex situ* characterization techniques giving detailed information on crystallographic orientation and structure, electronic and ionic transport, magnetism, ferroelectricity, etc. In addition, microstructural imaging and local spectroscopy, neutron scattering approaches, optical and soft x-ray spectroscopy, and interactions with theory play key roles in all aspects of this work. The resulting enhanced understanding of interface formation, interfacial behaviors, and interfacial effects on complex materials provide unprecedented guidance in the formation of technologically relevant materials for applications such as energy conversion and storage. Thus, the outcome of this approach will lead to new, highly controlled model systems, allowing us to explore the fundamental physics of functional oxides.

FY 2014 HIGHLIGHTS

We developed epitaxial SrCoO_x oxygen sponges that can shed or absorb oxygen in a short time (<1 sec). The oxygen sponges are also found to be good catalysts, which can effectively reduce oxygen at temperatures as low as 200°C. Moreover, a strong anisotropy in oxygen reduction kinetics in epitaxial brownmillerite SrCoO_(2.5) films, which led to a demonstration of a two orders of magnitude improvement in catalytic oxygen reduction, has been discovered. This result demonstrates that controlling the orientation of catalytically functional defects in cathode materials is a useful design strategy in the development of new materials for advanced energy technologies. Based on layer-by-layer growth technique, we also developed a new route to creating transparent conducting oxides (TCOs) based on the dimensional control of conduction pathways in 2D electron gases within an oxide heterostructure. The new TCO has transparency and electron mobility similar to those of the conventional, more expensive indium-tin-oxide and, thus, may be useful for many technological applications requiring

transparent electrodes. In the area of multiferroics, we clearly delineated the different polymorphs that exist (and co-exist) in strained films of BiFeO₃. It has been demonstrated that the phase coexistence between these polymorphs is not only a consequence of epitaxial constraints, but more importantly a prerequisite of the functionality in this multiferroic material. Moreover, in order to expand current *in situ* film growth capabilities to simultaneously probe atomic and electronic structure evolution in real-time, we developed next generation pulsed-laser epitaxy by combining existing surface x-ray diffraction capabilities with hard x-ray photoemission spectroscopy for understanding and controlling the synthesis processes of novel oxide heterostructures.

Emerging Materials

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: John Mitchell
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,304,000 (2014)

PROGRAM SCOPE

Emerging Materials takes up BES Grand Challenges of understanding and controlling matter at the atomic and electronic levels by exploring phenomena lying at the intersection of electron correlation and spin-orbit coupling (SOC). Our approach follows along a synthesis-science link, through which integrated materials discovery and materials physics leads to the unveiling and the understanding of these new phenomena. Guided by this principle, we explore novel states of matter that arise from frustration, either due to the physics of spin-orbit coupling and a d⁵ electron configuration (e.g., Kitaev interactions and quantum spin liquids), or from geometric constraints on long-range order (e.g., chiral spin liquids). Our work also directs us to explore an axis leading from 3d to 5d systems. This trajectory leads us (i) to test the current $J_{\text{eff}}=1/2$ model for iridates and more deeply explore magnetic interactions among these spin-orbit coupled entities, (ii) to go beyond $J_{\text{eff}}=1/2$ by doping chemically or electrochemically into a layered d⁵ Mott insulator assembled from $J_{\text{eff}}=1/2$ units, (iii) to create a pathway of diminishing spin-orbit coupling through 4d and 3d transition metal oxide (TMO) analogs. As its name would suggest, Emerging Materials also strives to discover new materials for new phenomena. In this spirit, we have launched floating-zone crystal synthesis at high pressure, targeting the physics of materials that simply cannot be grown from melts at ambient pressure. Here the enhanced fugacity of the process atmosphere moves phase boundaries and solubility limits. Our broad targets are correlated electron systems in nickel, cobalt, and manganese based transition metal oxides.

FY 2014 HIGHLIGHTS

With spin-1/2 moments on a quasi-two-dimensional square lattice, Heisenberg antiferromagnetic coupling, and no orbital degeneracy, Sr₂IrO₄ is considered a model analog to cuprate superconductors. Following this analogy, we used K atoms to donate electrons *in situ* to the surface of cleaved single-crystal Sr₂IrO₄ and then measured the electronic structure using ARPES as a function of K coverage and temperature. Our results indicate that the parallel between Sr₂IrO₄ and cuprates persists in the metallic phase induced by electron doping, and that the 'breaking up' of a Fermi surface into disconnected segments is a general phenomenon of a system containing certain generic characteristics of cuprates. The formation of an arc, as opposed to 'hot spots' at intersections with magnetic zone boundary,

indicates that the correlation strength in Sr_2IrO_4 , which has been under intense debate, is in the intermediate-to-strong coupling regime. Thus, Mott physics and local correlations are essential for understanding of the physics of Sr_2IrO_4 . We conclude that the phenomenology of the Fermi arc must be accountable within a minimal description of the physics of doping a single band, spin-1/2 antiferromagnetic Mott insulator, as shared by Sr_2IrO_4 and cuprates. Their differences in microscopic electronic structures help separate essential features of high temperature superconductors (HTSC) from material-specific features. Importantly, the nature of the charge gap as of Mott insulating (Sr_2IrO_4) or of charge transfer nature (cuprates) seems to have little bearing on the properties discovered in this work.

PROGRAM SCOPE

The Quantum Materials program focuses on condensed matter systems in which quantum mechanics plays an especially important role in determining the nature of ordered phases and the transitions that take place between them. In these systems, competing spin, orbital, and lattice interactions yield a multiplicity of nearly degenerate ground states and complex phase diagrams that can be challenging to characterize. The challenges and opportunities presented by this class of materials motivates the overarching goal of the program, to understand, manipulate, and control competing forms of order that arise through interactions shaped by quantum physics. The pace, scale, and complexity of quantum materials research requires a team-oriented, rather than individual PI, approach. The Quantum Materials group exemplifies this approach, combining theoretical and experimental efforts that comprise (i) extensive thin film and bulk crystal fabrication capabilities, (ii) advanced characterization tools including ARPES, ultrafast optical pump/probe, neutron and X-ray scattering, and transport and thermodynamic measurements, (iii) a theory group whose members are leaders in predictive and phenomenological methods. Currently the program is focused on three overlapping themes – high-temperature superconductivity, topological phases of matter, and strong-spin orbit coupling – in cuprate, iron-pnictide, and iridate compounds.

FY 2014 HIGHLIGHTS

Achievements in condensed matter theory Our theory team has made substantial progress in our two thrust areas: unconventional superconductivity and correlated electron systems with large spin-orbit coupling. In the area of superconductivity, we have developed a powerful effective theory that unifies

phenomena in systems where Cooper pairing is driven by antiferromagnetism. This theory accounts for all known electronic instabilities in the Fe-based, Cu-based and some heavy fermion superconductors. In the area of spin-orbit coupled systems we have developed a theory that accounts for the highly unusual noncoplanar spin helices recently discovered in lithium iridates synthesized for the first time by our group. The novel magnetism is shown to result from Kitaev-Heisenberg coupling on a variety of hyperhoneycomb lattices. Growth and characterization of new materials within the QM FWP Our bulk crystal synthesis and measurement team has achieved the first growth and characterization of an harmonic honeycomb iridate, Li_2IrO_3 , in work performed in collaboration with ALS scientists (Michael Martin) and outside collaboration (R. Coldea, Oxford). Measurements performed on high quality single crystals samples have identified the lattice and magnetic structure, revealed anisotropic magnetic susceptibility, and discovered optical properties associated with the unique magnetism. Our thin film synthesis and characterization team has succeeded in the growth of high quality epitaxial iridate films in both perovskite and pyrochlore structures. We have demonstrated experimental control of properties by utilizing both epitaxial and mechanical strain for potential spintronic applications.

Funding: \$1,044,000 (2014)

PROGRAM SCOPE

This effort is concerned with magnetism as it is manifested and controlled at the nanoscale. The focus ranges from spins at defects (detection, interrogation, control, and exploitation) to the growth and characterization of complex magnetic molecules, magnetic islands on surfaces, and to solids where nanoscale spin degrees of freedom can have profound consequences on bulk properties, as in the FeAs superconductors. There are comprehensive efforts in synthesis, characterization and theory/computation, performed with local as well as international collaborators. The key goals overall are to discover and then interrogate magnetic materials at the nanoscale to gain both fundamental new knowledge, but also to exploit that knowledge. The program engages in basic research to discover new magnetic materials with unique, useful and controllable/tunable properties. A major effort is put to establish novel measurement techniques, such as nitrogen vacancy (NV)-centers in diamond – based magnetometry, magneto-optics, fast optics and four – probe STM – based device capable of measuring the transport properties at the nano- and meso-scales.

FY 2014 HIGHLIGHTS

We have initiated construction of optical magnetometer based on NV centers in diamonds. This “Magnetic nanoScope” will be a non-invasive optical probe of magnetic field with nanometer resolution and nTesla sensitivity. A low-temperature (4.2 K) confocal microscope with scanning AFM-like capabilities has been ordered from the Swiss company Attocube. A postdoc with the knowledge of the technology (Nusran Naufer) has been hired to construct and operate the new setup and a new lab (Wilhelm 115/117) has been dedicated for this project. We explained the development of magnetism with Sr doping of LaCoO_3 , particularly the import of oxygen sites. Very small energy (3.2 meV/Co) difference between two extended (GGA) band state (magnetic and non-magnetic) minima explain ~50 year problems. X-ray absorption spectroscopy and magnetic circular dichroism at the O K-edge find magnetic oxygen states at the Fermi energy, with oxygen hole states increasing with Sr doping. First principles calculations reproduced the experimental results; attributing magnetism on oxygen to hybridization between Co d- and O p-states. The calculated ground state energy is very sensitive to the degree of rhombohedral distortion (Co-O-Co bonding angle). With experimental structure parameters, the ground state is non-magnetic. Dysprosium islands grown on graphene have fcc(111) and not the bulk hcp(0001) structure. Since nanoscale materials can have properties different from bulk, the fcc(111) Dy are expected to behave magnetically and electronically differently than bulk Dy. Ultrafast infrared magneto-optical spectroscopy provided preliminary evidence on photoinduced magnetism in LaCoO_3 with resonant pumping of crystal field excitation ~0.7 eV.

EARLY CAREER: Origin of Superconductivity in Structurally Layered Materials

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Athena Safa-Sefat
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$2,500,000 (2010-2014)

PROGRAM SCOPE

The overarching goal of this work is to develop a comprehensive and predictable design for superconductors that link the behavior of the high superconducting transition-temperature in various materials. The general issues in which we are interested include the following: the structural characteristics that cause superconductivity; the effects of various chemical substitutions, pressures and magnetic fields on superconductivity; the development of superconductivity from a normal correlated state; the anisotropic properties of the superconducting and normal states; the identification of the underlying electron pairing mechanism; the nature of the charge carriers and their role in causing superconductivity; and the possible interaction between magnetic ions and superconducting charge carriers. In addition to synthesizing known materials in high-quality single crystal forms for furthering the understanding of physics of superconductivity, we aim at synthesizing new phases by replacing the iron transition-metal element, or arsenic, in iron arsenide based superconductors. The synthesis of materials is accomplished by the use of a variety of advanced solid-state techniques. The physical properties of materials are studied as a function of the concentrations of the chemical constituents and types. Such research should lay a foundation in predicting new superconducting materials with improved properties.

FY 2014 HIGHLIGHTS

Much of our studies probed the nuclear, electronic, and magnetic details of known superconducting materials, in high-quality single crystals, in order to add fundamental knowledge about causes of superconductivity; a few research examples follow. For praseodymium-doped barium-iron-arsenide, we found non-uniform local distortions through isolated praseodymium atoms that prevent percolation path for bulk superconductivity [Phys. Rev. Lett.112 (2014), 047005.]. For calcium-iron-arsenide, we found that a large Fermi-surface reconstruction in the non-magnetic phase causes the non-superconducting ground state [Phys. Rev. Lett. 112 (2014), 186401.]; different crystalline domains with varying lattice parameters were identified for this material [Scientific Reports 4 (2014), 4120.]. For copper-doped barium-iron-arsenide, we found that an orthorhombic distortion below structural transition leads to magnetically ordered state of iron arsenide planes that destroy superconductivity [Phys. Rev. Lett. 113 (2014), 117001.]. In addition, we focused part of our research on understanding superconductivity in materials under applied pressures and reduced lattice sizes; a few research examples follow. Evidence for superconductivity was found in oxygen-deficient molybdenum oxide simple binary [Phys. Rev. B 90 (2014), 054505]. We found pressure-induced superconductivity and structural transitions in ruthenium-doped barium iron arsenide [Eur. Phys. J. B 87 (2014), 68.], while neutron diffraction measurements trace the antiferromagnetic susceptibility under uniaxial pressure [Phys. Rev. B 89 (2014), 214404.].

Funding: \$2,071,000 (2014)

PROGRAM SCOPE

The ultimate goal of our research is to attain a predictive understanding of the behavior of correlated and complex materials (CCM). The experimental tools of materials synthesis, compositional tuning, and crystal growth are used to address cutting edge issues in the physics of these systems, with particular focus on the discovery and investigation of novel cooperative phenomena and new forms of order in CCM. Phenomena such as charge and orbital ordering, coupling of magnetism and ferroelectricity, unconventional superconductivity, low carrier density helimagnetism, time dependent magnetization, ferromagnetism, magnon heat conduction, and anharmonic phonons in thermoelectric materials are investigated. A substantial fraction of the effort is devoted to the discovery of innovative materials and the growth of large single crystals of fundamental interest to material physics. The composition of these materials is carefully controlled, and the effects of compositional tuning on the basic physics of the materials are studied using X-ray and neutron diffraction, magnetization, specific heat, and electrical and thermal transport. Once the materials have been prepared and characterized, in-depth experiments such as inelastic neutron scattering, photoemission, and scanning tunneling microscopy are performed

in order to obtain a deeper understanding of the relevant physics. Some of the materials investigated are promising for energy-related applications such as superconductors for grid applications and thermoelectrics and new permanent magnets for energy conversion.

FY 2014 HIGHLIGHTS

- Discovered that BaFe_2As_2 and CaFe_2As_2 are not tetragonal but orthorhombic at room temperature with nanometer sized domains
- Found that size of orthorhombic domains at room temperature in $\text{BaFe}_{(2-x)}\text{Co}_{(x)}\text{As}_2$ correlates with estimated magnitude of dynamic iron magnetic moment, which mimics the magnetic-superconducting phase diagram found at much lower temperatures
- Discovered glassy and time-dependent magnetism in a stoichiometric compound, DyRuAsO , despite no evidence of disorder or frustration
- Grew and characterized the first single crystals of the Dirac material EuMnBi_2
- Discovered large magnetoresistance (600%) in EuMnBi_2 at low temperatures
- Showed that large anharmonicity in PbTe was due to nesting of phonon modes - a result that can be used to help predict new thermoelectric materials
- Grew and characterized high quality single crystals of WSe_2 and MoSe_2
- Showed that metal-insulator transition in Sr_2IrO_4 has a strong Slater character

Photonic Systems

PROGRAM SCOPE

Since ~1990, the Ames Laboratory has conducted pioneering development and studies of 3D photonic crystals (PCs), developed forefront organic light-emitting diodes (OLEDs) and procedures for characterizing them, and conducted pioneering optically detected magnetic resonance (ODMR) studies on organic semiconductors and OLEDs. PCs, artificial periodic dielectrics or metallic structures, have revolutionized control and manipulation of photons, similar to the control of electrons in semiconductors. Photon diffraction by PCs has opened new vistas to control spontaneous emission, chemical reactions, optical communications, sensing, energy-efficient lighting, displays, and, in particular, solar cells. In parallel, OLEDs and organic electronics are developing rapidly, with particular relevance for solid state lighting. These research areas are combined into four interrelated tasks that will be performed in the next three years. Besides continuing studies in each of these areas, we will use our vast expertise to enhance light emission from OLEDs, thereby combining the PC expertise with (organic) light-emitting structures. We will explore new functionalities of PCs, including lasing and non-linear effects and utilize low-cost methods to design and fabricate large-area PC and OLED structures relevant to energy-related applications. In close relation to ODMR, we will also explore organic spintronics. There will be a close synergy between theory, simulation, fabrication, and experimental studies in these interrelated tasks.

FY 2014 HIGHLIGHTS

We have just demonstrated a top-emitting (small molecule) OLED (TEOLED) with peak luminous efficiency $\eta_L = 217$ candela/A and power efficiency $\eta_p > 200$ lumens/W – among the highest reported to date for any light source (for the incandescent bulb, $\eta_p = 15$ lumens/W). Using high-quality microlens arrays (μ LAs), in collaboration with UCLA Profs Gang Li and Yang Yang, we are obtaining record setting organic solar cell efficiency, which the μ LAs enhance by $\sim 7 - 10\%$. We have simulated the enhancement due to the μ LAs and other surface patterns, which will determine the optimal pattern to enhance organic solar cell efficiency. After previously demonstrating an OLED-based spectrometer-on-a-chip for the 493 – 650 nm, we have expanded this spectrometer to include the near UV-blue bands at 370 – 469 nm. Moreover, we have launched our new effort on organic spintronics. It focuses on the spin relaxation rates of polarons in organic semiconductors in general and in organic magnetic spin valves, i.e., organic FETs (OFETs) with ferromagnetic contacts to the source and drain, in particular. Initial results indicate that spin polarization is enhanced by the applied electric field E_{appl} in the OFET. We derived and demonstrated a simple analytic Q factor model that elucidates the lasing threshold of a PC slab vs interface reflectivities (impedance), group velocity (band structure). It shows how the lasing threshold may be dramatically altered inside a band or, vitally, close to the band edge. Our simple model enables understanding and optimizing the design of PC-based lasing structures. We experimentally and theoretically demonstrated that a 2-layer dielectric structure can collimate and enhance transmission of a Gaussian beam passing through it. This demonstrates that low-loss purely dielectric resonant surface states can be leveraged for low loss beam collimation. A system of multiple cascading bilayers can sustain the beam for large propagation distances.

Electronic Complexity of Epitaxial Rutile Heterostructures

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Hanno Weitering
Sr. Investigator(s): Paul Snijders; Oak Ridge National Laboratory
Paul Kent; Oak Ridge National Laboratory
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$903,000 (2014)

PROGRAM SCOPE

Complex transition metal oxides exhibit a plethora of fascinating broken symmetry states that emerge from the intricate interplay between the various quantum mechanical degrees of freedom of these materials, including electronic and/or spin excitations, orbital ordering, and cooperative lattice deformation. While most investigations to-date have focused on complex perovskite systems and related heterostructures, rutile heterostructures offer a particularly unique and hitherto unexplored perspective for tuning electronic complexity and emergent properties in complex oxides. In particular, the presence of edge shared MO_6 octahedra (M =metal cation) and formation of direct cation-cation bonds in rutile tends to lower the effective dimensionality of the electronic structure, compared to corner-shared perovskite systems, and greatly facilitates the growth of non-polar (001) and (110)-oriented heterostructures. The existence of two growth orientations, along with the extreme anisotropy of the metal-metal sigma-bonds, offers a unique opportunity to vary the occupation of selected $3d-t_{2g}$ orbitals via quantum confinement, and their coupling to the other degrees of freedom. The investigations aim to understand and tailor the electronic, orbital, and spin degrees of freedom of

quantum-confined rutile heterostructures, and explore the existence of recently-predicted and/or other competing quantum phases for select heterostructures. We pursue a comprehensive and timely approach involving epitaxial synthesis, in-situ electron spectroscopy, and *ab initio* DFT and post-DFT calculations. Fundamental knowledge that will be gleaned from these studies will broaden and deepen our understanding of complexity and spontaneous symmetry breaking in correlated electron systems, and elucidate how collective materials properties can be controlled through manipulation of the electronic and orbital degrees of freedom.

FY 2014 HIGHLIGHTS

In this first year of the project, we designed, built and put into operation an oxide MBE system at ORNL, featuring transition metal sources, and oxygen plasma source, *in situ* electron diffraction, and a laser sample heater allowing for fast and high pressure sample annealing. We have developed a procedure to obtain TiO₂(001) substrate surfaces suitable for subsequent epitaxial growth of rutile films. The TiO₂(001) surface is notoriously difficult to prepare for heterostructure growth, because its high surface energy drives the surface morphology through an irreversible faceting transition that renders the surface unsuitable for subsequent growth. Our results reveal that the atomically flat morphology we obtain even survives after high temperature annealing in vacuum. We used a new method to dope TiO₂ by incorporating Cr-N dopant pairs. Using soft X-ray spectroscopies we elucidated the orbital nature and energy of the dopant-induced gap states, as well as the nature of the charge excitations. Moreover, an extraordinarily large (>1 eV) reduction of the TiO₂ bandgap, in part by delocalized dopant states, was established. We proposed and demonstrated an approach analyzing the speckle patterns formed by visible laser light upon reflection off of a VO₂ film. This approach allowed us to study mesoscopic phase separation associated with the metal-insulator transition of VO₂ with both high time and spatial resolution. Finally, preliminary theoretical results, obtained to benchmark the computational methods used for our heterostructures, indicated unexpectedly that the ground state of bulk RuO₂ is different from the accepted nature of the ground state. We have confirmed these findings with preliminary experimental results.

Novel sp²-Bonded Materials and Related Nanostructures

Institution:	Lawrence Berkeley National Laboratory
Point of Contact:	Xiang Zhang
Email:	XZhang4@lbl.gov
Principal Investigator:	Alex Zettl
Sr. Investigator(s):	Carolyn Bertozzi; Lawrence Berkeley National Laboratory Michael Crommie; Lawrence Berkeley National Laboratory Marvin Cohen; Lawrence Berkeley National Laboratory Alessandra Lanzara; Lawrence Berkeley National Laboratory Steven G. Louie; Lawrence Berkeley National Laboratory Feng Wang; Lawrence Berkeley National Laboratory
Students:	0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding:	\$1,052,000 (2014)

PROGRAM SCOPE

The sp² program studies, both theoretically and experimentally, sp²-bonded structures, which include carbon nanotubes, graphene, nanowires, onions, fullerenes, nanocrystals, hybrid structures, non-carbon

nanomaterials (including BN), and nanococoons. We are interested in the design, synthesis, characterization, and application of sp^2 -bonded materials whose dimensions range from 1-100 nm. This program has three major thrusts: (1) Fundamentals: Focus is placed on theoretical predictions of new stable structures, theoretical and experimental examinations of intrinsic electronic, magnetic, and mechanical responses, transport measurements (electrical resistivity, thermal conductivity, isotope effects, Raman, photoemission spectroscopy, TEM, STM), and mechanical properties and tensile strength. (2) Functionalized nanosystems: where two or more distinct nanostructures are brought together and allowed to interact. Here we focus on methodologies to integrate nanosystems comprised of nanotubes and other nanoparticles interfaced with complementary nanostructures. 3-Directed growth of nanostructures: where novel synthesis methods are explored for non-equilibrium growth of sp^2 -based and other nanoscale materials. This program also seeks to develop specialized instrumentation for synthesis, characterization, and applications.

FY 2014 HIGHLIGHTS

During the past fiscal year the sp^2 program embarked on an ambitious effort to scale-up the synthesis of pure boron nitride nanotubes (BNNTs). Such tubes are formed by sheets of sp^2 -bonded boron and nitrogen in a 1:1 configuration; and are uniform wide-band-gap semiconductors. The bandgap is predicted to be independent of tube diameter or chirality. BNNTs were discovered by LBNL-MSD researchers 20 years ago, but limited production methods have hampered extensive physical properties characterization and application. A new extended pressure, inductively-coupled thermal plasma system was designed and constructed from the ground up for nanomaterials synthesis. In initial trials, the system produced high quality, nearly pure double wall BNNTs at a record rate of 35g/h, using pure boron and nitrogen as precursor materials. For the next period, the BNNTs thus produced will be characterized via optical methods and mechanical methods. They will also be incorporated into membranes and composites for further electronic, magnetic, and thermal fundamental science and applications study. In another sp^2 -sponsored discovery, graphene was mated to 2-dimensional hexagonal boron nitride, and calcium dimers were dispersed on the graphene. A scanning tunneling microscope (STM) was then used to push the dimers together to form artificial atoms of tunable nuclear charge. Nuclear theorists had predicted 70 years ago that ultra-heavy nuclei could cause 'atomic collapse' where the ultrarelativistic electron spirals into the nucleus. It had never before been observed. For the artificial heavy atom living on graphene, STM spectroscopy unambiguously revealed the analogous atomic collapse state. A strong experimental/theoretical collaboration enabled this work. For the next period, the collapsed states will be further characterized as a function of charge, temperature, and underlying/overlying dielectric, dimensionality, and deposited atomic species type.

Point of Contact: Harald Ade
Email: harald_ade@ncsu.edu
Principal Investigator: Harald Ade
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$250,000 (2013-2014)

PROGRAM SCOPE

As a counterpoint to the largely Edisonian progress in the vast field of organic photovoltaics, we characterize the morphology of a limited number of high performance bulk-heterojunction devices and materials systems in great detail with novel methods and thus establish improved structure-function relationships and fundamental understanding. Our long term goal is to develop a predictive device paradigm based on understanding of the fundamental interactions and properties of the active materials and the processing solvents and additives used. High performance polymer:fullerene and small molecule:fullerene systems with efficiencies >7% will be investigated. This includes the best small molecule system as well as the materials system that has the best performance for thick films. The detailed understanding of the performance bottlenecks as well as elucidation of the controlling materials aspects of why these systems are the best to date will help facilitate a transition from a “trial and error” approach to a constructionist approach to device design and fabrication. The detailed characterization will be related to fundamental interactions such as the miscibility between the donor and the acceptor material and calculated and measured interaction with the solvents and solvent additives used to cast the active layers. Since most of the time, changes in processing affect a multitude of morphological parameters, these fundamental, thermodynamic quantities will be related to all measured aspects of the morphology determined and not just the overall device performance. Establishing a connection between fundamental properties and device morphology and performance will allow the construction of a predictive device design and fabrication model.

FY 2014 HIGHLIGHTS

Polymer solar cells are a promising renewable energy technology. Development of novel materials and device architecture for further enhancing their efficiency requires fundamental understanding of the impact of chemical structures on photovoltaic properties. Given that device characteristics depend on many parameters, deriving structure-property relationships has been very challenging. We have thus exhaustively studied devices based on fluorinated benzotriazole (FTAZ-a high performance donor) copolymers. In this case, a single parameter, hole mobility, determines the fill factor of several hundred nanometer thick bulk heterojunction photovoltaic devices based on a series of copolymers with varying amount of fluorine substitution. We attribute the steady increase of the hole mobility with the fluorine content to changes in polymer molecular ordering. Importantly, all other parameters, including the efficiency of free charge generation and the coefficient of non-geminate recombination are nearly identical. Our work emphasizes the need to achieve high mobility in combination with strongly

suppressed charge recombination for thick devices required by mass production technologies. The work was published in JACS and highlighted by the editor. We have also been able to achieve record photovoltaic performance in collaboration with the group of H. Yan from HKUST. In this work, aggregation controlled by a specific molecular motif was identified. It allowed for a temperature controlled aggregation during creation of the active layers of a device, and resulted in a robust morphology determined by the donor polymer. Consequently, the devices worked well with a number of different fullerenes, a novel achievement in its own right. The results were published in Nature Communications.

High Efficiency Biomimetic Organic Solar Cells

Institution: Massachusetts Institute of Technology
Point of Contact: Marc Baldo
Email: baldo@mit.edu

Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014)

PROGRAM SCOPE

Charge transfer states are bound combinations of an electron and hole located on separate molecules. They play a crucial role in organic photovoltaics and organic light emitting devices (OLEDs). In solar cells, charge transfer states mediate both photocurrent generation and recombination losses. In OLEDs, charge transfer states are traditionally the precursors to the light emitting exciton, but they have also been used more recently to directly generate efficient electroluminescence because the two spin configurations can easily mix given the small exchange splitting of most charge transfer states. Our program is a joint theory and experimental study of charge transfer state dynamics, focusing on the key questions of: How big should a charge transfer state be? What is the optimal spacing between the electron and hole that allows it to split efficiently into charge while still being readily formed from a photoexcitation? How do we control the spin of a charge transfer state, and how does its spin determine the light emission, recombination loss, and photocurrent generation properties? And finally, how can we engineer charge transfer states for efficient solid state lighting? In each case, we simulate charge transfer state dynamics and compare to experimental studies in prototype light emitting devices and solar cells.

FY 2014 HIGHLIGHTS

We have three primary results to report this year. First, we examined the question: How big should a charge transfer state be? We measured recombination losses as a function of the electron-hole spacing in fluorescent charge transfer states, including direct monitoring of both singlet and triplet charge transfer state dynamics. Large donor-acceptor separations minimize back transfer from the charge transfer state to a low-lying triplet exciton 'drain' or the ground state. The triplet drain quenches triplet charge transfer states that would otherwise be spin-protected against recombination. Future organic solar cell designs should focus on raising the energy of triplet excitons to better utilize triplet charge transfer mediated photocurrent generation or increasing the donor-acceptor spacing in order to minimize recombination losses. Second, we report the first direct nanoscale imaging of charge transfer states in solar cell donor-acceptor blends. After generation of a charge transfer state, we demonstrate that energy moves geminately over distances of 5-10nm, driven in part by energetic disorder and

diffusion to lower energy sites. Our direct imaging is complemented by magnetic field modulation of the charge transfer state fluorescence that demonstrates that charge transfer states 'breathe' during their diffusion, expanding before ultimately recombining, thereby providing an important method for mixing singlet and triplet states. Third, we report a new mechanism for the efficient generation of light through a charge transfer state in an OLED. We engineer the crystal packing of excimers to give the most efficient charge transfer state emitter reported to date with a peak external efficiency exceeding 8%. Scientifically, the work suggests that crystal packing can be crucial to the fine control of splitting between the emissive singlet and dark triplet configurations of charge transfer states.

Novel Pnictides with d- and f- Metals as Prospective Materials for Thermal Energy Conversion

Institution: Delaware, University of
Point of Contact: Svilen Bobev
Email: bobev@udel.edu
Principal Investigator: Svilen Bobev
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

Thermoelectric materials allow for the direct inter-conversion of electricity and heat and can be used in power generators, or conversely, in solid-state refrigerators. Such technologies with no moving parts have the potential for widespread applications; however, thermoelectric devices are not part of the everyday life because of their low efficiencies. This, in essence, is a result of the low values of the thermoelectric figure of merit for almost all known materials. Better understanding the relationship among the composition, structure, electronic structure and physical properties is critically needed for the development of improved thermoelectrics. This project seeks to identify new bulk materials for applications in solid-state energy conversion. Using rationally designed syntheses, we have begun thorough and systematic studies focused on the development of the fundamental chemistry and physics of novel intermetallic compounds at the borderline between the typical metals and the typical semiconductors (Zintl phases). The goal of the work is to identify new materials that are based on the metals from the lanthanide series, the transition metals with half-filled or completely filled shells and the heaviest group 15 elements, Sb and Bi. Ultimately, the derived structure-property relationships (established on the basis of experimental work and theoretical investigations) will be used as a solid ground for developing a rationale for the tuning of potentially interesting properties of the newly synthesized materials. These efforts are an integral part of a broad interdisciplinary program to investigate wide variety of lanthanide-based intermetallics with useful magnetic, electronic, and transport properties. Both the thermoelectric and the condensed matter communities at large will directly benefit from the results, which, undoubtedly, will advance not only the research on thermoelectric materials, but also our knowledge in solid-state sciences as a whole.

FY 2014 HIGHLIGHTS

Our prior work had established relationships, which provide some logical and reasonable predictions for possible new compounds in the targeted systems, their likely structures and potential properties. Highlighted below is just one new structural family. A striking observation surveying the structures of the known ternary pnictides is that they are all made up of isolated, edge-shared or corner-shared MPn_4 (M = metal) tetrahedra forming either one-dimensional 1D chains, 2D layers, or 3D frameworks. Such

structural topologies appear amenable to integration of new species. Taking advantage of this flexibility, we explored the possibility of creating more structural complexity in terms of chemical bonding and compositions in a related class of compounds by introducing the smallest alkali metal cation, Li⁺. The first set of quaternary pnictides with formula Ba₄Li₂Cd₃Pn₆ (Pn = P, As, and Sb) feature 1-D infinite chains of [Cd₄Pn₁₀] super-tetrahedral clusters. These chains are connected through Pn₂-dumbbells into corrugated 2-D layers. The adamantane-shaped T₂ is a second member of the series of supertetrahedral T_n cluster (where n is the number of tetrahedra along each edge), which can be viewed as fragments of the cubic ZnS-type lattice. We will also note here that the Ba₄Li₂Cd₃Pn₆ structure appears to be first example of a connectivity mode based on the large [Cd₄Pn₁₀] adamantane-like clusters. The second fascinating feature of the structure is the one-dimensional chain made up of supertetrahedral clusters, connected to each other via common Pn vertexes. Such atomic packing with T₂ cluster makes these materials to be structurally related to a family of layered compounds including In- or Ga-sulfides or selenides. The present work represents a rare case and the first instance of ordered quaternary pnictides built upon adamantane-like clusters assembled into infinite chains. Our studies have helped open a new field with great opportunities for new discoveries.

Low-Temperature Chemical Routes to Functional Complex Oxide Nanocrystals

Institution: Southern California, University of
Point of Contact: Richard Brutchey
Email: brutchey@usc.edu
Principal Investigator: Richard Brutchey
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014-2017)

PROGRAM SCOPE

Despite over fifty years of developments in the field of materials chemistry, there are still only a limited number of ways to rationally and reproducibly synthesize inorganic materials – the majority of which require harsh reaction conditions. In 2004, a DOE-sponsored Grand Challenge workshop on Nanoscience Research for Energy Needs recommended “developing, understanding, and optimizing synthesis methods for . . . [the] production of nanomaterials” as being a vital nanoscience research theme for energy applications. As such, there is a need to develop general methodologies, using rational chemical design principles, for the synthesis of functional nanomaterials under bench-top conditions. This will enable a “materials by design” approach to be taken, in which new functional nanomaterials can be rationally synthesized for use in next-generation energy applications. To address challenges such as these, more robust and general strategies are needed for the synthesis of high quality complex oxide nanocrystals (with a focus on small size, well-defined composition, and controlled surface chemistry). While there has been a great deal of progress over the past 25 years in the synthesis of high quality II-VI and lead-salt IV-VI semiconductor nanocrystals, there has been much less success in the synthesis of nanocrystals of other materials families, such as complex metal oxide nanocrystals. We will execute basic research in the area of complex oxide nanocrystals that can ultimately impact energy applications with the following three objectives: (1) Leverage the PI’s vapor diffusion sol-gel method to synthesize more compositionally complex oxide nanocrystals. (2) Perform high-level structural characterization of the resulting complex oxide nanocrystals to establish structure-property relationships at the nanoscale. (3) Assess the functionality of the resulting complex oxide nanocrystals.

FY 2014 HIGHLIGHTS

The project start date was September 1, 2014. Thus far, we have successfully extended our vapor diffusion sol-gel method to synthesize well-defined scheelite AWO_4 nanocrystals (where $A = \text{Ca, Sr, Ba}$). Such materials are of interest as host materials for solid-state phosphors, anode materials for Li-ion batteries, and as scintillators. While these alkaline earth tungstates have been previously synthesized under benign conditions using precipitation methods, the resulting material is typically ill defined and microstructured. We can make well-defined nanocrystals under benign conditions (i.e., atmospheric pressure, 100 °C, pH 7), and demonstrated that the resulting sub-30 nm AWO_4 nanocrystals could be compositionally tuned by both facile isovalent and aliovalent substitution using this synthesis method. A thorough local structure study of the as-synthesized scheelite nanocrystals is currently underway using a combination of variable temperature Rietveld and pair distribution function X-ray analysis (APS, Argonne National Laboratory, 11-ID-B). These data are being used to investigate the effect of chemical substitution on the known orientational disorder in these systems in order to probe whether it is static or dynamic in nature.

New Superconducting Materials

Institution: Princeton University
Point of Contact: Robert J Cava
Email: rcava@princeton.edu
Principal Investigator: Robert J Cava
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$558,000 (2014-2017)

PROGRAM SCOPE

With the goal of discovering new superconductors, this program concentrates on the discovery and chemical, structural and electronic characterization of compounds in three chemical families: ThCr_2Si_2 -type pnictides, tungsten oxide bronzes, and intermetallic compounds with the half-Heusler crystal structure. As a result of previous DOE-sponsored research, the PI has previously found a variety of unusual structure-property relationships that arise in these phases due to the presence of a pnictogen dimer in their crystal structures – in effect, a molecule imbedded inside a metal. Now we are following these relationships for new groups of compounds. The tungsten oxide bronzes were among the first oxide superconductors discovered. They are unusual because they display superconductivity in non-perovskite oxide crystal structures with very low electron counts, with the electrons in orbitals that are derived from tungsten 5d states, which are therefore expected to be broad in energy and relatively uninteresting from an electronic perspective. The PI has developed an understanding of these potential superconductors that suggests that O-W-O bonding with angles other than 180 degrees in their crystal structures can lead to sharper than expected features in their electronic density of states and therefore greater potential for superconductivity. Finally, the half-Heusler crystal structure hosts relatively few superconductors but the ones that do form are very interesting from the perspective of condensed matter physics. We are currently performing a set of studies to try to determine how common superconductivity will be in compounds with this crystal structure, and the primary chemical requirements for the superconductivity when it does occur. All three of these families fall within the PI's general belief that new superconductors can best be found in chemical systems where the bonding cannot be considered as either fully ionic or fully covalent.

FY 2014 HIGHLIGHTS

The superconducting $M_x\text{WO}_3$ tungsten bronzes show several distinct crystal structures. They can have hexagonal bronze (HTB), tetragonal bronze (TTB-I), or perovskite-derived tetragonal (TTB-II) and cubic (CTB) structures. Although the HTBs have been well studied, a detailed investigation of the superconducting properties of the tetragonal tungsten bronze (TTB-I) system was lacking until our work. In the past, superconductivity in TTB-I bronzes was reported for Na_xWO_3 $0.2 < x < 0.5$, K_xWO_3 $0.4 < x < 0.57$ and $\text{Ba}_{0.13}\text{WO}_3$, but contradicting this, TTB-I $\text{K}_{0.58}\text{WO}_3$ has also been reported as a semiconductor. In the past year we completed a detailed study on the superconducting K_xWO_3 tetragonal tungsten bronze TTB-I phase. This was possible because we realized that such systems can be extremely sensitive to air and moisture exposure and thus we were able to make this study through very careful handling of the samples. Our experimental characterization was supplemented by electronic structure calculations. The calculations indicated that close to the HTB-TTB structural phase boundary, the Fermi Level in the TTB-I phase transitions through a van Hove singularity; the highest T_c in the tetragonal-I system corresponds to this doping level. This result falls in line with our other studies that have shown the maximization of superconductivity at a structural phase boundary. Finally, we presented a phase diagram for superconductivity across the full HTB, TTB-I, and CTB tungsten bronze family, which has not been previously possible. We found that the highest superconducting T_c is observed in general at the lowest electron doping level for the WO_3 framework globally (for all members of the family), and also at the lowest doping level for the HTB and TTB-I superconductors individually; it is almost independent of doping for the CTB. The new data that we have provided suggests that a modern theoretical treatment of all the compounds in this family of superconductors would be of interest.

Functionalization of Metal-Organic Frameworks - From Hydrogenase Biomimetics to Polymer Hybrids

Institution: California-San Diego, University of
Point of Contact: Seth Cohen
Email: scohen@ucsd.edu
Principal Investigator: Seth Cohen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$720,000 (2014-2017)

PROGRAM SCOPE

This continuing proposal in the area of Materials Chemistry describes the use of advanced synthetic methods to prepare functional metal-organic frameworks (MOFs). Many of the advanced synthetic methods that will be used to prepare functional MOFs were developed during the last funding period and have been widely adapted in the chemical community. This research program has also served to train a large number of graduate students and postdoctoral fellows, including several women and members of underrepresented groups. This continuing research program will develop new MOFs for both the production and storage of H_2 (Specific Aims 1-3). These efforts will focus on several innovative studies, all of which involve new chemistry and new materials. For H_2 production, the inclusion of functional, biomimetic hydrogenase models into MOFs will be developed (Specific Aim 1). Preliminary results show that these H_2 -producing catalysts are greatly stabilized within the matrix of a MOF. For H_2 storage, our efforts will focus on examining the MOFs containing metal-catecholato sites that have been theoretically predicted to meet 2017 DOE goals for deliverable H_2 capacity (Specific Aim 2), as well as fundamental studies on MOFs with self-organized aryl substituents that show enhancements in capacity and gating (i.e. hysteresis, Specific Aim 3). Finally, an additional topic of investigation will be on polymer-

MOF hybrid materials with emergent properties (Specific Aim 4). MOFs are being increasingly explored as templates for soft materials with a high degree of organization. Here we propose the use of 'polymeric ligands' that upon exposure to metal ions will form MOF or MOF-like porous domains. This concept is based on substantial preliminary results with crosslinked and oligomeric ligands that we have shown readily form MOFs. We will also explore these new ligands as a strategy to introduce a new class of coordinatively unsaturated metal centers into MOFs.

FY 2014 HIGHLIGHTS

Our work on the modification and functionalization of metal-organic frameworks (MOFs) in order to tune gas sorption and other physical properties of these materials has been very productive. On average, we have published more than one DOE-supported paper every-other month since the beginning of this grant. These publications have appeared in top-tier chemistry journals and many have been highlighted as 'hot articles' or 'top downloaded' articles by various journals. Some of our accomplishments include: Chem. Commun. 2013, 49, 3200-3202. The synthesis of canonical isoreticular metal-organic frameworks (IRMOFs) containing interligand crosslinks was reported. Chemically crosslinking two molecules of 2-amino-1,4-benzene dicarboxylic acid gave ligands that readily form IRMOF-1 analogs, producing crosslinked MOFs that may be designed to have novel properties. Inorg. Chem. 2014, 53, 7014-7019. A series of geometrically constrained, cross-linked benzene dicarboxylic acid (bdc) derivatives were synthesized and incorporated into the canonical isoreticular metal-organic framework (IRMOF) lattice. This work provided a new dimension to rational ligand design for metal-organic frameworks. Chem. Commun. 2014, 50, 12154-12157. The use of presynthetic and postsynthetic modification (PSM) approaches to regulate the structural organization of functional groups in the pores of isoreticular metal-organic frameworks (IRMOFs) was presented. It was found that the structural ordering of aryl groups within the IRMOF pores results in hysteretic hydrogen sorption, while the same aryl groups introduced in a disordered manner displays reversible hydrogen sorption that is more typical of the IRMOF family. Chem. Commun. 2014, 50, 5737-5740. 1,3,5-Tris(4-phosphonophenyl)benzene was synthesized via a microwave heating assisted route and used for the preparation of a new zirconium phosphonate with honeycomb-like structure displaying remarkable thermal stability and hydrolysis resistance.

EARLY CAREER: Electronic and Ionic Conductors from Ordered Microporous Materials

Institution: Massachusetts Institute of Technology
Point of Contact: Mircea Dinca
Email: mdinca@mit.edu
Principal Investigator: Mircea Dinca
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The proposed work aimed to establish metal-organic frameworks and covalent organic frameworks (MOFs and COFs) as new classes of high-surface area microporous electronic and ionic conductors. MOFs and COFs are crystalline materials with pore sizes ranging from 0.2 to ~ 2 nm (or larger for the latter) defined by inorganic or organic building blocks connected by rigid organic linkers. Myriad applications have been found or proposed for these materials, yet those that require electron transport or conductivity in combination with permanent porosity still lag behind because the vast majority of

known frameworks are electrical insulators. Prior to our proposal and subsequent work, there were virtually no studies exploring the possibility of electronic delocalization in these materials. Therefore, our primary goal was to understand and control, at a fundamental level, the electron and ion transport properties of this class of materials, with no specific application proposed, although myriad applications could be envisioned for high surface area conductors. Our goals directly addressed one of the DOE-identified Grand Challenges for Basic Energy Sciences: designing perfect atom and energy-efficient syntheses of revolutionary new forms of matter with tailored properties. Indeed, the proposed work is entirely synthetic in nature; owing to the molecular nature of the building blocks in MOFs and COFs, there is the possibility of unprecedented control over the structure and properties of solid crystalline matter. The goals also tangentially addressed the Grand Challenge of controlling materials processes at the level of electrons: the scope of our program is to create new materials where charges (electrons and/or ions) move according to predefined pathways.

FY 2014 HIGHLIGHTS

We have crystallized our approach towards conductive MOFs in three different formalisms: charge hopping (Marcusian transport), through-space conduction (π -stacking), and through-bond conduction (as in molecular wires). We have shown that charge hopping is responsible for charge transport in thick films of a MOF that is also electrochromic. In this context, we reported a zinc-naphthalenediimide MOF as the first material in this class that is electrochromic. This material exhibits fast switching under 60s and good coloration efficiency rivaling that of organic electrochromic polymers. In MOFs containing tetrathiafulvalene (TTF) infinite stacks, we showed that increasing the ionic radius of the constituent metal ion has the effect of pinching the inter-TTF distance, thereby causing an increase in electrical conductivity by almost three orders of magnitude. We have also demonstrated for the first time in this field metal-mediated ligand redox 'non-innocence'. Oxidation of Mn-MOF-74 (a material made from Mn^{2+} ions and 2,5-dioxidoterephthalate, DOBDC) with a Cl_2 analog (PhICl_2), resulted in transient oxidation of the Mn centers, followed by electron transfer to DOBDC. This was the first demonstration of ligand redox non-innocence in such a material, showing that the broad synthetic toolbox of molecular inorganic chemistry can be applied successfully to MOFs. Finally, by also using redox-active ligands such as hexaaminotriphenylene, we have synthesized a new material based on Ni and the imine form of the above ligand. The new material is permanently porous, and is the most conductive MOF made thus far, with a film van der Pauw (4 point probe) conductivity of 40 S/cm. This is in the same range as that of graphite and surpasses other materials in this class by nearly two orders of magnitude.

EARLY CAREER: Rational Design and Nanoscale Integration of Multi-Heterostructures as Highly Efficient Photocatalysts

Institution: California-Los Angeles, University of
Point of Contact: Xiangfeng Duan
Email: xduan@chem.ucla.edu
Principal Investigator: Xiangfeng Duan
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The central goal of this project is to rationally design and synthesize highly complex multi-hetero-nanostructures and fundamental investigation of their potential as efficient and robust photocatalysts.

Specifically, the research program aims to integrate a nanoscale semiconductor as the light harvesting antenna with two distinct redox nanocatalysts in a single multi-hetero-nanostructure, in which the photoexcitation of the semiconductor creates electron-hole pairs that are quickly separated and transported towards the integrated nanocatalysts to drive thermodynamically uphill reactions and convert solar energy into chemical energy on site. Systematic studies have been proposed to develop general strategies for the synthesis of integrated nanostructures, and to investigate their fundamental electronic, optical and photocatalytic properties. The specific scopes include: the design and synthesis of highly complex nanostructured semiconductors for efficient harvest of solar energy through a precise control of chemical composition, physical size and the multi-heterostructure interface; the investigation of their fundamental electronic, optoelectronic properties, and optimization of the material interface for efficient charge separation, transport and photon-to-electron conversion; the development of rational chemistry to integrate the semiconductor with effective redox nanocatalysts to facilitate the interface charge transfer in photocatalytic reactions; and the investigation of such multi-hetero-nanostructures as highly efficient photocatalysts in model photocatalytic reactions.

FY 2014 HIGHLIGHTS

In the past year, we have designed and synthesized a hybrid photocatalyst by enwrapping silicon nanowires (SiNWs) with reduced graphene oxide (rGO) nanosheets to achieve greatly enhanced photoactivity and superior photoelectrochemical stability. In this novel heterostructure, the SiNWs function as the light harvest antenna; the rGO can not only function as a physical protection layer to isolate the SiNWs from the harsh electrochemical environment for greatly improved photostability, but also as a charge mediator to facilitate the charge separation and transport processes, and as the redox catalysts to ensure efficient utilization of photo-carriers for the desired redox reactions. Additionally, by using an implantation approach to dope TiO₂ nanowires with nitrogen, we have achieved a significant enhancement of visible light photoactivity in TiO₂. We have conducted systematic investigations to demonstrate that the substitutional nitrogen plays an essential role in modifying the electronic structure, optical properties and photoelectrochemical behavior of TiO₂.

Molecular Magnets Based on a Modular Approach: Investigation of Coupling, Anisotropy and Electronic Factors on Bistability

Institution: Texas A&M University
Point of Contact: Kim Dunbar
Email: dunbar@mail.chem.tamu.edu
Principal Investigator: Kim Dunbar
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$720,000 (2014-2017)

PROGRAM SCOPE

This project is aimed at exploring the role of magnetic anisotropy in determining the properties of molecular magnets. In addition to continuing to probe the role of strong first-order spin-orbit coupling and anisotropic exchange interactions on the magnetic properties of paramagnetic molecules and assemblies that contain cyanide or reduced organocyanide bridging ligands, we are preparing new lanthanide and transition metal mononuclear Single Molecule Magnets (SMMs). The modular approach to designing homologous series of compounds has led to families of structurally related molecules with the same geometrical arrangement of spin centers; this approach continues to be exploited. Armed with

the successful elaboration of record magnetic coupling and blocking temperatures for cyanide-based SMMs, we are poised to further advance fundamental knowledge about how single-ion anisotropy profoundly manifests itself in terms of magnetic bistability. We continue to be interested in early transition metal ions from groups V and VI that have been very little explored or entirely unexplored in cyanide chemistry. We are also targeting families of mononuclear compounds of transition metal and lanthanide ions that display bistability in spite of the few number of spins that they possess, a topic that is growing quite rapidly in the literature. The concept of using organocyanide radicals as bridges for SMMs was not elaborated to any great extent in the previous grant period due to an emphasis on cyanide chemistry, but these studies are figuring prominently into this phase of the research.

FY 2014 HIGHLIGHTS

In the period since September 2014, we have made considerable progress towards the goals of the project and have submitted or have five papers published or in press. The highlights of our recent 2014 activities are as follows: Discovery of a tape-like chain based on the anisotropic building block hexacyanomanganate(III) which exhibits long-range magnetic ordering below 5.1 K as well as single chain magnetic behaviour at lower temperatures with an effective energy barrier of 40.5(7) K. An unusual feature of the magnetism is that single chain magnetic behavior in competition with long range ordering which is rare. Efforts to minimize the interchain interactions and extend this chain architecture to other cyanide building blocks are underway. The elucidation of a mononuclear trigonal bipyramidal Co(II) complex with easy-plane anisotropy that displays Single Molecule Magnet Behavior. A comparison with other previously reported Co(II) complexes with TBP coordination environments revealed that relatively minor structural changes can lead to distinct differences in the magnetic properties. Theoretical calculations to aid in determining what factors may be responsible for these differences are currently underway. Another major finding is a new erbium SMM that exhibits slow relaxation of the magnetization under zero dc field with $\Delta E_{\text{eff}}/k_B = 66.4$ K and magnetic hysteresis up to 3 K. This work helps in the refinement of the theory that oblate or prolate lanthanides must be stabilized with the appropriate ligand framework to maximize axial anisotropy in order for SMM behavior to be favored. A spin-crossover Co(II) cation in conjunction with partially charged organocyanide radicals led to the observation of a spin-transition-induced anomaly in the semiconducting behavior of a salt of Co-tris(terpy). The synergistic interactions between the semiconducting organic radical stacks and SCO properties are a consequence of structural variations with temperature.

Small Gas Storage and Selective Carbon Dioxide Capture by Nanoporous Organic Polymers

Institution: Virginia Commonwealth University
Point of Contact: Hani El-Kaderi
Email: helkaderi@vcu.edu
Principal Investigator: Hani El-Kaderi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

Our research targets the synthesis of porous organic polymers (POPs) that have adjustable pore size, surface area, and chemical composition for use in gas separation and storage applications. Of particular interest to our research goals is the use of N-rich POPs in selective carbon dioxide (CO₂) capture from gas mixtures such as flue, natural, and landfill gases because of the greenhouse nature of CO₂. CO₂

Capture and sequestration (CCS) from fossil fuels burning is essential for stabilizing CO₂ concentration in the atmosphere until affordable and efficient carbon-free energy sources become widely accessible. The current technology for CCS employs aqueous amine solutions to chemically trap CO₂ in the form of carbamate. In spite of its effectiveness, such adsorbents suffer many drawbacks including solvent decomposition and evaporation, toxicity, and corrosiveness in addition to the large energy penalty needed for solvent regeneration. Among the promising materials for CO₂ capture from flue gas and methane-rich gases are nitrogen-functionalized porous materials such as organic polymers, organic-inorganic hybrid materials, and porous carbons. Integrating nitrogen Lewis basic sites into the frameworks of porous organic polymers is essential for attaining high CO₂ uptake and selectivity over other gases present in gas mixtures. Several synthetic routes for N-functionalized organic polymers were evaluated wherein the basicity of the N-sites can be modified. Both pre-synthesis and post-synthesis modification methods of porous organic polymers endow polymers with enhanced CO₂ uptake and selective capture properties. Upon polymers synthesis and characterization, their performance in gas separation and storage can be evaluated using gas sorption measurements. The structure-function relationship of the polymers can be further assessed using first-principles theory, which can predict gas interaction sites and binding affinities.

FY 2014 HIGHLIGHTS

We have demonstrated the use of pyrene- and triazine-based benzimidazole-linked polymers (BILPs) in CO₂ removal from flue and methane-rich gases. The implication of different physical properties (pore size and surface area) on selective CO₂ uptake or separation from N₂ and CH₄ under pressure swing adsorption (PSA) and vacuum swing adsorption (VSA) were investigated. The Ideal Adsorbed Solutions Theory (IAST) data show that BILPs exhibit high CO₂/N₂ selectivity values. Furthermore, the optimal porosity and CO₂ enthalpy of adsorption render highly porous BILPs very efficient in landfill and natural gas separation by PSA. On the other hand, polymers that have moderate porosities and higher CO₂ binding affinities are better fit for flue gas separation by VSA. Interestingly, the diverse physical properties of BILPs and their N-rich pores place them among the top performing materials for landfill gas and flue gas separation by VSA and PSA. We used a synergistic experimental and theoretical study (DFT) to highlight the impact of material design at the molecular and electronic levels on the binding affinity and interaction sites of CO₂ with BILPs. DFT calculations indicate that CO₂ is stabilized by benzimidazole units through Lewis acid-base (N...CO₂) and aryl C-H...O=C=O interactions. We also reported the synthesis of azo-linked polymers (ALPs) that have high surface area and high CO₂ uptake at room temperature. Azo-linkage formation (-N=N-) was catalyzed by Cu(I) to link triptycene and other 3D organic building units to construct highly porous organic polymers having high N-functionality. In addition to their high CO₂ uptake, ALPs display very good selectivity toward CO₂ over CH₄ and N₂. However, their selectivity levels remain below those of BILPs. Our study indicated that the use of azo-linkage in porous organic polymers could provide physicochemically stable materials for gas separation applications.

Pore Space Engineering and Functionalization in Porous Metal-Organic Framework Materials

Institution: California-Riverside, University of
Point of Contact: Pingyun Feng
Email: pingyun.feng@ucr.edu
Principal Investigator: Pingyun Feng
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$185,000 (2013-2014)

PROGRAM SCOPE

The proposed research seeks to develop innovative and transformative synthetic concepts and methods for creating crystalline porous metal-organic framework (MOF) materials. The aim is to integrate novel architectural and chemical features for high-performance gas-sorption-based and other energy related applications. The project combines synthesis with structural and topological analysis to design materials with advanced properties. Different properties are evaluated to establish composition-structure-property correlation that can be further utilized to refine the materials design strategy. A key innovative feature of this project is its novel architectural design strategy. To efficiently harness the pore space, the project seeks to develop a new architectural design strategy called pore space engineering and partitioning, for example, through nested cage-within-cage architecture to partition the pore space into multiple smaller functionalized and size-optimized domains. This design strategy has the advantage of creating suitable pore sizes commensurate with the size of gas molecules to enhance solid-gas interactions. A versatile synthetic strategy is to use the mixed-ligand system in which properties of two ligands are complementary with one type of ligand serving as the framework-forming ligand and the other type of ligand serving as pore-space-partitioning ligand. A related strategy is to use the mixed-metal system in which two different metal types play roles of the framework formation and pore-space-partitioning separately. These two strategies can be combined to allow exquisite control over the architectural and chemical features. Such materials hold great promise for applications requiring high-capacity gas uptake, especially at or near ambient conditions.

FY 2014 HIGHLIGHTS

Prior to this study, MOFs with the highest CO₂ uptake capacity were those equipped with open metal sites. During this funding period, alternative strategies and mechanisms have been successfully developed for creating high-performance CO₂ adsorbents. Through a ligand insertion pore space partition strategy, crystalline porous materials (CPMs) with superior CO₂ uptake capacity have been synthesized. Specifically, a new material, CPM-33-Ni without any open metal sites, has been designed and it has the exceptional CO₂ uptake capacity comparable to the best performing MOF-74 with the same metal at 298 K and 1 bar. The use of MOFs for other energy-related applications was also explored. One useful property found in this funding period is the use of pre-designed MOFs for creating non-precious-metal oxygen reduction catalysts (ORR) with the potential to replace high-cost Pt-based catalysts in fuel-cell technologies. By pyrolysis of such MOFs with uniquely distributed metal sites, nitrogen-doped carbons embedded with different metallic (for example, cobalt) nanoparticles were obtained. The synthesized materials showed high electrocatalytic activity comparable to the commercial Pt/C catalyst, but with better durability and methanol-tolerance performance in alkaline conditions. In addition, a general method capable of converting neutral frameworks into cationic ones with concurrent generation of mobile anions has been developed. This method is based on differential affinity between different metal ions and anions attached to the framework metal sites. Specifically, Al³⁺ was used to strip F⁻ anions away from framework Cr³⁺ sites, leading to cationic frameworks with mobile Cl⁻ anions. The subsequent anion exchange with OH⁻ led to a porous network with mobile OH⁻ anions. New materials prepared by anion stripping showed much improved ionic conductivity. This new materials design method represents a novel approach for developing solid electrolytes for energy applications.

EARLY CAREER: Atomically Defined Edge-Doping of Graphene Nanoribbons for Mesoscale Electronics

Institution: California-Berkeley, University of
Point of Contact: Felix Fischer
Email: ffischer@berkeley.edu
Principal Investigator: Felix Fischer
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The outstanding transformative potential of graphene, an infinite two-dimensional sheet of carbon atoms tightly packed into a honeycomb lattice, has been recognized mostly due to its exceptionally high charge carrier mobility, thermal conductivity, and tensile strength. These undeniably very desirable properties, however, represent only a very small facet of the true potential of all- sp^2 carbon materials and its promise to revolutionize the field of molecular electronics. Graphene's most unusual characteristics can be observed when the infinite two dimensional sheet is scaled down to nanometer dimensions. The central objective of this research is to develop the technology and the tools required to synthesize and to fine-tune the properties of atomically defined graphene nanoribbons (GNR) with a particular focus on controlling the absolute dimensions (length, width), the symmetry, and the edge-substitution pattern of mesoscale carbon materials. Specific goals of this project are: To develop a complementary set of bottom-up strategies toward atomically defined GNRs from small molecule building blocks, to tune the intrinsic band gap of semiconducting GNRs by controlled edge-doping, to devise a strategy to fabricate segmented GNRs featuring heterojunction architectures, and to identify mesoscale structure-performance relationships.

FY 2014 HIGHLIGHTS

We have developed three new families of molecular building blocks for the fabrication of atomically defined GNRs from small molecule precursors on solid supports and in solution. We expanded the substrate scope for a surface catalyzed bottom-up synthesis of semiconducting armchair GNRs (AGNRs) on Au(111) surfaces. Chemical modification of a common building block gives access to 7-, 13- and 17- armchair GNRs featuring atomically smooth edge-structures varying in width between 0.7 and 2.0 nm. UHV STM imaging confirms the predicted molecular structure while dI/dV spectroscopy gives direct access to the band gap of the resulting GNRs. We have been able to perform the simultaneous copolymerization of two distinctive molecular building blocks on surfaces. The co-deposition of a precursor for 7-AGNRs and 13-AGNRs yields structures featuring a random alternating pattern of wide and narrow GNR segments. The interphase between 7-AGNRs and 13-AGNRs represents the first demonstration of the rational synthesis of a functional Type I heterojunction within an individual graphene nanoribbon. Current efforts are dedicated to explore the performance of these heterojunction devices in tunneling transistor architectures. Furthermore we explored polymer-based strategies to control the assembly of block copolymers as precursors for segmented GNRs. Living ring-opening metathesis provides access to linear poly(phenylene ethynylene) that can be converted into a polyphenylene precursor for armchair graphene nanoribbons using post polymerization benzannulation techniques. This polymeric precursor can be oxidized either in solution or on a substrate to yield the extended GNR. The inherent advantage of this technique is that the living polymerization enables the absolute control over the length and the segmentation of the GNR.

EARLY CAREER: Chemical Frustration: A Design Principle for the Discovery of New Complex Alloy and Intermetallic Phases

Institution: Wisconsin-Madison, University of
Point of Contact: Daniel Fredrickson
Email: danny@chem.wisc.edu
Principal Investigator: Daniel Fredrickson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 3 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Intermetallic phases represent a broad class of solid state compounds with an immense structural diversity. A limiting factor in developing materials based on the valuable physical properties exhibited by intermetallics (which can include superconductivity, thermoelectric effects, and a range of magnetic phenomena) is the difficulty of predicting or controlling their crystal structures. An emerging theme that provides an avenue toward such control is a link between structural complexity and the coexistence of competing bonding or packing types, a conflict we refer to as chemical frustration. In this project, we aim to develop the concept of chemical frustration into a predictive framework for the discovery of new complex intermetallic phases and guiding aspects of the structures of these phases. To achieve this goal, we are pursuing three main research objectives: (1) the synthesis and characterization of new complex intermetallics in systems designed to exhibit chemical frustration, (2) the creation of theoretical tools for analyzing chemically frustrated phases, and (3) the merging of our experimental and theoretical insights into guidelines for the synthesis of new phases. In our synthetic work, our strategy to induce frustration is to create ternary combinations of metallic elements such that incompatibilities arise between the preferred bonding modes of the binary subsystems. Ternary phases forming in these systems must then reconcile these conflicts, with microscopic phase segregation being one likely result. Our theoretical work is focused on developing tools for analyzing how spatial segregation in electronic features accompanies chemical frustration. One approach here is the fitting of Hückel models to DFT results and the analysis of these models with the Method of Moments, a technique which provides a direct link between local geometrical features and aspects of the electronic density of states.

FY 2014 HIGHLIGHTS

One hallmark of chemical frustration in intermetallics is the spatial segregation of differing interaction types within a crystal structure. Here we highlight two instances of this segregation that we studied during FY 2014. In our theoretical investigations of complex structures appearing on the Sc-rich side of the Sc-Ir phase diagram, we found that the stability of the phases could be understood in terms of our recently developed μ_3 acidity model. Sc metal is a strong μ_3 acid, while Ir is a moderate μ_3 base. For Sc-rich compositions, then, the majority Sc atoms are faced with the challenge of achieving neutralization with only a relatively small number of Ir atoms. The solution to this issue is found in dividing the structure into domains of two different packing types: tetrahedral close packed (TCP), where the average interaction strength is relatively strong, and simple close packed (SCP), where the average interaction strength is weaker. The Sc atoms create icosahedra around the Ir atoms, forming TCP units to maximize Sc-Ir interactions. The Sc-Sc contacts outside of these icosahedra are arranged to create octahedra, units found in SCP arrangements, so that the interference of Sc-Sc interactions in the neutralization process is reduced. Our second example is the structure of Ta_4Ga_5 , a phase we synthesized that exhibits a new binary structure type. While in binary phases, heteroatomic interactions

are generally considered to provide the dominant impetus for phase formation, in this phase substantial homoatomic clustering is observed in both the Ta and Ga sublattices. Our electronic structure analysis revealed that this clustering emerges from the drive of the Ta atoms to achieve 18 electron configurations with only a small number of electrons. Ta-Ta clustering allows covalent sharing of electrons, with the Ga atoms then being positioned to the outskirts of the clusters to preferentially stabilize Ta-Ta bonding functions over antibonding ones.

Towards Molecular Engineering of Polymer Glasses

Institution: Chicago, University of
Point of Contact: Karl Freed
Email: freed@uchicago.edu
Principal Investigator: Karl Freed
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

Glass-formation has been central to fabrication technologies since the dawn of civilization. An understanding of polymer glass-formation is essential to design advanced glassy materials with applications in high resolution photoresists, electronics, non-linear optics, nano-imprint patterning (for memory storage and device fabrication), organic photovoltaics and plastic crystals (for batteries), polymer films (as coatings and templates), and in energy storage, generation and power conversion where polymeric glasses are structural entities. The huge variations of 14 orders of magnitude in the viscosity, structural relaxation time and other dynamical properties over rather narrow temperature ranges are universal properties of glass-formation are common to both small molecule and polymeric glass-formers and impede theoretical progress. Despite the fundamental nature of glass-formation and the regularities observed in this process, a generally accepted theoretical description of this ubiquitous and conceptually vexing form of matter remains elusive. The present project seeks to rectify this deficiency by extending and applying our theory that explains the universal characteristics of glass-formation and the dependence of the physical properties of polymer glass-formers on molecular structure, molecular weight, pressure, temperature, etc. The focus of the present project is to extend our generalized entropy theory of glass formation a) to describe the combined influence of chain stiffness and cohesive energy on the glass transition temperature and the fragility, the two quantities that determine whether the material can be processed by extrusion, casting, ink jet, etc., b) to extend this treatment to describe the influence of polar side groups on the properties of polymer glass-formers, and c) to extend the theory to treat polymer melts and explain the molecular factors governing the appearance of two structural relaxation times in partially miscible polymer blends.

FY 2014 HIGHLIGHTS

Despite the long-recognized fact that chemical structure and specific interactions greatly influence the thermodynamic properties of polymer systems, a predictive molecular theory that enables systematically addressing the role of chemical structure and specific interactions has been slow to develop even for polymer melts. Our analysis of the combined impact of the microscopic cohesive energy and chain stiffness on the magnitudes of the fragility parameter and the glass transition temperature of polymer glass-formers predict that polymers with rigid structures and weak nearest neighbor interactions are the most fragile, while the glass transition temperature becomes larger when

the chains are stiffer and/or nearest neighbor interactions are stronger. The work leads to the identification of some important design concepts, such as iso-fragility lines where several thermodynamic properties are found to remain invariant. We have introduced a major extension of our theory to describe the dependence of the fragility and glass transition temperature of polymer melts upon the presence of polar groups in the chain side groups in order to provide guidance for the control of glass properties by modification of the polar groups. Computations based on this theory are currently in progress. Most technological polymer materials are mixtures, called blends, of different polymers chosen to achieve desired properties. Thus, we have begun the extension of our generalized entropy theory to describing the perplexing appearance of two structural relaxation times in the one phase region of partially miscible blends where a single relaxation time is expected. The theory successfully explains this phenomenon and why the relaxation of the one phase system behaves like a composite material.

Cathode Catalysis in Hydrogen/Oxygen Fuel Cells: New Catalysts, Mechanism, and Characterization

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Andrew Gewirth
Email: agewirth@illinois.edu
Principal Investigator: Andrew Gewirth
Sr. Investigator(s): Paul Kenis; Illinois-Urbana Champaign, University of
Ralph Nuzzo; Illinois-Urbana Champaign, University of
Thomas Rauchfuss; Illinois-Urbana Champaign, University of
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$350,000 (2014)

PROGRAM SCOPE

In this project, we are engaged in a comprehensive plan of research directed at developing new catalysts and new understandings relevant to the operation of low temperature hydrogen-oxygen fuel cells. The focal point of this work is one centered on the Oxygen Reduction Reaction (ORR), the electrochemical process that most fundamentally limits the technological utility of these environmentally benign energy conversion devices. It is therefore to the single greatest challenge limiting wide-spread implementation of hydrogen-oxygen fuel cells -- providing robust low cost cathodes that efficiently reduce dioxygen to water -- that we address the work described in this project. Utilizing support from this project, we developed a new class of ORR catalysts, based on Cu dimers and multimers. These new materials exhibit ORR onsets at potentials higher than any other Cu-based material in neutral and basic environments and are inspired by the three-Cu active site in laccase which has the highest ORR onset potential of any material known. Over the last grant period, we synthesized a series of Cu trimers, and interrogated their activity. Based on these results, we will focus our efforts going forward on further synthetic and characterization of different Cu trimers. A feature of the program will evaluate the stability of these supported catalysts and develop methods to enhance catalyst survival on the electrode. Insight from characterization activities will inform synthetic efforts.

FY 2014 HIGHLIGHTS

In 2014 we showed that we could measure the stress-thickness of a Pt surface with and without the presence of O₂. In the presence of O₂, the stress-thickness curve is displaced in a more compressive direction over the entire potential window interrogated, which shows that the Pt surface dynamically responds to the presence of O₂ by Pt-Pt bond elongation. Interestingly, the stress calculated from EXAFS-

derived Pt-Pt bond length changes match very well with those from the corroborating surface stress measurements. This is a new method to examine strains arising from electrochemical reactivity as a consequence of adsorbate association with the electrode. We also designed a robust, active, dinuclear Cu oxygen reduction reaction (ORR) catalyst embedded inside a hybrid bilayer membrane (HBM) system. We demonstrated that proton delivery to the catalyst through the lipid layer can be controlled through the use of an alkyl phosphate proton carrier. Specifically, we showed that we could use the HBM to switch the ORR on and off, a so-called 'pcet switch', by changing the ability of the proton delivery agent to transport protons through the lipid layer. We further used the HBM as an electrochemical platform to study anion diffusion through a lipid monolayer. Our results demonstrate that anion transport in a HBM is best described by the solubility-diffusion mechanism, not the pore mechanism. We envision this approach can be used ultimately to acquire unique mechanistic insight into PCET reactions, including the rate of O–O bond cleavage of the bound oxygen species. We also examined the temperature dependence of the ORR in a high pressure, high temperature reactor, showing that (as expected) increasing the temperature leads to increased ORR rates.

Low-Temp Synthesis of Carbide-Derived Carbons from Binary and Ternary Carbides in the Si-Ti-C Systems

Institution: Drexel University
Point of Contact: Yury Gogotsi
Email: gogotsi@drexel.edu
Principal Investigator: Yury Gogotsi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$240,000 (2013-2014)

PROGRAM SCOPE

Carbide-derived-carbons (CDCs) are a growing class of nanostructured carbon materials with properties that are desirable for many applications. The scope of the current project is to gain a fundamental understanding of CDC formation at room temperature through electrochemical etching. The major research tasks were: 1. Room-temperature electrochemical etching of binary (e.g. SiC and TiC) and ternary carbides (e.g. Ti₃AlC₂ and Ti₃SiC₂ MAX phases) to produce CDCs; 2. Parameter study of CDC formation conditions, such as different etching electrolytes, electrochemical conditions, types of the starting carbides, etc.; 3. Characterization of structure and properties of CDCs produced by electrochemical etching; 4. Characterization of electrochemical properties of the as-produced materials. The current project was expected to produce new carbon materials with unique structures, pore networks and surface chemistry using an energy efficient method. Furthermore, we also expected to explore the possibility of selective etching of metal atoms from ternary carbides for synthesis of novel two dimensional carbide structures.

FY 2014 HIGHLIGHTS

A summary of the accomplishments is listed as follows: (1) Room-temperature synthesis of CDC film from binary carbide SiC [1]: The selective extraction of Si from SiC was achieved by electrochemical etching with hydrofluoric acid (HF) in different organic solvents. The role of polarity, surface tension, density, and viscosity of the organic solvents was investigated. Formation of ordered carbon on the surface of etched SiC was confirmed. (2) Room-temperature synthesis of CDCs from ternary carbide - the MAX phases [2]: We succeeded in selective extraction of metal atoms from the ternary layered carbides, Ti₃AlC₂, Ti₂AlC and Ti₃SiC₂ (MAX phases) at ambient temperature. The result is a predominantly

amorphous CDC with a narrow distribution of micropores around 0.5 nm. This process can be achieved by placing the carbides in HF, HCl or NaCl solutions and applying anodic potentials. The etching kinetics for Ti_3AlC_2 in HF was quantified. (3) Room-temperature synthesis of carbon/sulfur nanolaminates from the MAX phase Ti_2SC [3]: We achieved, for the first time, the selective extraction of the M element (Ti) from the Ti_2SC MAX phase to form carbon/sulfur, C/S, nanolaminates at room temperature by electrochemical etching. Covalent bonding between C and S is observed, which renders these nanolaminates promising candidates as electrode materials for Li-S batteries. It is also possible to extract Ti from other MAX phases, such as Ti_3AlC_2 , Ti_3SnC_2 , and Ti_2GeC , suggesting that electrochemical etching is a general method for selectively extraction of the 'M' elements from the MAX phases, to produce a new family of materials - 'AX' layered structures. The latter in turn hold promise for a variety of applications, such as energy storage, catalysis, etc. References: [1] Senthilnathana J, *et al.* Synthesis of Carbon Films by Electrochemical Etching of SiC with Hydrofluoric Acid in Nonaqueous Solvents, *Carbon*, 2014, 71, 181-189. Materials and Interfacial Chemistry for Next-Generation Electrical Energy Storage

Institution: Texas-Austin, University of
Point of Contact: John Goodenough
Email: jgoodenough@mail.utexas.edu
Principal Investigator: John Goodenough
Sr. Investigator(s): Arumugam Manthiram; Texas-Austin, University of
Students: 14 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$700,000 (2014)

The Oak Ridge National Laboratory part of this project is listed separately under Principal Investigator: Sheng Dai.

PROGRAM SCOPE

Electrochemical energy storage systems are critically needed for electric vehicles and for effective use of renewable energy sources. Cost, cycle life, safety, energy, and power density are all parameters that depend critically not only on the materials used and their morphologies for the different battery components, but also on their compatibility with one another and, therefore, on the chemistries at their interfaces. Factors influencing cost include the materials and fabrication costs, cycle and calendar life, and the management requirements for safety and life of a battery consisting of many cells. The present-day battery technologies fall short of the requirements for electric vehicles and stationary grid storage. Alternative strategies must consider ways to increase safely the voltage and capacity of the individual cell without compromising rates of working-ion transfer between the anode and the cathode. Can new strategies allow the use of metallic Li or Na anodes and liquid flow-through or air cathodes in place of insertion compound hosts? If not, can alloy anodes be tailored to permit a fast charge at minimum cost in cell voltage and in irreversible capacity loss on first charge? Can multiple-electron redox couples be used? This project addresses several of such key material questions associated with both alternative battery strategies and the stretching of present strategies. The program of work involves intuitive design of new materials based on basic chemistry/physics principles, novel chemical synthesis approaches, and

advanced *ex situ* and *in situ* characterization in order to establish an understanding of how to optimize the basic structure-composition-property relationships. The basic understanding gained through the proposed program of work is critical for realizing next-generation electrical energy storage systems with long life at an affordable cost, alleviating our dependence on foreign oil and CO₂ emissions.

FY 2014 HIGHLIGHTS

The project focused on the following aspects this year: (1) new composite porous-polymer/oxide membranes as separators that block dendrites from an alkali-metal anode, (2) low-cost electrocatalysts and novel cell configurations for hybrid lithium-air batteries, (3) carbon-coated separators for lithium-sulfur batteries, (4) high-voltage cathodes for lithium-ion batteries, (5) new cathodes for sodium-ion batteries, and (6) nanocomposite alloy anodes for lithium-ion and sodium-ion batteries. We have developed low-cost porous-polymer/oxide composites saturated with the conventional organic liquid-carbonate electrolyte that act as flexible and mechanically robust separators and block anode dendrites. We have developed low-cost nitrogen- and oxygen-doped carbons for the oxygen reduction reaction and low-cost nickel cobalt oxide catalysts grown on nickel-metal foam for the oxygen evolution reaction; these catalysts in a decoupled cell configuration exhibit performance and durability superior to conventional noble-metal catalysts. We have also developed a low-temperature form of lithium cobalt oxide as a bifunctional catalyst. A thin layer of microporous carbon coated onto a polymer separator traps the dissolved polysulfides and improves significantly the cycle life of lithium-sulfur cells. We have explored doping and heat treatment to stabilize the high-voltage lithium manganese nickel oxide spinel cathode against reaction with the electrolyte. An insertion compound for the cathode of a sodium-ion battery is normally either a layered compound or has a framework structure containing a polyanion. We have investigated vanadium fluorophosphate cathodes for a sodium-ion battery. With an aim to realize fast charge with both lithium-ion and sodium-ion batteries, we have explored a number of nanocomposite alloy anodes consisting of intermetallic active components such as FeSb and an inactive component such as TiC or aluminum oxide, which exhibit life over 500 cycles.

Cyclometalation Syntheses of Phosphorescent Complexes

Institution: Case Western Reserve University
Point of Contact: Thomas Gray
Email: txg37@case.edu
Principal Investigator: Thomas Gray
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2013-2014)

PROGRAM SCOPE

This award in Basic Energy Sciences supports fundamental research in organometallic materials. Specific targets are organometallic complexes that act as light-emitting elements in electroluminescent devices. Transmetalation reactions from boron precursors are being developed as synthetic methods leading to cyclometalates that, by design, are phosphorescent. Reaction of ligand precursors bearing boronic acids or boronate esters with metal complexes and a supporting base leads to metal-carbon bond formation, possibly coupled to closure of a chelate ring. The new method is mild and high-yielding; redox side-reactions are avoided. Metals of immediate importance include iridium, copper, platinum, and gold. New families of complexes are sought through boron transmetalation methods, and new compounds are characterized by ground state and optical methods.

FY 2014 HIGHLIGHTS

A new synthetic method for gold-carbon bond formation that relies on arylboronic acids, a supporting base, and palladium catalysis was published. Cyclometalated gold(III) chloride complexes react as electrophiles in palladium-mediated Suzuki-Miyaura coupling reactions. Both mono- and diarylation reactions have been demonstrated. The first aryl to bind gold does so opposite nitrogen; the shorter (and presumably stronger) gold-chloride bond is sacrificed first. An arylation mechanism was proposed where oxidative addition of the Au-Cl bond to palladium is coupled to a rearrangement that yields the thermodynamically stable mono-aryl. The new complexes are triplet-state lumophores. The first fluoride-bridged cyclometalated iridium(III) dimers have been identified as high-efficiency lumophores, some with quantum yields exceeding 50%. Emission lifetimes are microsecond-length at room temperature, and emission profiles show vibronic structure indicating ligand dominance of the light-emitting state(s). One such complex has been crystallographically characterized. Static and time-dependent density-functional theory calculations indicate that phosphorescence originates from perturbed ligand-centered states.

Solid State Electronic Structure and Properties of Neutral Carbon-Based Radicals

Institution: California-Riverside, University of
Point of Contact: Robert Haddon
Email: robert.haddon@ucr.edu
Principal Investigator: Robert Haddon
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$242,000 (2014)

PROGRAM SCOPE

The goal of our work is the synthesis and characterization of a new class of organic molecular metals and superconductors based on neutral carbon-based spin = ½ radicals. Our current molecular family of choice is the spiro-bis(phenalenyl)boron radicals, and they remain the only class of neutral carbon-based radicals that may be crystallized and studied in the solid state without requiring bulky substituents to inhibit σ -dimerization.

FY 2014 HIGHLIGHTS

Substitutional doping is an extremely important industrial process, most notably in the semiconductor industry where crystalline silicon is doped with atoms from neighboring columns of the periodic table such as boron or nitrogen to create holes or electrons in the lattice, thereby modulating the carrier concentration and the electrical properties. Such an approach has never been successfully applied to organic molecular solids. By making use of a spiro-bis(phenalenyl)boron radical we have been able to grow substitutionally doped organic crystals directly from solution in which the carrier concentration is systematically varied by the introduction of dopant molecules into the lattice which differ only by the replacement of boron with beryllium. The method depends on the use of a host lattice composed of spiro-bis(phenalenyl)boron radicals, and by co-crystallization from solutions of spiro-bis(9-oxidophenalenone)boron radical $[\text{PLY}(\text{O},\text{O})]_2\text{B}$ mixed with select amounts of spiro-bis(9-oxidophenalenone)beryllium $[\text{PLY}(\text{O},\text{O})]_2\text{Be}$ we are able to isolate a series of solid state solutions of composition $[\text{PLY}(\text{O},\text{O})]_2\text{B}_{(1-x)}\text{Be}_x$. The dopant molecules $[\text{PLY}(\text{O},\text{O})]_2\text{Be}$ serve to introduce holes into the lattice of spins provided by the $[\text{PLY}(\text{O},\text{O})]_2\text{B}$ radicals and lead to a systematic increase in the

conductivity while decreasing the activation energy of the conduction process and leaving the solid state structure relatively unperturbed. While the energies of the hole sites are expected to be high, the results are consistent with the interpretation of the electronic structure of $[\text{PLY}(\text{O},\text{O})]_2\text{B}$ in terms of the resonating valence bond (RVB) model.

EARLY CAREER: Crystallization-Driven Assembly of Conjugated-Polymer-Based Nanostructures

Institution: Massachusetts, University of
Point of Contact: Ryan Hayward
Email: rhayward@mail.pse.umass.edu
Principal Investigator: Ryan Hayward
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project focuses on harnessing solution-state crystallization of conjugated polymers to construct well-defined crystalline building blocks that will facilitate fabrication of optoelectronic devices, especially photovoltaic cells, in scalable and cost-effective ways. We seek to provide transformative impacts on the control of organization, and therefore the electronic properties, of matter on three different length-scales: 1) the molecular scale, in the sense of achieving highly crystalline semiconducting polymer-based materials capable of efficient charge transport, 2) the nanoscale, in terms of positioning n- and p-type materials with domain sizes comparable to exciton diffusion lengths (~ 10 nm) to facilitate charge separation, and 3) the colloidal scale, such that well-defined crystalline nanoscale building blocks can be hierarchically organized into device layers with optimal structures. The project relates to the mission of the DOE Basic Energy Sciences program, which seeks to “...understand, predict, and ultimately control matter and energy at the electronic, atomic, and molecular levels...”² and the Materials Chemistry program’s goals of supporting “new chemical means to direct and control the non-covalent assembly of materials, such as strategies to organize electron donors and acceptors”² and “to control and design interfaces between dissimilar materials”.

FY 2014 HIGHLIGHTS

During FY 2014, the project has led to major advances in three areas: 1) tailored growth of acceptor nanowires using conjugated polymer additives; 2) controlled nucleation of conjugated polymer nanofibers; 3) enhanced stability and functionalization of conjugated polymer nanofibers. First, we found that polythiophenes serve as crystal modifiers during growth of perylene diimide (PDI) crystals, providing great flexibility for tailoring PDI crystal size and morphology. Adsorption of poly(3-hexyl thiophene) (P3HT) to PDI crystals slows their growth and promotes formation of high aspect-ratio nanowires. Coupled with ultrasound to facilitate crystal nucleation, this yields PDI nanowires with highly uniform lateral dimensions down to 20 – 30 nm. Short PDI nanowires can be extended, leading to well-controlled nanowire lengths and branched crystal architectures. Second, we have established that graphene surfaces can be used as highly selective nucleating agents for growth of P3HT crystals from metastable solutions. Under conditions where homogeneous nucleation of P3HT is very slow, but the equilibrium degree of crystallinity is high, nanofibers grow selectively on multilayer graphene or highly oriented pyrolytic graphite. These results provide a useful platform for further fundamental studies of crystal growth, and a possible route toward solution processed, vertically oriented semiconducting polymer nanofibers. Finally, using a copolymer of P3HT and a polythiophene bearing an azide group, we

have demonstrated robust and easily functionalized polymer nanofibers. Remarkably, the azide group is incorporated at molar ratios of up to 0.2 without disrupting the solution crystallization of the polymers, or their charge-transport properties. Subsequent photo-crosslinking renders the fibers stable against solvent and temperature treatments, while the presence of excess azides allows for 'click' functionalization, for example to yield dispersion in polar solvents including water.

Optical Spectroscopy and Scanning Tunneling Microscopy Studies of Molecular Adsorbates and Anisotropic Ultrathin Films

Institution: California-Irvine, University of
Point of Contact: John Hemminger
Email: jchemmin@uci.edu
Principal Investigator: John Hemminger
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$534,000 (2014-2017)

PROGRAM SCOPE

The emphasis of our research is to develop sufficient fundamental understanding to allow the controlled preparation of nano-, and meso-structured surfaces with novel optical properties and chemical reactivity. The research places an emphasis on the synthesis of, sometimes complex, surface structures under conditions that allow for detailed control and understanding of the composition and structure and the subsequent relationship to properties and chemical reactivity. In this research we combine the use of optical probes with surface imaging experiments (electron microscopy (SEM, TEM), and variable temperature ultra high vacuum scanning tunneling microscopy (STM)). These experiments are combined with UHV surface spectroscopies (High Resolution Electron Energy Loss Vibrational Spectroscopy (HREELS), Auger electron spectroscopy (AES), x-ray photoelectron spectroscopy (XPS) and thermal desorption spectroscopy (TDS)). We use a combination of STM and SEM/TEM to study the growth of mesoscopically ordered nanometer sized metal and metal oxide structures on well defined substrates such as highly ordered pyrolytic graphite (HOPG). We will continue to develop methods (e.g. photoelectrochemical deposition) to decorate nanometer scale metal oxide structures with transition metal nanoparticles generating Nanoparticles on Nanoscale substrate materials (NpNs). The electronic structure and chemical properties of these new structures will be studied and contrasted with those of the more conventional nanoparticles on macroscopic substrate materials.

FY 2014 HIGHLIGHTS

During the 2014 fiscal year we have (1) completed a scanning tunneling microscopy study of the dehydrogenation of mono-olefins on aluminum oxide films that are decorated with Pt nanoparticles. Our experiments demonstrate that while small Pt nanoparticles on alumina are active for the dehydrogenation of mono-olefins this does not lead to carbon particle formation on the Pt nanoparticles as happens on macroscopic Pt surfaces. Rather at high temperatures spill-over from the Pt onto the alumina occurs. Carbon that spills onto the alumina does not form graphite even at high temperature, rather carbon clusters are formed at the grain boundaries of the alumina film, (2) developed methods simple methods for the preparation of a high density of iron oxide nanoparticles on highly oriented pyrolytic graphite and characterized these iron oxide nanoparticles using SEM, TEM, and synchrotron based x-ray photoelectron spectroscopy and x-ray absorption spectroscopy, (3) developed

photoelectrochemical deposition methods to deposit Pt nanoparticles on the high density of iron oxide nanoparticles, and (4) studied the catalytic activity of the Pt decorated iron oxide nanoparticles.

Relationships Between the Adhesion, Friction and Nano/Micro-Structure of Materials, Surfaces and Films

Institution: California-Santa Barbara, University of
Point of Contact: Jacob Israelachvili
Email: jacob@engineering.ucsb.edu
Principal Investigator: Jacob Israelachvili
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$846,000 (2014-2017)

PROGRAM SCOPE

There are two main focus areas, I and II, which are divided into 4 sub-projects. The two focus areas are: I Continue to apply recently developed, and develop new, experimental techniques based on the Surface Forces Apparatus (SFA) to measure and characterize complex dynamic molecular interaction potentials and force-laws between various surfaces in air or liquids at the atomic (sub-nano) level to gain fundamental understandings of adhesion, friction, lubrication and wear (damage) to surfaces of 'engineering interest'. These are not ideal-atomically smooth surfaces, which are now well understood, but rough or micro- or nano-structured (patterned, textured) surfaces; and in particular investigate the dynamics, i.e., the roles of rate, time, and previous history on these highly non-equilibrium interactions. Develop equations/models for the adhesion, friction and wear for such surfaces, similar to what is currently available for smooth, homogeneous surfaces and materials. II Correlate chemistry with the measured (physical) interaction forces by further developing and applying new experimental techniques for measuring the above and other types of interactions (see below) while simultaneously measuring and controlling the voltages and currents between or flowing through the solid-liquid interfaces, including any dissolution/adsorption, to establish the (electro)chemical reactions going on at each interface. The liquid films between the two surfaces can be aqueous (water based) or non-aqueous (e.g., oils, lubricant fluids, ionic liquids). The 4 sub-projects: The two focus areas are divided into 4 distinct sub-projects: (1) Adhesion, friction and wear; (2) self-sealing/self-healing interfaces; (3) new experimental techniques for electrochemical studies using both conducting and non-conducting surfaces; and (4) physical and electrical properties of non-aqueous liquids (ionic liquids, liquid crystals) in thin films, for energy storage and imaging applications.

FY 2014 HIGHLIGHTS

(1) Adhesion, friction and wear/damage: We have measured the adhesion, friction and wear of randomly rough and patterned surfaces, both 'dry' and 'lubricated', and developed a Johnson-Kendall-Roberts (JKR)-type model in terms of effective stiffness and adhesion energy parameters that quantitatively described their 'adhesion/contact mechanics' and friction behavior. We also found that, in general, damage is not directly related to the friction coefficient but to the existence of 'stiction' and/or stick-slip', rather than smooth, sliding. These findings should enable the design of surfaces and lubricant fluids to avoid costly material damage of working surfaces. (2) Self-sealing interfaces: We have synthesized and processed a new class of polymer materials that on being cut expose multiple H-bonding groups that readily reseal on bringing the surfaces back together, even in aqueous solutions. Such materials are important for both biomedical and non-biological applications. New experimental

techniques for electrochemical studies: We further developed the electrochemical (EC-SFA) allowing direct quantitative (model-independent) simultaneous measurements of physical interaction forces and chemical reactions in liquids in real time, and have applied this to a number of phenomena, including surface dissolution, identification of reacting species, corrosion, etc. – see below. (3) Molecular properties of non-aqueous liquids in thin films using the EC-SFA: Our new results on ionic liquids show that with increasing temperature the concentration of excess ‘free’ (conducting) ions increases. This work validates a previous model and is relevant for energy storage devices such as batteries. We also measured the molecular forces while imaging electric-field induced structuring and flow of confined liquid crystal molecules, opening up new methods in liquid crystals research. Award: The PI was awarded the 2013-14 Tribology Gold Medal – “the world’s highest honor in tribology”.

EARLY CAREER: Theory and Simulations of Tailored Assembly in Rod-Coil Polymer Nanocomposites

Institution: Colorado, University of
Point of Contact: Arthi Jayaraman
Email: arthi.jayaraman@colorado.edu
Principal Investigator: Arthi Jayaraman
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The focus of the proposed research is to use molecular simulations to link molecular features of conjugated polymers (electron donors) and fullerene derivatives or hybrid nanoparticles (electron acceptors) to the morphology of the polymer nanocomposite. We have developed and validated appropriately detailed coarse-grained models to capture the experimentally relevant length and time scales in our simulation. We have then made predictions that serve as design rules on how changing each molecular feature would allow one to tailor the composite morphology.

FY 2014 HIGHLIGHTS

Since October 1 2013 to September 30 2014 we have published 8 peer-reviewed papers in journals including Macromolecules, ACS Macroletters, and Soft Matter. PI Jayaraman has given 9 invited talks (including talks at AIChE, ACS and XPV meetings and department seminars) where DOE supported results were presented. Jayaraman's students also presented posters and talks at APS march meeting, AIChE annual meeting, MRS fall meeting and XPV (excitonic photovoltaic) meeting. Student Ms. Hilary Marsh won Best Research Poster award for her DOE supported work at the XPV meeting.

Fundamental Studies of Charge Transfer in Nanoscale Heterostructures of Earth-Abundant Semiconductors for Solar Energy Conversion

Institution: Wisconsin-Madison, University of
Point of Contact: Song Jin
Email: jin@chem.wisc.edu
Principal Investigator: Song Jin
Sr. Investigator(s): John Wright; Wisconsin-Madison, University of
Robert Hamers; Wisconsin-Madison, University of
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 1 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

We create new earth-abundant semiconductor nanostructures and their heterojunctions with well-defined surface chemistry and develop new laser spectroscopies and atomic force microscopy integrated with ultrafast spectroscopy that probe charge transport at the quantum mechanical level in nanoscale heterostructures. They provide the fundamental understanding required to enable transformative coherent solar energy nanotechnologies.

FY 2014 HIGHLIGHTS

We discovered that chemical exfoliation of nanostructures of MoS_2 , WS_2 , and other layered MX_2 materials and the simultaneously conversion of the MX_2 material from its semiconducting 2H to the metallic 1T polymorph result in dramatically enhanced electrocatalytic activity for hydrogen evolution reaction (HER). Structural characterization and electrochemical studies confirm that the metallic MX_2 nanosheets exhibit facile electrode kinetics, low-loss electrical transport, and possess a proliferated density of catalytic active sites, which made these metallic 1T- MX_2 nanosheets highly competitive earth-abundant HER catalysts. Furthermore, 1T- MoS_2 nanosheets have been coupled to p-type silicon to enable highly efficient solar-driven hydrogen evolution due to the excellent HER activity of 1T- MoS_2 and the high-quality catalyst-semiconductor interface. We have also developed vertical heterostructures of MX_2 materials enabled by van der Waals epitaxy. MoS_2 , WS_2 , and WSe_2 layers were grown uniformly onto microplates of SnS_2 via mild CVD growth and the heteroepitaxy was unequivocally characterized. New photoluminescence properties emerge due to electronic coupling and charge separation between MoS_2 and SnS_2 . We have further expanded the nanoscale heterostructures to QDs linked with MoS_2 nanosheets. The charge transfers across the heterostructures could be important for enabling heterojunction solar conversion devices. We have used multiresonant coherent multidimensional spectroscopy to probe the dynamics of the electronic states in MoS_2 . The coherent and incoherent dynamics of the substructure of states within the A and B excitons of MoS_2 have been revealed. The narrow anti-diagonal width represents the excitonic homogeneous width resulting from coherence dephasing and the diagonal width represents the inhomogeneous width determined by the different environments. The population dynamics that appear at longer negative delay times show how energy flows between states.

Bi-Continuous Multi-Component Nanocrystal Superlattices for Solar Energy Conversion

Institution: Pennsylvania, University of
Point of Contact: Cherie Kagan
Email: kagan@seas.upenn.edu
Principal Investigator: Cherie Kagan
Sr. Investigator(s): Christopher Murray; Pennsylvania, University of
James Kikkawa; Pennsylvania, University of
Nader Engheta; Pennsylvania, University of
Students: 1 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$760,000 (2014)

PROGRAM SCOPE

Our program explores three-dimensional multi-component nanocrystal (NC) superlattices, wherein combinations of NCs self-assemble into well-defined, crystalline architectures. We focus on crystal

structures having bi-continuous NC sub-lattices and identify n- and p-type semiconductor building blocks that form Type-II energy offsets to drive charge separation onto electron and hole transporting sub-lattices and provide wide coverage of the solar spectrum. We aim to discover the design rules and optimize the architectures of bi-continuous, multi-component NC superlattices to efficiently convert solar radiation into electricity. Our interdisciplinary team combines NC synthesis, assembly, and structural characterization with optical spectroscopy, electrical measurements, and modeling of nanoscale materials to uncover the physical phenomena that govern the flow of energy and the transfer and transport of charge important in converting solar energy into electricity.

FY 2014 HIGHLIGHTS

We demonstrated the deposition of ordered, polycrystalline nanocrystal (NC) superlattices over large, 4" wafer scales via dipcoating of NCs. This method extends to the assembly of several bi-continuous, binary NC superlattices including AlB_2 , NaZn_{13} , CaCu_5 and MnZn_2 structures. We combined grazing-incidence and transmission small-angle x-ray diffraction with electron microscopy studies to characterize ordered NC superlattices. X-ray mapping enabled us to statistically characterize the grain size, orientation, uniformity, strain or crystal projections and polymorphs to complement real-space imaging of the superlattices. Building on our previous work demonstrating high-mobility, extended-state transport in NC assemblies, we used optical spectroscopies and electrical measurements to probe the transition from localized to extended-state transport as we engineer NC coupling via ligand exchange and carrier type and concentration via doping. In CdSe NC assemblies, we used low-temperature ultrafast spectroscopies to show that the ligand exchange and annealing, which yields enhanced interparticle coupling, is consistent with faster surface state electron trapping. Gate-controlled, low-temperature resistance and magnetotransport measurements on indium-doped CdSe NC thin films indicates that the gate induces electron accumulation and increases the localization product (localization length times dielectric constant) describing transport. Our measurements suggest the gate bias delocalizes electrons beyond the NC diameter, consistent with a decrease in the mobility gap to an insulator-metal transition. In PbS and PbSe NC assemblies we showed that the polarity and magnitude of transport depends on the contact metallurgy, the strength of NC coupling, and the surface passivation and doping. With increased coupling and doping, we observe an insulator-metal transition and fabricate high-performance n-type and p-type transistors, from which we demonstrate complementary NC circuits.

Molecular Designed Localized Static Charging for Energy Efficiency in Organic Electronics

Institution: Johns Hopkins University
Point of Contact: Howard Katz
Email: hekatz@jhu.edu
Principal Investigator: Howard Katz
Sr. Investigator(s): Daniel Reich; Johns Hopkins University
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$275,000 (2014)

PROGRAM SCOPE

The goal of this project is to synthesize charged dielectric heterostructures and evaluate their effects on adjacent and overlying organic semiconductors. The dielectrics are predominantly polystyrenes with different capabilities to accept and stabilize implanted static charge designed therein. These polymers are synthesized by a combination of chain, controlled radical, and postfunctionalization methods. The use of these static charges to control mirror charges in organic semiconductors will increase the

efficiency of organic semiconductor devices in both transistor and diode structures and also enable improved mechanisms for energy conversions, such as from electricity to light. New organic semiconducting polymers are synthesized to be compatible with the dielectric heterostructures. The heterostructures, in both vertical and lateral geometries, are characterized by morphological methods such as atomic force microscopy, scanning Kelvin probe microscopy, x-ray reflectivity, XPS/Auger depth profiling, and neutron scattering, as well as electronic methods such as determination of transistor characteristics, capacitance-voltage, thermally stimulated discharge, and charge extraction in a linearly-increasing voltage (CELIV) method. Poisson's equation modulation of voltage profiles gives charge densities as a function of distance from semiconductor interfaces.

FY 2014 HIGHLIGHTS

Polystyrenes with strong donor or acceptor side chains, as well as controlled crosslinking functional group densities, have been synthesized. Polystyrene heterostructures with different functional groups have been made. The fidelity of heterostructure formation was characterized by x-ray reflectivity and neutron scattering, from which scattering length densities and interfacial roughnesses could be calculated. Transistors using these polystyrenes as gate insulator materials have been demonstrated, including current modulations arising from charging of the polystyrene layers. Use of the heterostructures in gate materials is in progress. Lateral organic field-effect transistors (OFETs), consisting of a polystyrene (PS) polymer gate material and a pentacene organic semiconductor (OSC), were electrically polarized from bias stress during operation or in a separate charging step, and investigated with scanning Kelvin probe microscopy (SKPM) and current-voltage determinations. The charge storage inside the polymer was indicated, without any alteration of the OFET, as a surface voltage with SKPM, and correlated to a threshold voltage (V_T) shift in the transistor operation. The SKPM method allows the gate material/OSC interface of the OFET to be visualized and the surface voltage variation between the two gate material interfaces to be mapped. The charge distribution for three samples derived from the surface voltage maps using Poisson's equation agreed with those derived from the V_T shifts and the lateral gate-OSC capacitance. This is the first demonstration that surface voltage on a working OFET gate material can be related to the quantity of static charge responsible for bias stress and nonvolatility in OFETs.

Unconventional Clathrates Based on Transition Metal Pnictides: A Paradigm-Shifting Approach to Materials with Enhanced Thermoelectric Properties

Institution: California-Davis, University of
Point of Contact: Kirill Kovnir
Email: kkovnir@ucdavis.edu
Principal Investigator: Kirill Kovnir
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Thermoelectrics convert heat into electric energy and vice versa and as such are promising materials for waste heat reduction or recovery. The development of novel materials where charge and heat transport are partially de-coupled is a key factor for the next generation of thermoelectrics. If significant breakthroughs in the area of thermoelectrics materials are to be achieved, new classes of bulk materials need to be discovered. This project seeks to develop a new class of bulk thermoelectric materials with

record-breaking characteristics. Materials where charge and heat transport are de-coupled will be found among semiconducting Zintl clathrates with a host-guest type of structure. In the crystal structure, guest cations are encapsulated within the oversized polyhedral cages of a 3D host framework. In this project we seek new thermoelectric clathrate and clathrate-like materials with frameworks comprised of the late transition metals and pnictogens, group 15 elements, P, As, or Sb. The rattling of guest cations situated in the framework cages provide effective scattering of heat carrying phonons while the host framework is responsible for charge carriers transport. Extensive metrology will be used to characterize the crystal and electronic structures of the new compounds. The thermoelectric properties of novel clathrate phases will be studied in a wide temperature range for cooling and waste heat conversion applications.

FY 2014 HIGHLIGHTS

We continued searching for new thermoelectric materials, optimized the syntheses of previously discovered phases, and adjusted the charge carrier concentrations. We have successfully synthesized several clathrates with M-P frameworks, M = Cu and Ni. These compounds exhibit the known clathrate-I framework topology as well as a novel clathrate topology due to the high flexibility of the local coordination of M and P atoms. The charge carrier concentrations in the new phases were adjusted by means of aliovalent substitutions. For example, the clathrate $\text{Ba}_8\text{Cu}_{16}\text{P}_{30}$ exhibits metallic resistivity with holes as the main charge carriers. The charge carrier concentration can be regulated by substitution of Zn for Cu. We investigated the solid solution $\text{Ba}_8\text{Zn}_x\text{Cu}_{16-x}\text{P}_{30}$. The incorporation of Zn atoms resulted in significant structural rearrangements in the framework. For materials with $x=2$ crystallize in the cubic substructure where each framework position is jointly occupied by Zn, Cu, and P atoms. Zn and Cu are neighbors in the periodic system and cannot be distinguished by means of X-ray diffraction techniques. To determine the exact distribution of these elements across the clathrate framework, we collected high-resolution time-of-flight neutron powder diffraction data on representative samples. Analysis of neutron diffraction data indicates that in the cubic disordered phase, Cu and Zn are uniformly distributed over the framework positions. We also performed a search for clathrate-like compounds containing rare-earth cations. Several new phases in the La-Cu-P and La-Zn-P systems have been synthesized and structurally characterized. Both the Cu-P and Zn-P frameworks are very flexible and are able to accommodate different amounts of La cations. In all of the compounds produced, the coordination number of La is typically 14-18, which is smaller than in conventional clathrates.

Biaxiality in Nematic and Smectic Liquid Crystals

Institution: Kent State University
Point of Contact: Satyendra Kumar
Email: skumar@kent.edu
Principal Investigator: Satyendra Kumar
Sr. Investigator(s): Mohan Srinivasarao; Georgia Institute of Technology
Quan Li; Kent State University
Alejandro Rey; McGill University
Dena Agra-Kooijman; Kent State University
Students: 4 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$350,000 (2014)

PROGRAM SCOPE

The project's goal is to understand the phenomena of biaxiality and its origin in nematic (N) and smectic liquid crystals (LCs). Known and newly synthesized compounds will be investigated to establish the role of molecular structure and symmetry in the formation of stable biaxial LC phases. A team of five interdisciplinary researchers are probing the biaxiality in the nematic and smectic phases using micro-Raman spectroscopy, x-ray scattering, fluorescence confocal polarizing microscopy, and dielectric permittivity augmented by *ab initio* density functional theory simulations. Specific objectives of the project are: (1) Synthesis of New LC Materials: An important component of the project is the synthesis of (a) bent-core molecules having (i) 5- and 6-membered rings and different terminal/linkage groups, (ii) a chiral center, and (iii) terminal groups replaced with calamitic moiety to form the biaxial phases, and (b) the calamitic mesogens with different aromatic cores and the ratio of siloxane/fluoroalkyl to hydrocarbon segment lengths. DFT simulations will be used to design/improve the molecular structures and stability to obtain the desired properties. (2) Phase Diagrams and Physical Properties: Phase diagrams of new compounds will be determined to test the theoretical predictions, e.g., existence of the Landau point, phase boundary between the isotropic, the uniaxial, and the biaxial phases, and the precise molecular organization; orientational and positional orders in the phases of interest. (3) Biaxial Order and Defect Textures: The uniaxial and biaxial order parameters and the effect of biaxiality on elastic constants and viscosities of LC phases, statics and dynamics of topological defects in both the uniaxial and biaxial N phases will be measured. The project will significantly advance our ability to predictively design mesogens with desired phases and physical properties.

FY 2014 HIGHLIGHTS

- A total of twenty new mesogens ranging from bent-core, hybrid, to calamitic were synthesized to understand the molecular features that give rise to unique phases such as the twist bend nematic and smectic phases with minimal layer shrinkage in the SmC phase.
- Bent-Core analogs of the calamitic mesogens with similar terminal groups were synthesized and found to form the corresponding de Vries smectic and heliconical twist-bend nematic. This result strongly suggests the terminal groups' chemical properties are most important in the formation of these phases.
- Orientational order parameters, molecular distribution function, defects, and dynamics were investigated followed by molecular dynamic simulation using density functional theory with tight binding. Our results provided significant insight into the structure and defect dynamics of de Vries smectic, chromonic, and elastomer main chain liquid crystals.
- A new technique, differential dynamic microscopy, was developed and applied to measure viscoelastic properties of the nematic phase in several systems.
- The project activities led to the publication/submission of 18 peer-reviewed papers, eight plenary/invited presentations at international professional meetings, and nine contributed conference presentations.

Symmetry Breaking for the Synthesis of Nanostructured Porous Materials

Institution: Michigan, University of
Point of Contact: Adam Matzger
Email: matzger@umich.edu
Principal Investigator: Adam Matzger
Sr. Investigator(s): Antek Wong-Foy; Michigan, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$244,000 (2013-2014)

PROGRAM SCOPE

The overarching theme of this program is to develop, understand, and deploy new methods for sorbent synthesis. Porous solids are a ubiquitous class used in chemical manufacturing, water purification, and environmental remediation. Many of these applications are highly energy intensive and the development of better sorbents holds the potential to reduce the energy expended in a process while lowering overall cost. In addition, the development of new high performance sorbents is critical for emerging technologies such as hydrogen/methane storage and carbon dioxide capture. The particular class of sorbents that form the basis of this program are microporous coordination polymers (MCPs). Built from organic and inorganic components, the potential exists to combine the best attributes of established materials such as zeolites and carbons. Nonetheless there have been challenges associated with deploying these materials commercially. The basic science this program strives to understand and control is the self-assembly events that lead to MCP formation. This is a particularly attractive area to exploit because a given set of components can assemble in different arrangements to yield properties that differ vastly. By controlling assembly more nimbly, targeted properties can be optimized. The specific methods to be employed as control elements are spatio-temporal manipulation through a networked reactor system and polymer-induced heteronucleation; these methods have met with considerable success in several other materials synthesis problems but remain almost unexplored in MCP synthesis. In a second major aspect of the project, methodology for the assembly of organic polymers on the outer surfaces of MCPs will be developed and deployed. This is a potentially general approach for making MCPs better suited for large scale use in gas storage, separations, and catalysis by manipulating properties ranging from the mechanical stability to kinetic selectivity for gas sorption.

FY 2014 HIGHLIGHTS

Formation of MCPs by existing synthetic methods relies on secondary building unit (SBU) assembling with organic linkers. The SBU assembles dynamically whereas the linker is relatively static. However, if the ligand structure can change, then competition among assembly of different ligand structures as well as different SBUs has the potential to lead to new structures. We demonstrate this concept using the linker 4-amino-4',4'',4'''-benzene-1,3,5-triyl-tribenzoic acid where the central benzene ring preferentially reacts with terephthalaldehyde and show that formation of different MCPs is achieved by the timed addition of a second reagent. Different addition times yield 2 different phases that are permanently porous: phase I (Surface Area by BET (SABET) = 2820 m²/g) at early delay times and phase II (SABET = 4631 m²/g) at the later stages of addition. Phase I consists of octahedral Zn₄O(O₂CR)₆ SBUs linked together by two amine modified 1,3,5-Tris(4-carboxyphenyl)benzene (BTB) linkers condensed with a single terephthalaldehyde residue via imine linkages whereas phase II is amino functionalized MOF-177. Open space in MCPs is the key to their sorptive properties but also limits aspects of their performance. If pores are too large they offer only a weak attractive potential for gases and residual void space after sorption leads to poor volumetric sorption capacity. To highlight this we have modified naphthalene-2,6-dicarboxylate (NDC), to produce 4-t-butylethynyl-2,6-naphthalenedicarboxylate (tBuNDC) or 4-phenylethynyl-2,6-naphthalenedicarboxylate (PhNDC). The tbutylethynyl or phenylethynyl functional groups occupy part of the pore and serve as additional adsorptive surfaces. Moreover, these functional groups prevent the cubic structure from self-interpenetration. This tuning allows the excess volumetric uptake of methane at room temperature to be increased by as much as 25% compared to the unfunctionalized parent MCP.

Synthesis of Molecule/Polymer Based Magnetic Materials

Institution: Utah, University of
Point of Contact: Joel Miller
Email: jsmiller@chem.utah.edu
Principal Investigator: Joel Miller
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$237,000 (2014)

PROGRAM SCOPE

New discovery of new materials exhibiting the technologically important property of bulk magnetic ordering as well as those combining magnetism with other technologically important properties (e.g. electrical, optical, and mechanical) is the research focus that is based on the design/synthesis/characterization/exploitation of organic-based magnets (OBMs) using Earth abundant elements. These materials are crucial for future electronic/-photonic devices, especially due to the need to replace rare earth critical materials with Earth-abundant elements, and for reduced energy consumption and environmentally friendlier processing and disposal. We are expanding the $M^{II}(TCNE)_{3/2}I_{3/2}$ (TCNE = tetracyanoethylene) by replacing the anion with triflate by a new post-synthetic modification, as well as making new high T_c V-based magnets via a different route using new iodide-based V(II) compounds. The controlled formation of high T_c $V(II)_x(V(III)_{1-x})[Cr(CN)_6]$ as a function of x are sought via the preparation and controlled use of high purity V(II) and V(III) sulfates. Co-based TCNE magnets have been elusive, with most attempts forming only paramagnetic materials. Nonetheless, we have succeeded in preparing an example with a 66 K T_c , which is being studied.

FY 2014 HIGHLIGHTS

Among several results, the most intriguing is the formation of a Co-based TCNE complex that has a T_c of 66 K that is much higher than any other related Co material - the detailed identification of the composition and magnetic behavior is in progress. Also, albeit not a main-stream project we made $[NMe_4]_2[TCNE]_2$ that exhibits a new type of long (3.04 Å) multicenter CC bond. It has nominal C_2 symmetry and 12 sub-van der Waals interatomic contacts <3.3 Å, and differs for the more common eclipsed D_{2h} π -[TCNE] $_{22}$ - dimer possessing a 2e-/4c bond as it has a 2e-/6c bond. It has diamagnetic ground state with a thermally populated triplet excited state 1400 cm^{-1} above the ground state.

Ion Association for Materials Development

Institution: Oregon State University
Point of Contact: May Nyman
Email: May.Nyman@oregonstate.edu
Principal Investigator: May Nyman
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

This project on one level is directed towards advancing polyoxometalate (POM) chemistries, of group V and open-shell transition metals. More broadly, we seek to understand the relationship between

aqueous phase cation-anion association, the solubility behavior of POM salts, and exploiting cation-anion association to stabilize and capture elusive POM compositions and geometries. The POMs of this study provide a unique opportunity due to anomalous solubility behavior. That is, conditions of maximum ion-association correlate with highest solubility. Foundationally, we endeavor to provide a more global understanding of solubility and ion-association in aqueous media, beyond POM chemistry. This work will impact design of materials obtained from aqueous media by exploiting counterion association: both POM-based materials and other metal oxide materials. In addition to synthesis, major experimental techniques include X-ray scattering, multi-nuclear and multi-dimensional NMR, and conductivity. Since the Nb and Ta POMs featured in this study present a solubility trend with their counterions that provides highest solubility where ion-pairing is most prevalent (opposite trend to the tungstates and molybdates), we have an ideal and unique situation to probe the aqueous phase characteristics that define solubility as it relates to ion-association. As part of this inquiry, we are expanding the system of mixed niobate-tungstate POMs to create a series which spans the end-member solubility behaviors to pinpoint reversal in behavior. These series ranging from normal to anomalous solubility behavior will also be explored by thermodynamics of dissolution and computational studies. More broadly, we endeavor to provide guidelines to universally predict solubility behavior and ion-association of any cation-anion assembly in water. The open-shell transition metals have thus far eluded substantial development, and new insights will be gained through understanding counterion effects.

FY 2014 HIGHLIGHTS

Major highlights include 1) understanding differences between aqueous tantalate and niobate clusters, based on their counterion-association behavior in water, 2) detailed characterization of cesium hexaniobate, the workhorse of these studies, and 3) a significant advancement in iron-oxo cluster chemistry. These are discussed briefly below. [1] In a recent publication, (Contrasting ion-association Behaviour of Ta and Nb polyoxometalates Fullmer *et al*, Dalton Transactions, 43(41), 15295, 2014) we present a detailed X-ray scattering study that provides an understanding as to the difference between the chemistry of Nb and Ta in water, based on the behavior of their counterion association. More broadly, this study delineated the relationship between acid-base and counterion behaviors of metal oxides in water. [2] Cs hexaniobate is the POM cluster-salt with the highest solubility and highest counterion-association, and thus has been the focus of many early studies on this project. We have carried out both aqueous and molten salt thermochemistry on Cs, K and Li hexaniobate. The aqueous thermochemistry revealed a much greater concentration dependence on enthalpy of dissolution, which indicated dissolution without complete dissociation is prevalent. This in turn suggests the key to anomalous solubility lies in close association of counterion-cluster, even when dissolved in water. [3] We have isolated the iron-Keggin ion from water, a cluster considered the molecular building block of iron oxide materials such as ferrihydrite. This specie is a long-sought synthon of geochemists, but has never been captured due to its high reactivity in water. We were able to isolate it by first recognizing that the iron Keggin-ion is a highly-charged polyoxoanion rather than the presumed polyoxocation, and by providing equally highly-charged countercations. This manuscript, 'Capture and manipulation of the elusive iron-oxo Keggin ion in water', is currently in review in Science.

EARLY CAREER: Elucidating the Determinants of Alkali Ionic Conductivity in Oxide and Sulfide Frameworks

Institution: California-San Diego, University of
Point of Contact: Shyue Ping Ong
Email: ongsp@eng.ucsd.edu
Principal Investigator: Shyue Ping Ong

Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

The facile conduction of alkali ions in oxide and sulfide host structures is of critical importance in energy storage. Today, the dominant form of energy storage in portable electronics, and increasingly in automotive applications, is the rechargeable alkali-ion battery, a device that functions entirely on the basis of the reversible transport of alkali ions. The Li^+/Na^+ conductivity of a cathode (typically a transition metal oxide) has a direct influence on the rate capability of a Li/Na-ion battery. Alkali conductivity is arguably of even greater importance in the solid oxide and sulfide electrolytes currently being investigated for high safety, all-solid-state batteries, where the diffusion length scales are significantly larger than in the electrodes. This project will elucidate the structural and chemical factors determining alkali conductivity in oxide and sulfide frameworks using large-scale first principles calculations and topological analysis. We will approach this problem through a series of detailed investigations into prototypical structures and chemistries, as well as a broader study carried out over a large number of materials using data mining techniques. The ambition of this project is to go beyond mere screening of materials and acquire the insights necessary to achieve true “reverse design” capability to build high alkali conductivity structures from constituent anion frameworks, cation chemistry, and topology design.

FY 2014 HIGHLIGHTS

The focus of FY 2014 has been on the development of the necessary software infrastructure and scientific methodologies to support automated computational investigations of alkali conductivity in materials. For this effort, we have adopted known high conductivity superionic conductors, such as the $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$ material, as test structures. Computations of the conductivity of such fast conductors converge fairly rapidly, and they therefore useful for testing of infrastructure and methods. A robust computational framework has been developed to enable the efficient conduct of automated weeks-long AIMD simulations using resources with limited wall-times, and is currently applied to the study of several cathode and electrolyte chemistries.

EARLY CAREER: Measuring the Importance of Valence to Chemistry of Nanocrystal Surfaces

Institution: Columbia University
Point of Contact: Jonathan Owen
Email: jso2115@columbia.edu
Principal Investigator: Jonathan Owen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal of this project is to understand and control the interplay between nanocrystal stoichiometry, surface ligand binding and exchange, and the optoelectronic properties of semiconductor nanocrystals in solution and in thin solid films. We are pursuing three research directions with this goal in mind: 1) We aim to characterize nanocrystal nonstoichiometry and its influence on the number of L-type and X-type binding sites, the thermodynamics of ligand binding, and the kinetics and mechanisms of ligand

exchange. 2) We aim to develop a quantitative understanding of the relationship between surface ligand passivation and photoluminescence quantum yield. 3) We aim to develop methods to replace the organic ligands on the nanocrystal with halide ligands and controllably deposit these nanocrystals into thin films. Electrical measurements on these films will make it possible to evaluate the effect of the nonstoichiometric ligand layer on surface passivation and internanocrystal electronic coupling.

FY 2014 HIGHLIGHTS

We recently discovered a new surface passivation mechanism that involves the reversible binding of metal complexes to the nanocrystals surface. Using nuclear magnetic resonance spectroscopy we demonstrated that metal carboxylate and metal halide complexes reversibly bind to nanocrystal surfaces. A dramatic relationship between the photoluminescence quantum yield and the coverage of the metal ion complexes was observed. This is one of the first quantitative measures of the relationship between ligand coverage and photoluminescence quantum yield. A second highlight comes from nanocrystal thin films prepared using a carboxylate for halide ligand exchange procedure developed in earlier years of the project. Halide terminated cadmium selenide nanocrystal inks were cast from solution and annealed to eliminate weakly bound organic ligands and obtain conductive thin films. Field effect transistor measurements demonstrated record high electron mobilities. Grazing incidence X-ray scattering measurements and electron microscopy allowed us to correlate the nanocrystalline structure to the transport characteristics and unambiguously demonstrated that high mobilities can be obtained within a nanocrystalline film.

Activation of Hydrogen under Ambient Conditions and Unusual Element Hydride Reactivity by Main Group Molecules

Institution: California-Davis, University of
Point of Contact: Philip Power
Email: pppower@ucdavis.edu
Principal Investigator: Philip Power
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2013-2014)

PROGRAM SCOPE

The main theme of this project is the investigation of the reactions of small, important molecules such as hydrogen, olefins, alkanes, amines, isocyanides, carbon monoxide, carbon dioxide, and related species, with main group element compounds. The reactivity of the compounds arises from the presence of both occupied and unoccupied frontier orbitals, which are separated by modest energies of four electron volts or less. The reactions generally occur by a synergic route that involves a push-pull redistribution of electron density that facilitates bond making and breaking. The conditions for reaction reversibility are determined by the energy and symmetry of the molecular energy levels in the compounds, which can be manipulated by changing the electronic and steric properties of the substituents. In principle, the information from these studies can be used to design inexpensive catalysts for fundamental organometallic reactions based on earth-abundant elements, rather than on rare and expensive noble metals. The major focus is on compounds of the elements silicon and aluminum, which are the second and third most abundant elements in the earth's crust. Unfortunately, there are few stable low-coordinate silicon and aluminum compounds with suitable frontier orbital properties for reversible small molecule binding. A program is underway to synthesize low-valent and/or multiple-

bonded derivatives of these elements with a range of different substituents. The synthesis and reactivity of small molecular clusters of these elements with reactive exposed atoms is also being investigated. In the clusters, the coordination of their constituent elements can resemble that of the surfaces of the pure elements, which generally possess highly reactive surface atoms that interact readily with small molecules. The clusters also offer multiple coordination sites for synergistic reactions.

FY 2014 HIGHLIGHTS

Over the past year, work has concerned a variety of topics relevant to the proposal theme. The first reversible complexation of ethylene by a silylene under ambient conditions was studied and the energetics of the reaction were determined. It was shown that the silylene also reacted readily with a variety of substituted alkynes, but not with substituted alkenes, except for conjugated alkenes. A diarylgermylene was shown to react reversibly with white phosphorus at room temperature. A cage germanium-phosphorus compound was formed and characterized spectroscopically and structurally. Photolysis in toluene resulted in regeneration of the germylene and phosphorus. It was shown that the reaction cycle could be repeated up to ten times with little decomposition. In addition, diarylgermylene or stannylene was shown to insert readily into a phosphorus-hydrogen bond of phosphine to generate primary phosphide products. In anticipation of their use as synthons, four bulky primary organoalanes were synthesized and characterized. They were shown to react with ammonia and phosphine to give primary amido alanes or cages with aluminum-phosphorus frameworks. The primary alanes were also reacted with alkenes and alkynes. The latter readily underwent a cis-addition to the Al-H moiety under mild conditions. The ready addition to both terminal olefins and alkynes was attributed to the bulky aluminum substituent, which generated high concentrations of the more reactive unassociated alane. An inverse relationship between the size of the alane substituent and reactivity was established experimentally. The reaction of methylisocyanide with a diarylgermylene afforded isocyanide coupling/oligomerization through carbon-carbon bond formation. Investigation of the reaction mechanism showed that the initial step involved isocyanide complexation, followed by sequential migratory insertion into the germanium carbon bond and subsequent carbon-hydrogen bond activation.

Molecular Processes Underlying the Structures and Assembly of Thin Films and Nanoparticles at Complex Interfaces

Institution: Oregon, University of
Point of Contact: Geraldine Richmond
Email: richmond@oregon.uoregon.edu
Principal Investigator: Geraldine Richmond
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$260,000 (2014)

PROGRAM SCOPE

Over the past few decades there has been a tremendous growth in our molecular level understanding of adsorption processes at a variety of solid surfaces. One remaining frontier of discovery is the interface between water and a hydrophobic fluid, an interface that is ubiquitous in the environment, our bodies and a wide range of industrial and commercial products. Our studies explore some of the most fundamental issues that contribute to the adsorption, transport and assembly of macromolecules at this dynamic, complex and important fluid interface. Such issues include understanding how factors such as adsorbate hydrophobicity, charge, water solvation, molecular rigidity, metal-ion complexation and

solubility play a role in the adsorption and assembly process. The first set of studies are designed to examine these issues on adsorbates that range in complexity from simple charged polyelectrolytes (PEs), to polymers of increasing molecular charge and structural complexity, to mixtures of PEs and surfactants that are known to act synergistically, to the structure and assembly of peptoid nanosheets and nanoparticles at this interface. The second set of studies has involved studying the assembly of peptoid nanosheet assembly at the oil/water interface. The fundamental insights sought from these oil/water (O/W) studies underpin some of the most unknown and important areas of interfacial science today. Our approach uses a combination of thermodynamic measurements (surface tension), surface spectroscopy (vibrational sum frequency spectroscopy) and molecular dynamics. The vibrational sum frequency spectroscopic technique that we use is ideally suited for such interfacial studies of molecular assembly at the O/W interface.

FY 2014 HIGHLIGHTS

(1) Polyelectrolyte studies: Whether or not a charged macromolecule remains solvated or adsorbs to the interface between two immiscible fluids depends on a variety of complex factors. Ions, in particular, have the capability of affecting the degree of macromolecular hydrophobicity through charge screening as well as through Hofmeister series effects. In these studies we have used sum frequency spectroscopy and interfacial tension measurements to probe the roles of ions in the oil-water interfacial behavior of a model carboxylic acid-containing macromolecule. Specifically, the structure, conformation, and extent of carboxylate-cation interactions of poly(methacrylic acid) at the carbon tetrachloride-water interface was deduced as a function of CaCl_2 and KCl ionic strength. Additionally, the role of polymer backbone in interfacial behavior is explored through tacticity studies. Results show for the first time that macromolecular charge screening is an important factor in the induced adsorption of the isotactic isomer of poly(methacrylic acid) under solution conditions when it is not strongly surface active, yet does not affect the behavior of the syndiotactic isomer. Additionally, while the salting-out effect does not appear to play a strong role in induced adsorption, there is a balance between polymer salting-in and charge screening with excess calcium. (2) Peptoid Studies Peptoid nanosheets are a recently discovered class of two-dimensional nanomaterials that form from the self-assembly of a sequence specific peptoid polymer at the air-water interface. In our recent studies we have found that the oil-water interface provides another opportunity for growth of these unique and highly ordered peptoid sheets. We have found that nanosheets formed at this interface are highly ordered and that the reason for this is due to electrostatic interactions between charged moieties, namely carboxylate and ammonium residues on the peptoids.

Research Project on the Recruitment Retention and Promotion of Women in the Chemical Sciences

Institution: Oregon, University of
Point of Contact: Geraldine Richmond
Email: richmond@oregon.uoregon.edu
Principal Investigator: Geraldine Richmond
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014)

PROGRAM SCOPE

Committee on the Advancement of Women Chemists (COACH) is a grass-roots organization working to expand its highly successful nationwide efforts at increasing the number, retention and success of

women and minorities in STEM fields. Started in 1998 with an initial focus in the field of chemistry, its programs and impact now extends across the STEM disciplines. Basic Energy Sciences (BES) of the Department of Energy was the first federal agency to recognize the importance of COACH activities and to provide funding for its efforts since 1998. This initial and continued funding for its research on workforce building activities has been critical to the continued success of the organization. Today COACH is widely recognized nationwide for its innovative programs that continue to be adopted by other organizations and institutions, and its high degree of impact on women scientists and institutional administrators that have participated in its programs. BES funding has been the primary supporter of the research arm of COACH. The DOE sponsored research has been a critical element in the evaluation, planning and implementation of nearly all COACH programs.

FY 2014 HIGHLIGHTS

COACH conducted surveys at the following workshops: • American Chemical Society Spring workshop – Jr & Sr. Faculty, Dallas, TX • American Chemical Society Fall workshop – postdoctoral associates, San Francisco, CA • Argonne National Labs – Faculty • Society for the Advancement of Chicanos and Native Americans in Science conference – graduate students, postdoctoral associates, faculty • National Organization for the Professional Advancement of Black Chemists and Chemical Engineers – graduate students, postdoctoral associates, faculty Each survey is a powerful tool in learning more about participant’s career concerns, coping skills, achievement and mentoring; both in their early career and in their current position, how they adapt to career concerns that are always changing (based on the skills learned at the COACH workshops) and how we can offer new skills that the participants need. The results are extremely satisfying in showing the powerful impact that these workshops are having on our participants as they report positive outcomes through follow up emails and correspondence with our facilitators and the COACH office. Two publications based on the surveys are written, one in progress and one has been submitted for review.

Programming Function via Soft Materials

Jeffrey Moore; Illinois-Urbana Champaign, University of
Randy Ewoldt; Illinois-Urbana Champaign, University of
Students: 7 Postdoctoral Fellow(s), 24 Graduate(s), 4 Undergraduate(s)
Funding: \$1,607,000 (2014)

PROGRAM SCOPE

The overarching goal of the proposed program of collaborative research is to develop, understand, and apply in energy-relevant contexts new classes of responsive materials with functionalities that derive from and/or exploit structural dynamics from the nanometer to mesoscopic to continuum scale. The cluster has established a unique enabling vision for such materials that embraces the dynamically

reconfigurable 3-dimensional organization of building blocks into architectures that facilitate ion and electron transport and the harvesting of mechanical energy, with potential for broad utility in advanced energy applications. To achieve this goal we will utilize materials of diverse chemistry in a broad range of organizations (amorphous, crystalline, soft organic, hard inorganic) that are designed to allow programmed reversible transformations between equilibrium and nonequilibrium states with qualitatively different properties. Our cluster's vision for Programming Function via Soft Materials integrates two tightly connected core areas: 1. Reconfigurable and Dynamic Assemblies, and 2. Responsive 3D Mesoscale Networks. As elementary units we will employ function-encoded colloids, nanoparticles, large mesh fibrillar gels, deterministically fabricated networks, and their hybrid mixtures. In addition, we will employ top-down methods to create larger scale systems with a 3-dimensional spatial organization of the material components engineered to provide useful functional behaviors. The scientific and technological implications of the cluster's research will provide new approaches to challenging problems in basic energy science including energy harvesting, transport and storage. To achieve these goals the cluster has brought together a team of recognized world-leaders in complex materials synthesis and processing, characterization, theory and modeling, and materials design, integration and fabrication, organizing their efforts into two synergistic thrusts.

FY 2014 HIGHLIGHTS

Our cluster reported new discoveries in the design and assembly of colloid large-mesh fibrillar polymer gel composites, as a first step in creating dynamically and reversibly reconfigurable percolated networks. Underpinning this work, new optical characterization methods, and a microscopic theory of equilibrium colloidal assembly and electrical conductivity based on using fibrillar polymer networks as templates were developed. Continued strides were made in reversible-deactivation fibril assembly, a possible route to forming structurally well-defined polymer filaments with narrow polydispersity. Synthetic strategies for mechanically optimized objects, both colloids with shape bistability and high energy density battery electrodes with minimized plastic strain upon cycling, were developed. Mechanical modeling was used to understand the properties of these systems. Mechanically optimized silicon battery electrodes were found to have significantly increased cycle lifetimes compared to conventional electrode designs. Complex, 3D mesoscale networks were formed by exploiting the geometric transformation via compressive buckling of 2D micro/nanostructures into extended 3D layouts. Demonstrations include experimental and theoretical studies of more than forty representative geometries, from single and multiple helices, toroids and conical spirals to structures that resemble spherical baskets, cuboid cages, starbursts, flowers, scaffolds, fences and frameworks, each with single and/or multiple level configurations. Modeling of electric fields within such structures was performed, and studies of their dynamical behavior are ongoing. The developed process can be implemented with any substrate capable of controlled, large-scale dimensional change. It expands and complements the capabilities of other approaches in 3D materials assembly, and suggests many new possibilities for achieving sophisticated classes of 3D electronic, optoelectronic, and electromagnetic devices.

EARLY CAREER: Dielectric Ceramics in Nanosheet Form

Institution:	Georgia, University of
Point of Contact:	Tina Salguero
Email:	salguero@uga.edu
Principal Investigator:	Tina Salguero
Sr. Investigator(s):	
Students:	0 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding:	\$150,000 (2014)

PROGRAM SCOPE

Nanosheets are characterized as being freestanding nanomaterials from one to several monolayers thick and up to tens of micrometers in lateral dimensions. The nanosheet morphology has several unique features that put it at the frontier of materials development, foremost the fact that nanosheets can combine remarkable, quantum effect-derived properties with large surface areas and the advantages of solution-based manipulation methods. To date, well-defined nanosheets have been derived from lamellar materials via exfoliation processes; examples include selected perovskites, various transition metal oxides and chalcogenides, hexagonal boron nitride, and graphene. We are interested in materials for energy applications that go beyond these examples, specifically ternary oxide ceramics. The important initial challenge is that there is no bulk precursor that can simply be exfoliated to provide nanosheets of these materials. However, when this preparative hurdle is surmounted, these nanosheets will provide an opportunity to better understand the properties of complex oxide ceramics at a size regime down to one monolayer, as well as allow us to study the roles of surface functionalization and interface interactions. Our approach in this area of two-dimensional ceramic nanomaterials encompasses synthesis, characterization, and deposition methods.

FY 2014 HIGHLIGHTS

The first step is to prepare dielectric ceramics as nanosheets, a non-natural form of these materials. Our innovation is to apply template-based and topotactic chemical transformations to pre-existing nanosheet starting materials. We have focused on two classes of ternary oxide materials that have well-characterized ferroelectric properties: the titanate-based perovskites ATiO_3 ($A = \text{Ba, Sr, Pb}$) and the bismuth-based Aurivillius materials Bi_2MO_6 ($M = \text{Mo, W}$). Our synthetic studies to produce ATiO_3 nanosheets have focused on the topotactic conversion of titania- or titanate-containing nanosheet precursors. For example, we have developed direct TiO_2 (B) nanosheet to BaTiO_3 nanosheet conversion chemistry. A large part of this effort has involved an in-depth study of the mechanism of BaTiO_3 nanosheet formation. Structure analysis of BaTiO_3 nanosheets by Raman spectroscopy and synchrotron X-ray diffraction reveal that the material is tetragonal at room temperature, which is a key prerequisite for ferroelectric properties. Recent piezoresponse force microscopy (PFM) measurements with collaborators (Prof. Matt Dawber, SUNY Stony Brook, Physics) have shown that BaTiO_3 nanosheets show a clear piezoresponse at room temperature. In the Bi_2MO_6 system, we developed a double nanosheet template route to preparing high-quality Bi_2WO_6 and Bi_2MoO_6 nanosheets. The most successful reactions involve two nanosheet materials under hydrothermal conditions, such as surfactant-free cesium tungstate $\text{Cs}_4\text{W}_{11}\text{O}_{36}^{2-}$ nanosheets with bismuth oxide-based $[\text{Bi}_6\text{O}_6](\text{OH})_3(\text{NO}_3)_3$ nanosheets that are generated *in situ* from $\text{Bi}(\text{NO}_3)_3$, or with isolated $[\text{Bi}_6\text{O}_6](\text{OH})_3(\text{NO}_3)_3$ nanosheets. We characterized the band gaps of Bi_2MO_6 nanosheets compared to other nanomorphologies and bulk material, an important factor in its well-known photocatalytic properties, and discovered that Bi_2WO_6 is reversibly chromic with respect to both UV irradiation and lithium intercalation.

Hybrid Halide Perovskites: Novel Materials with Contraindicated Properties

Institution: California-Santa Barbara, University of
Point of Contact: Ram Seshadri
Email: seshadri@mrl.ucsb.edu
Principal Investigator: Ram Seshadri
Sr. Investigator(s): Michael Chabiny; California-Santa Barbara, University of
Fred Wudl; California-Santa Barbara, University of
Mercuri Kanatzidis; Northwestern University

Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$468,022 (2014)

PROGRAM SCOPE

We have worked on the synthesis and characterization of the hybrid organic/inorganic germanium perovskite compounds, $AGeI_3$. The systematic synthetic study of this reaction system led to the isolation of 6 new inorganic semiconductors by incremental variation of the A organic cation. Using $CsGeI_3$ (1) as a reference compound we have prepared the methylammonium, $CH_3NH_3GeI_3$ (2), formamidinium, $HC(NH_2)_2GeI_3$ (3), acetamidinium $CH_3C(NH_2)_2GeI_3$ (4), guanidinium, $C(NH_2)_3GeI_3$ (5), trimethylammonium, $(CH_3)_3NHGeI_3$ (6), and isopropylammonium, $(CH_3)_2C(H)NH_3GeI_3$ (7), analogues. The crystal structures of the compounds were solved and refined and they are classified based on their dimensionality with 1-4 forming 3D perovskite frameworks and 5-7 1D infinite chains. The binary compound GeI_2 (8), prepared under the same synthetic protocol, has a layered 2D structure and lies between the two structural families. Compounds 1-8, with the exception of compound 5, crystallize in strongly polar space groups, a property that can be attributed to the tendency of the Ge^{2+} ion to form pyramidal $[GeI_3]^-$ rather than octahedral $[GeI_6]^{4-}$ building blocks in the solid state, in contrast with the tendency observed in the heavier iodometallates. Complementing this work, we have prepared a number of Bi-based halide compounds of the general formula $A_3Bi_2I_9$ where A is either an alkali metal cation or an organic amine-derived mono cation. The structures and phase transitions of some of these and their optical properties have been studied. To study the behavior of charge carriers in these materials, we have begun to set-up a transient THz system to study the lifetime and spectral features of photogenerated carriers. We have also prepared the proposed zwitterionic molecule that can act as both electron and hole transporter interface molecule, and are now incorporating these into devices.

FY 2014 HIGHLIGHTS

Some of the highlights obtained so far include a careful DFT study of valence and conduction band absolute positions of PbI_2 and $APbI_3$ compounds with different dimensionalities of structures that has been published in the Journal of Physical Chemistry. The chemistry of many new Ge, Sn, and Bi compounds has been studied as well.

Computation-Guided Synthetic Strategies for Nanocomposite Electrode Structures Designed to Probe Critical Size Effects on Charge Storage and Transport

Institution: Minnesota, University of
Point of Contact: Andreas Stein
Email: a-stein@umn.edu
Principal Investigator: Andreas Stein
Sr. Investigator(s): Donald Truhlar; Minnesota, University of
William Smyrl; Minnesota, University of
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$250,000 (2014)

PROGRAM SCOPE

One of the premises of this project is that materials with high theoretical capacities for lithium ion storage may serve as active electrode materials for electrical charge storage devices such as lithium ion batteries (LIBs) even if they are poor electronic or ionic conductors, given that the materials are present

as nanoparticles and that they are in good electronic contact with a conducting phase. To achieve efficient charge storage and transport in such materials, it is necessary to control size and morphologies of active material particles and their distribution in the conductive phase. During this project period we focused on two particular systems: titania/carbon nanocomposites for anodes in LIBs and the lithium zirconate (LZO) platform for potential novel cathode materials. For the former, we investigated the influence of the source of carbon and titania on the nanocomposite to improve control over the carbon:titania ratio, nanoparticle size, and titania distribution in the carbon phase. These parameters were correlated to electrochemical properties. The LZO platform is attractive because of the layered structure in some phases that allows for cation intercalation/deintercalation and because of its high theoretical specific capacity for charge, which exceeds that of current commercial cathode materials. Several challenges must be overcome for LZO electrodes, related to the low conductivity of LZO and its high charging potential. These challenges are addressed through the development of syntheses of materials with small grain size, some of which directly incorporate LZO in a conductive carbon phase. Furthermore, dopants are introduced into the active material to enhance electronic conductivity, ionic conductivity, or both. We have made tremendous progress in understanding how to manipulate grain size and electrochemical properties of the LZO-based system. Much of this progress has been guided by computational insight.

FY 2014 HIGHLIGHTS

We demonstrated that by using a polymeric template with mixed precursors for carbon and titanium complexed by different ligands, it was possible to position titania nanoparticles either at the interface of pores or embedded within a carbon matrix. The relative placement influenced the capacity of the material to store lithium ions and depends on the interactions (relative polarity) of the complexed titanium precursor with the carbon precursor and the template surface. The carbon content is also affected by the ligand. Embedding titania within carbon limits grain growth, whereas surface titania grows nearly unrestrictedly. Excessive carbon limits ion transport, reducing capacity at high charge/discharge rates. These observations are also relevant for other hard templating processes to fabricate nanocomposite electrodes. For the LZO platform several properties were computed, including geometries and electronic structures of delithiated configurations, delithiation energy, and stability of the delithiated materials. Li ion transport mechanisms were explored, and the lowest energy path of Li hopping was identified. Surface effects and doping effects on the electronic structure of the cathodes and the delithiation energy were simulated. This information guided the selection of dopant atoms. Multiple approaches were evaluated to reduce the grain size of LZO particles, shorten diffusion paths through active material and increase electrochemical utilization, including ultrasonic exfoliation, synthesis from nanostructured precursors, synthesis in confinement of carbon phases, and synthesis from sinter-resistant precursors. By correlating grain size with charge storage capacities, we deduced a target size of 5-20 nm crystallites for full utilization. Capacities were enhanced by doping with selected transition metals through providing either defect sites in the structure for improved ion conductivity or through enhancing electronic conductivity.

Electrochemically Smart Bimetallic Materials Featuring Group 11 Metals: In-Situ Conductive Matrix Generation & Its Impact on Battery Capacity, Power and Reversibility

Institution: New York-Stony Brook, State University of
Point of Contact: Esther Takeuchi
Email: esther.takeuchi@stonybrook.edu
Principal Investigator: Esther Takeuchi
Sr. Investigator(s): Kenneth Takeuchi; New York-Stony Brook, State University of

Students: Amy Marschilok; New York-Stony Brook, State University of
0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

This research on energy storage is centered on the syntheses and electrochemical studies of new classes of bimetallic energy storage materials. There are three interrelated objectives that we are pursuing. 1) Develop new classes of improved materials based on bimetallic oxides, oxyphosphates and phosphorous-oxides: $M_wM'_xO_z$, $M_wM'_xOP_yO_z$, $M_wM'_xP_yO_z$. The investigation includes a) rational identification of next generation target materials, b) performing detailed chemical and physical characterization of the materials and c) control of the material properties via the synthetic manipulation of the material composition and nanostructure. 2) Conduct electrochemical evaluation of the interrogated materials to determine energy density, electrochemical reversibility, and power capability, under a variety of conditions. 3) Fundamentally interrogate the reduction/oxidation mechanisms of the materials. This program is focused on the synthesis, characterization, electrochemical evaluation of novel bimetallic compounds in three major classes: 1) manganese centered materials, 2) vanadium centered materials and 3) iron based compounds. The research probes the impact of structure and in particular crystallite size on the electrochemistry. A focus on synthetic methods enabling control of physical properties of materials such as crystallite size, surface area, and particle size, as well as chemical composition can result in control of the bulk properties of materials, critical to mechanistic electrochemical studies. Novel low temperature synthetic techniques that provide the ability to control crystallite size along with composition yielding molecular level architectural design capability are developed which enable systematic studies of specific factors as related to their electrochemistry. The studies are supported by mechanistic studies using ex-situ and in-situ measurements.

FY 2014 HIGHLIGHTS

Significant findings in three topic areas were realized in 2014: 1) demonstration of a synthetic method allowing composition and size control yielding 200% increase in delivered capacity, 2) in-situ studies of intact batteries yielding kinetic insight on the formation of the electrochemical reaction front within the cathode and 3) demonstration of reversibility of copper based bimetallic materials yielding nanosized copper which reincorporates into the parent structure. A paradigm for concomitant control of crystallite size and composition of bimetallic composites via co-precipitation was introduced where the direct preparation of a composite of silver ferrite, $AgFeO_2$ and amorphous maghemite, $\gamma-Fe_2O_3$ via nonstoichiometric synthesis was demonstrated. X-ray powder diffraction confirmed systematic variation of crystallite size. The composite nature of crystalline silver ferrite and non-crystalline maghemite was established by Raman and x-ray absorption analyses. The low silver composites exhibited capacities ~200% higher relative to stoichiometric silver ferrite. Our strategy to address low electrical conductivities of cathode materials is designing bimetallic materials that in-situ form an electrically conductive metallic matrix. In-situ energy-dispersive x-ray diffraction enabled three dimensional spatial imaging of intact $Li/Ag_2VP_2O_8$ and $Li/Ag_2VO_2PO_4$ cells. Formation of silver metal during discharge enabled visualization of discharge pathways within the battery cathode. Studies of cells discharged under different rates provided unique insight into the role of rate as a deterministic factor in the reduction mechanism. Synthesis, characterization and electrochemical studies of $Cu_{0.5}VOPO_4 \cdot 2H_2O$ and $Cu_{0.25}MnO_2 \cdot H_2O$ were completed where both materials showed reversible electrochemistry. Formation of copper metal on reduction was not detectable by XRD, but was identified by x-ray absorption spectroscopy providing insight into the reversible reduction mechanisms.

EARLY CAREER: Transition Metal Oxides Spinel Nanomaterials for Supercapacitor Reactions

Institution: New Hampshire, University of
Point of Contact: Xiaowei Teng
Email: XW.Teng@unh.edu
Principal Investigator: Xiaowei Teng
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project will focus on the fundamental structure-property relationship of transition metal oxides (TMOs) nanostructures made from liquid phase synthesis with defined morphology, chemical composition and crystalline structure, including faceted simple spinel (e.g., Mn_3O_4) and binary spinel (e.g., $Co_{1-x}Mn_{2-x}O_4$ and $Fe_{1-x}Mn_{2-x}O_4$), and layered TMOs (e.g., MnO_2 , V_2O_5). The hypotheses of our research are: (i) nanosized TMOs will have high specific surface area for ionic conductance; (ii) faceted spinel nanoparticles with higher percentages of reactive and/or stable surfaces will facilitate the fast charge-transfer reaction and long cycle life; (iii) layered nanostructures will provide large interplanar distance for facile cation insertion/extraction. Various analytical tools (electron microscopy, thermogravimetric analysis and XPS) will be used to characterize the structure of TMOs. Cyclic voltammetry and electrochemical impedance spectroscopy analyses (in half-cell), and galvanostatic charge-discharge analyses (in button-cell) will be used for electrochemical characterization. Particularly, through the interplay between novel material syntheses, structural and functional characterizations, and synchrotron-, neutron-based *in situ* X-ray diffraction (XRD), X-ray adsorption (XAS), neutron scattering and pair distribution function (PDF) analyses; the ultimate goal of the proposed research is to provide fundamental understanding of electrode materials for supercapacitors that can store more energy while maintaining a stable electrode/electrolyte interface.

FY 2014 HIGHLIGHTS

We synthesized Mn_3O_4 spinel, and Co- and Ni-doped Mn_3O_4 ($Co_xMn_{3-x}O_4$, $Ni_xMn_{3-x}O_4$, X: 0, 0.2, 0.5, 1, and 3) spinel metal oxide nanoparticles, and V_2O_5 layered nanostructures, and fabricated electrodes for supercapacitor devices and studied their electrochemical performance. We conducted several *ex situ* X-ray and neutron diffraction experiments at ORNL-SNS and ANL-APS, and *in situ* XRD and XAS measurements on V_2O_5 , Co- Mn_3O_4 . Future efforts will focus on understanding the effect of crystalline structure on potential window of the electrochemical devices, and the PDF analyses of X-ray and neutron scattering data.

Mesoscale Photophysical Properties of Anisotropic Hybrid Nanostructure Assemblies

Institution: Georgia Institute of Technology
Point of Contact: Vladimir Tsukruk
Email: vladimir@mse.gatech.edu
Principal Investigator: Vladimir Tsukruk
Sr. Investigator(s): Mostafa El-Sayed; Georgia Institute of Technology
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$250,000 (2014)

PROGRAM SCOPE

Hybrid (organic-inorganic) mesoscale assemblies of functionalized anisotropic nanocrystals with tailored shapes and facet-to-facet interactions with conjugated photoluminescent polymers will be investigated in this project. We use shaped noble metal nanocrystals coated with functionalized materials including conjugated polymers and satellite nanoparticles to control their inter-particle interactions as well as light interactions and conversion. Building blocks with different shapes and functionalized facets self-assemble to yield mesoscale structures in a pre-programmed fashion offers a unique opportunity to create hierarchical structures and materials with inherently anisotropic properties such as optical, transport, mechanical, or magnetic depending upon the nature of building blocks. We focus on the plasmonic-mediated changes of the light absorption of core-shell metal-conducting polymers nanostructures which can serve as efficient light-harvesting and converting hybrid materials. Specific objectives include: (1) synthesis of different complex shaped nanostructures (nanocubes, nanoframes, nanocages) from noble metals with well controlled dimensions, shapes, and stability and their functionalization in order to control their assembling ability; (2) fabrication of core-shell hybrid nanostructures with controlled placement of different conjugated polymer shells; (3) comprehensive multi-length scale characterization of microstructure, morphology, thermal, and optical properties of these hybrid nanostructures; (4) directed assembly of these functionalized nanostructures into the organized mesoscale ensembles with controlled interparticle distances via competing interactions of functionalized facets and surfaces. The ability to control light interaction of core-shell, metal-polymer nanostructures is a critical requirement for designing hybrid materials with novel light harvesting and conversion properties for energy materials, catalysts, biosensing, and photonics.

FY 2014 HIGHLIGHTS

Monolayers of polyethylene glycol (PEG)-functionalized gold nanocubes (AuNCs) were fabricated with the separation controlled by the PEG chain length (J. Phys. Chem. C 2014, in print). The alignment of the AuNRs resulted in a strong longitudinal localized surface plasmon resonance (LSPR) when excited by polarized light. A variable surface pressure allows continuous size gradient of nanocubes with poly(isopropylacrylamide) shells with variable interparticle coupling (ACS Nano 2014, 8, 9410). On the contrary, the ensembles of nanoparticle arrays on periodic wrinkled templates show strong plasmonic coupling due to minute interparticle spacing of 2 nm resulting in well-defined plasmonic modes, such as resonance splitting and multiple radiant modes (NanoLett. 2014, 14, 6863). Furthermore, we observed strong plasmonic coupling within aggregates of silver nanocubes on different substrates that lead to a substantial enhancement of the refractive index sensitivity (Particles, 2014, 31, 274). Top down and directed assembly methods such as electron beam lithography and layer-by-layer assembly were exploited to engineer metal-dielectric-metal nanostructures with broadband absorbing properties. Coupling of silver nanocubes and gold nano-gratings mediated by a dielectric polymer spacer with controllable nanoscale thickness results in a large enhancement of light absorption (Adv. Funct. Mater. 2014, 24, 6797). Precise design of optical scattering sites in a 3D stacking yields plasmon resonance modes not observed in common 2D metal nanostructures (J. Phys. Chem. C 2014, 118, 5453). Finally, real time plasmonic tunability was achieved by embedding silver nanocubes into an electrochromic polymer matrix and applying electrical field. A significant reversible plasmon peak shift was observed when the nanocube-polymer layer was electrochemically oxidized due to initiated changes in the refractive index of the polymer matrix as supported by Finite Difference Time Domain (FDTD) simulations (ACS Nano 2014, 8, 6182).

Optical, Electrical and Magnetic Studies of pi-Conjugated Systems

Institution: Utah, University of
Point of Contact: Z. Valy Vardeny
Email: val@physics.utah.edu
Principal Investigator: Z. Valy Vardeny
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$205,000 (2014)

PROGRAM SCOPE

The thermodynamic limit of organic photovoltaic (OPV) solar cell is ~25% for single-junction cells. So far the world record certified power conversion efficiency (PCE) of OPV solar cells is 10.6%, for a solar cell based on low bandgap (LBG) polymers. Despite aggressive efforts in the past two years, only minor progress in PCE of organic solar cells has been made, and thus game-changing fundamental understanding is critically needed for the next breakthrough in PCE enhancement. This may be achieved by finding new energy transfer pathways that circumvent the loss mechanisms known to exist in organic donor (D)-acceptor (A) bulk heterojunction (BHJ) blends. Consequently, our goal in the present DOE project is to seek, understand and provide new energy transfer processes in polymeric and molecular D-A OPV devices, through a concerted research effort using ultrafast and continuous wave (CW) spectroscopy that include transient magnetic field effect, device fabrication and electrical characterization; and advanced computation via collaboration. Based on the deeper understanding gained by our research progress, new materials and processes will be developed to reduce losses in the basic processes of charge photogeneration, transport, and collection in OPV cells that will boost the device PCE.

FY 2014 HIGHLIGHTS

Our approach to fulfill this goal has involved understanding why charge photogeneration at the polymer-fullerene interface with the state-of-the-art LBG polymers is significantly higher than with traditional donor materials. Our recent experimental research indicates that there exist in LBG polymers unusual charge photogeneration channels with yield above that of the normal charge photogeneration channel of singlet exciton (SE) dissociation; which involve either a triplet exciton that results from singlet fission (SF), or a spin-singlet state that is a quantum entangled triplet-triplet (TT) state. These conclusions were reached from novel ultrafast spectroscopy measurements under the influence of an external magnetic field that were completed in our laboratories on pristine and blends based on LBG, which show the ultrafast photogeneration of a novel intrachain TT state that undergoes SF and ionizes at the D-A interface to polaron-pairs. Also sophisticated calculations of ground state and excited state absorptions within correlated-electron models of π -conjugated polymers justify our conclusions. These calculations show that intrachain TT pairs may be readily photogenerated in LBG polymers upon photon absorption, as a result of their intrachain D-A backbone structure.

Linking Metal Ions via Inorganic Click (iClick) Reactions

Institution: Florida, University of
Point of Contact: Adam Veige
Email: veige@chem.ufl.edu
Principal Investigator: Adam Veige
Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Inorganic click (iClick) is the cycloaddition reaction between a metal-azide and a metal-acetylide providing metal ions linked by a triazolate bridge. This reaction was first elucidated in the Veige laboratories in 2010. The iClick reaction has the potential to transform synthetic methodologies that rely on the controlled linkage of two or more metal ions. Although metallopolymers are versatile and have extensive applications, most notably as light harvesters in photovoltaic devices, these materials are hampered by a limited range of the metal coordination environments, limited synthetic access to regular heterometallic compounds, and limited methods for post-synthetic modification. iClick methodology can afford controllable incorporation of metal ions into a polymer chain with complimentary properties afforded by the ancillary ligands. However, the underlying fundamental chemistry that governs the iClick reaction is unknown. This one-year project aims to determine the scope of the iClick reaction, including a CuI-catalyzed version and extension to tri- and tetra-metallic complexes that will serve as models for future metallopolymer materials. Over the past year we have garnered preliminary results that substantiate iClick chemistry as an effective method to link metal ions. This project delineates experiments that will afford a detailed understanding of the electronic and steric effects of the monomer units that govern this reaction. Our initial target molecules are di- tri- and tetra-metallic compounds, which approximate extended structures and will elucidate how metal ion type and ancillary ligands affect electronic exchange/communication across the triazolate bridge. The goal is to firmly grasp both the advantages and limitations of this new technology to facilitate, beyond this project, the controlled synthesis of one- and two-dimensional metallopolymers and metal-containing networks.

FY 2014 HIGHLIGHTS

The major highlight from the previous project year is that we transitioned the iClick reaction from a reaction that links two and three metal ions, to a reaction that links multiple metal ions to provide metallopolymers and oligomers. This marks the first use of an iClick reaction to form new materials previously unattainable. In one case, we employ iClick to link two Au(I) units together that then self-assemble into rare Au₄ clusters. The Au₄ clusters then, depending on steric constraints from the ancillary ligands, forms oligomers through aurophilic interactions. The significance is that our system is a rare example of oligomer formation driven via gold-gold bonds. Another approach was applied that employs the cycloaddition of an organodiazide to a metal-diacetylide. Setting up a step-growth polymerization, for the first time we demonstrate metallopolymer formation, with in-chain metal ions via iClick. Lastly, we elucidated an alternative iClick reaction that employs the cycloaddition of an isonitrile with an Au-azide to form new tetrazole coordination polymers. These three highlights cement iClick as a versatile method for accessing new materials that feature in-chain metal ions rather than pendant metals attached to a polymer backbone.

Donor-Acceptor Extended Porphyrins as Light Harvester for Solar Energy Conversion

Institution: Miami University
Point of Contact: Hong Wang
Email: wangh3@muohio.edu
Principal Investigator: Hong Wang
Sr. Investigator(s): Lei Kerr; Miami University

Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$210,000 (2014)

PROGRAM SCOPE

This funded project is focused on the design, synthesis and characterization of pi-extended porphyrins bearing donor and acceptor groups at the porphyrins beta-positions, as well as the evaluation of these pi-extended porphyrins as light harvesters for dye-sensitized solar-cells (DSSCs). Pi-extended porphyrins possess unique combination of photophysical and electronic properties. These organic materials have great potentials in applications ranging from organic electronics to biomedicines. Due to the very limited synthetic methods, this area remains largely unexplored. We have developed concise and versatile synthetic methods to access a large number of pi-extended porphyrins. The goal of this project is to establish basic understandings of the structure-property-efficiency relationships through systematic functionalization of pi-extended porphyrins.

FY 2014 HIGHLIGHTS

In the year of 2014, we completed the synthesis and characterization of four types of pi-extended porphyrins including linearly conjugated pentacene-fused porphyrin dimers, cross-conjugated quinone-fused dinaphtho[2,3]porphyrins, unsymmetrical push-pull monobenzoporphyrins and push-pull opp-dibenzoporphyrins. The linearly conjugated pentacene-fused porphyrin dimer and the cross-conjugated quinone-fused dinaphtho[2,3]porphyrins display non-typical UV-visible absorptions of either porphyrins or pentacenes/quinones. UV-visible, emission and MCD spectroscopy suggest strong electronic interactions among the multichromophores in the system. DFT calculations revealed the delocalization of the HOMOs and LUMOs spanning the entire dimer and linker assembly. It is notable that the pentacene-fused porphyrin dimer is significantly more stable than both the corresponding pentacene and the heptacene derivatives. Both the unsymmetrical push-pull monobenzoporphyrins and push-pull opp-dibenzoporphyrins exhibit anticipated broadening and red shifting of UV-visible absorptions. An unusual flipping over in magnetic circular dichroism spectroscopy (MCD) of unsymmetrical push-pull monobenzoporphyrins was observed for the first time for porphyrins. We are in the process of measuring cyclic voltammograms (CVs) and other properties for these four types of pi-extended porphyrins. The performance of these porphyrins in dye sensitized solar cells (DSSCs) will also be measured. We expect five to six papers from these results. One article has been published (Chem. J. Eur., 2014, 1-7; selected as a hot paper by the editors). One article has been submitted to Chem. Commun. Two manuscripts are near submission for publication.

Extracting Hot Carriers from Photoexcited Semiconductor Nanocrystals

Institution: Columbia University
Point of Contact: Xiaoyang Zhu
Email: xz2324@columbia.edu
Principal Investigator: Xiaoyang Zhu
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$210,000 (2013-2014)

PROGRAM SCOPE

This research program addresses a fundamental question related to the use of nano-materials in solar energy -- namely, whether semiconductor nanocrystals (NCs), also called quantum dots (QDs), can help surpass the efficiency limits in conventional solar cells. As is known as the so-called "Shockley-Queisser" limit, the maximum theoretical efficiency of a single-junction solar cell is ~31%. This is because absorption of photons with energies above the semiconductor bandgap generates "hot" charge carriers that quickly "cool" to the band edges before they can be utilized to do work. If instead, all of the energy of the hot carriers could be captured, solar-to-electric power conversion efficiencies could be increased, theoretically, to as high as 66%. Two proposals have been put forward: one increases photocurrent by converting the hot carrier energy to multiple electron-hole pairs; and the other increases photovoltage by capturing the hot carriers. In both scenarios, it is essential to understand charge carriers or excitons significantly above the bandgap. The PI is addressing two questions: How does quantum confinement affect hot carrier/exciton dynamics? How to harvest hot carriers from quantum confined materials, including quantum dots? Understanding hot carriers and excitons in semiconductor materials, including quantum-confined materials, is a necessary step in laying a mechanistic foundation for the application of these materials in solar energy conversion. The second question is specifically related to the potential implementation of the hot carrier solar cell idea. The key to the success of the hot carrier solar cell concept lies not only in the efficient harvesting of hot carriers before phonon relaxation, but also in the possibility of hot carrier – hot carrier scattering and quasi equilibration in the electronic degrees of freedom with realistic concentration of solar radiation.

FY 2014 HIGHLIGHTS

The PI has made two major advances in understanding hot carrier relaxation in the model system in PbSe QDs. The PI has successfully applied femtosecond time-resolved two-photon photoemission spectroscopy for a complete mapping in time- and energy-domains of hot electron relaxation and multi-exciton generation (MEG) dynamics in PbSe quantum dots functionalized with 1,2-ethanedithiols. This experiment led to the discovery of a linear scaling law between the hot electron relaxation rate and its energy above the conduction band minimum. There was no evidence of MEG from intra-band hot electron relaxation for excitation photon energy as high as three times the bandgap ($3E_g$). Rather, MEG occurs in this system only from inter-band hot electron transitions at sufficiently high photon energies ($\sim 4E_g$). More insight into the behavior of hot carriers in PbSe QDs comes from transient absorption experiments. Here, the PI and students have discovered a transient Stark effect imposed by a hot electron-hole pair on optical transitions in PbSe QDs. The hot electron-hole pair does not behave as an exciton, but more bulk-like as independent carriers, resulting in a transient and varying dipole moment which breaks the symmetry of the QD. As a result, we observe redistribution of optical transition strength to dipole forbidden transitions and the broadening of dipole-allowed transitions during the picosecond lifetime of the hot carriers. The magnitude of symmetry breaking scales with the amount of excess energy of the hot carriers, diminishes as the hot carriers cool down, and disappears as the hot electron-hole pair becomes an exciton. Such a transient Stark effect should be of general significance to the understanding of QD photophysics above the band gap. More recently, the PI and students have made a breakthrough discovery on a new class of solar harvesting materials, organic-inorganic lead halide-based perovskites, on charge and exciton trapping, as well as light emission.

Spectroscopy of Charge Carriers and Traps in Field Doped Organic Semiconductors

Institution: Columbia University
Point of Contact: Xiaoyang Zhu
Email: xz2324@columbia.edu
Principal Investigator: Xiaoyang Zhu
Sr. Investigator(s): Daniel Frisbie; Minnesota, University of
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$290,000 (2013-2014)

PROGRAM SCOPE

The proposed research aims to achieve quantitative, molecular level understanding of charge carriers and traps in field-doped crystalline organic semiconductors via *in situ* linear and nonlinear optical spectroscopy, in conjunction with transport measurements and molecular/crystal engineering. Organic semiconductors are emerging as viable materials for low-cost electronics and optoelectronics, such as organic photovoltaics (OPV), organic field effect transistors (OFETs), and organic light emitting diodes (OLEDs). - Despite extensive studies spanning many decades, a clear understanding of the nature of charge carriers in organic semiconductors is still lacking. It is generally appreciated that polaron formation and charge carrier trapping are two hallmarks associated with electrical transport in organic semiconductors; the former results from the low dielectric constants and weak intermolecular electronic overlap while the latter can be attributed to the prevalence of structural disorder. These properties have led to the common observation of low charge carrier mobilities, e.g., in the range of 10^{-5} - 10^{-3} cm²/Vs, particularly at low carrier concentrations. However, there is also growing evidence that charge carrier mobility approaching those of inorganic semiconductors and metals can exist in some crystalline organic semiconductors, such as pentacene, tetracene and rubrene. A particularly striking example is single crystal rubrene, in which hole mobilities well above 10 cm²/Vs have been observed in OFETs operating at room temperature. Temperature dependent transport and spectroscopic measurements both revealed evidence of free carriers in rubrene. Outstanding questions are: what are the structural features and physical properties that make rubrene so unique? How do we establish fundamental design principles for the development of other organic semiconductors of high mobility?

FY 2014 HIGHLIGHTS

We have carried out transport measurements on ionic liquid (electrolyte) gating of two benchmark organic semiconductors, poly(3-hexylthiophene) and rubrene. The goal of these experiments is to use the giant capacitance of ionic liquids to induce large carrier densities in the organic semiconductors and to explore transport in the high carrier density regime. We find that in the case of P3HT, the mobility becomes high enough at the 3D highest charge densities, near 10^{21} cm⁻³, that the Hall effect can be reproducibly observed. Furthermore, it is clear from extensive resistivity measurements versus temperature that a metallic state in P3HT is approached, though it is not realized likely due to gating induced disorder. In the case of rubrene single crystals, carrier mobilities as large as 4 cm²/V.s are achieved at 2D hole densities of 0.15 charges/rubrene, $\sim 3 \times 10^{13}$ cm⁻². These large mobilities lead to an easily detected Hall signal that verifies the charge density estimated from capacitance-voltage measurements. Furthermore, at optimum carrier densities, the near-onset of metallic behavior is clearly observed for rubrene. Concurrent with transport experiments, we carried out spectroscopic measurements to quantify the density of doping upon the formation of the rubrene/ionic liquid (ion gel) interface. Based on charge modulation FTIR spectroscopy, we discovered that there is an intrinsic doping of the rubrene capacitor with an ionic gel dielectric of $\sim 1.5 \times 10^{13}$ cm⁻² holes (manuscript in preparation).

Such an intrinsic density of doped holes can be removed with a positive gate bias of $V_G = 0.8$ V. These intrinsically doped holes are believed to result from the stabilization of hole carriers at the interface by counter ions (anions) in the ionic gel, a process similar to the trap healing mechanism discovered recently by Podzorov and coworkers. For negative gate bias up to $V_G = -1.0$ V, we find addition hole doping up to $\sim 3 \times 10^{13} \text{ cm}^{-2}$, in agreement with transport.

A Synthetic Strategy to Prepare New Complex Uranium and Thorium Containing Oxides: Predictive Solid State Synthesis of New Composition using Radius Ratio Rules and Materials Discovery Based on Crystal Growth from High Temperature Solutions

Institution: South Carolina, University of
Point of Contact: Hans-Conrad zur Loye
Email: zurloye@mailbox.sc.edu
Principal Investigator: Hans-Conrad zur Loye
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

The synthesis of new complex uranium-containing materials and the investigation of their physical properties are of interest and of national importance for identifying new ceramics for long term waste storage, for developing new materials for fuel rod assemblies, and for training the next generation of radiation worker. Achieving these goals will require complex uranium-containing materials with substantially new compositions and structures and the involvement and training of graduate students and postdocs in the synthesis process. However, the preparation and characterization of new oxide compositions is not a trivial undertaking and requires a targeted approach. Our research continues to focus on expanding the boundaries of uranium(IV) and uranium(VI) materials chemistry via two approaches: 1) the targeted synthesis of complex oxides with compositions and structures predicted by radius ratio rules and 2) the crystal growth of new complex uranium oxides from high temperature solutions as an effective method for materials discovery. A third approach, 3) the mild hydrothermal crystal growth method, enables us to obtain large high quality crystals of uranium (IV) containing fluorides via an in-situ reduction step. In all cases, we perform the structural characterization of these crystals and characterize the physical properties of the new materials synthesized.

FY 2014 HIGHLIGHTS

During the past year we focused on a successful area of crystal growth that yielded new ternary U(IV) containing fluorides and a new series of U(VI) containing oxy-chlorides. We also began to explore the uranium silicate phase space that has yielded very promising results so far. We relied extensively on the use of mild hydrothermal reactions for the synthesis of single crystals of new binary, ternary and quaternary fluoride phases and on the use of high temperature fluxes for the preparation of ternary and quaternary oxides and oxychlorides. We developed robust synthetic methodologies that enabled us to synthesize and characterize numerous new uranium-containing phases including (1) fluorides: $\text{Na}_4\text{MU}_6\text{F}_3\text{O}$ ($M = \text{Mn}^{2+}, \text{Co}^{2+}, \text{Ni}^{2+}, \text{Cu}^{2+}, \text{and Zn}^{2+}$), $\text{Na}_3\text{MU}_6\text{F}_3\text{O}$ ($M = \text{Al}^{3+}, \text{Ga}^{3+}, \text{Ti}^{3+}, \text{V}^{3+}, \text{Cr}^{3+}, \text{Fe}^{3+}$), and LiUF_5 , KU_2F_9 , $\text{K}_7\text{U}_6\text{F}_{31}$, RbUF_5 , RbU_2F_9 , and $\text{RbF}_3\text{F}_{13}$ (2) oxychlorides: $\text{Cs}_5\text{U}_7\text{O}_{22}\text{Cl}_3$, and AUO_3Cl ($A = \text{Rb}, \text{Cs}$) and (3) oxides: $\text{Cs}_{2.2}\text{U}_5\text{O}_{16}$ and $\text{Cs}_2\text{U}_4\text{O}_{13}$. In addition, we have prepared several new uranium containing silicates and several complex transition metal containing uranates via high temperature flux growth. One significant success was the application of mild hydrothermal routes and, in particular, the

development of the two step approach for synthesizing U(IV) containing fluorides. This approach is general and can be used for the preparation of a wide variety of systems, such as the preparation of V(III) and V(IV) containing oxides. In addition to the successful preparation of uranium containing phases, we also prepared non-uranium containing phases, including vanadates (α - $\text{Na}_5\text{V}_3\text{F}_{14}$, β - $\text{Na}_5\text{V}_3\text{F}_{14}$, $\text{Na}_4\text{V}_2\text{O}_2\text{F}_8$, Pb_2VOF_6 , $\text{Pb}_7\text{V}_4\text{O}_8\text{F}_{18}$, and $\text{Sr}_4\text{V}_3\text{O}_5\text{F}_{13}$), titanates ($\text{PbTiF}_5(\text{H}_2\text{O})$ and K_2TiOF_4), copper salts, $[\text{Cu}(\text{H}_2\text{O})_4]_3[\text{M}(\text{III})\text{F}_6]$ ($\text{M} = \text{V}, \text{Cr}, \text{Mn}, \text{Fe}$) and other fluorides ($\text{PbMn}(\text{III})\text{F}_5\text{H}_2\text{O}$).

DOE National Laboratories

Physical Chemistry of Inorganic Nanostructures

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Xiang Zhang
Email: XZhang4@lbl.gov
Principal Investigator: Paul Alivisatos
Sr. Investigator(s): Stephen Leone; Lawrence Berkeley National Laboratory
Peidong Yang; Lawrence Berkeley National Laboratory
Students: 1 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$975,000 (2014)

PROGRAM SCOPE

Advancement in the synthetic control of nanocrystals and nanowires for their use in integrated systems; establishment of core science and technology to produce, separate, and transport charges; and measurement and interpretation of the interactions of nanostructured materials at interfaces, including inorganic-organic, semiconductor-semiconductor, and semiconductor-catalyst interfaces.

FY 2014 HIGHLIGHTS

The research project is a collaborative effort to understand fundamental interfacial charge transfer. We have developed a table-top high harmonic generation spectroscopy setup in the extreme ultraviolet that combines the ultrafast time resolution of optical methods with the electronic structure sensitivity of X-ray techniques to probe detailed carrier dynamics in solid-state semiconductor systems in vacuum and in solvent environments. Pumping with 400 nm light, we detected the ligand to metal charge transfer (LCMT) of Fe_2O_3 (Vura-Weiss *et al.*, *Phys Chem Lett*, 2014). Similar studies were conducted on the Co M-edge of the mixed-valence spinel Co_3O_4 (Jiang *et al.*, *J. Phys. Chem. C*, 2014). We then extended this technique to studying charge dynamics of Co_3O_4 in methanol (Baker *et. al.* *Nano Lett.* 2014). Co_3O_4 decays to ground state in liquid methanol in 600 ps compared to 1.9 ns in vacuum, and the faster dynamics in methanol is associated with hole transfer and recombination at the liquid interface. Other advances include theoretical studies demonstrating that hole transfer from photoexcited quantum dots (QDs) to surface-bound ferrocene occurs in the Marcus inverted region (Tarafer *et al.* *JACS* 2014). Promising new materials and heterostructures have also been made. We used a solid state diffusion method that utilizes atomic layer deposition to controllably alter the composition of rutile TiO_2 nanowires to incorporate Mn dopants, achieving improved electrocatalytic properties for water oxidation (Resasco *et. al.* *JACS* 2014). A synthesized $\text{WO}_3/\text{BiVO}_4$ core/shell nanowire photoanode also achieved the highest product of light absorption and charge separation efficiencies among BiVO_4 -based photoanodes to date (Rae *et. al.* *Nano Lett* 2014). In the next period, we will utilize the developed X-ray techniques to study the fundamental charge dynamics of promising heterostructures and materials.

Two-Dimensional Chalcogenide Nanomaterials

Hongtao Yuan; Stanford University
Students: 3 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$1,100,000 (2014)

PROGRAM SCOPE

Our long-term vision is to build a cutting-edge research program developing an exciting class of two-dimensional (2D) chalcogenide (O, S, Se, Te) nanomaterials, which can generate high impact on a wide range of DoE BES priorities in materials design and control. Our central focus is understanding and utilizing the modification of the physical properties of these materials by their heterogeneous ionic environment. Here this ionic environment is realized through synthesis of heterostructured interfaces, electric double layer gating, electrochemical intercalation and chemical tuning. Based on the past excellent research accomplishments in this area, the co-PI's (Yi Cui, Harold Hwang, Jun-Sik Lee and Shoucheng Zhang) integrate their research activity synergistically to explore an exciting territory of 2D nanomaterials discovery, computational design, synthesis and novel properties. To reach this long-term vision, this proposal outlines three thrusts of research to be conducted within the next three years:

- Thrust 1. Design and synthesis of novel 2D nanomaterials focusing on interfaces between different ionic environments.
- Thrust 2. Ionic tuning of 2D nanomaterials by electric double layer gating, electrochemical interaction and chemical tuning.
- Thrust 3. Probe and manipulate the exciting electronic and photonic properties of these novel materials.

FY 2014 HIGHLIGHTS

This project was initiated in September 2014. Highlights are forthcoming in fiscal year 2015.

Nanostructured Carbon Films

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Larry Curtiss
Sr. Investigator(s): Stefan Vajda; Argonne National Laboratory
Michael Pellin; Argonne National Laboratory
Peter Zapol; Argonne National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$946,000 (2014)

PROGRAM SCOPE

In this program we seek a fundamental understanding of a novel class of materials based on supported subnanometer clusters and support materials under electrochemical conditions. We use our unique capabilities to synthesize well-defined small clusters of specific size and composition, which we have demonstrated that on the right type of support they can be stable, highly active, and selective for a variety of catalytic reactions. Materials based on size-specific subnanometer clusters are attractive for catalysis because (1) they have well-defined and identical catalytic sites, (2) the number of sites can be precisely controlled, (3) their activity can provide valuable insights into catalytic mechanisms, and (4) calculations can be done at sufficient accuracy to allow guidance for design of optimal clusters. Two other key parts to this program are the support materials and computational materials design. One of the supports that we are using is a new form of diamond referred to as ultrananocrystalline diamond (UNCD), which has many unique properties due to combining sp^3 diamond grains with sp^2 -like carbon grain boundaries in one material. We also use our capabilities to synthesize metal oxide supports for the clusters. This can open up many more opportunities to tailor the catalytic activity as the choice of support can have dramatic effect on the catalytic properties of subnanometer clusters. Another key part of this program is the use of characterization and computational capabilities to both understand the properties of the new cluster/nanocarbon composites as well as to perform screening to find optimal candidate clusters to be used on the supports.

FY 2014 HIGHLIGHTS

(1) Size selected Ag clusters for understanding Li-O₂ electrochemistry: In this study of the discharge product morphology Li-O₂ electrochemistry based on precisely controlled subnanometer transition metal cluster catalysts added to a carbon cathode has revealed that these small clusters can be sites for oxygen reduction and that nucleation and growth occurs on separate sites on the cathode suggesting a solution phase process is involved during discharge. This study of specific and well-defined size ORR active sites provided evidence for the first time that metal catalysts can be used to control discharge products in Li-O₂ electrochemistry and provides a potential avenue to reduce the charge overpotentials and increase capacities with less reactive surface morphologies. (2) Characterization of size selected Ag clusters: High resolution transmission electron microscopy has been used to image subnanometer Ag clusters for the first time. The images were taken of fifteen atoms clusters on a carbon surface and have revealed their shape as well as provided direct evidence that the clusters do not agglomerate until a high enough coverage on the surface is reached. This study was part of the study of Li-O₂ electrochemistry described in the first bullet. (3) Electrocatalytic CO₂ reduction on metal clusters: Computational studies of electrochemical reduction of CO₂ to CO, HCOOH and CH₄ were carried out using tetra-atomic transition metal clusters (Fe₄, Co₄, Ni₄, Cu₄ and Pt₄). Novel catalytic properties were predicted for these subnanometer clusters, suggesting that they may be good candidate materials for electrocatalytic CO₂ reduction. Experimental studies are planned to confirm the theoretical predictions. (4) Water splitting on iron oxide supports: Subnanometer Co clusters have been investigated as water splitting electrocatalysts and electrophotocatalysts. The studies identified sub-nm Co cluster supported on iron oxide as active in water splitting.

Materials and Interfacial Chemistry for Next Generation Electrical Energy Storage

Institution: Oak Ridge National Laboratory

Funding: \$582,000 (2014)

The University of Texas at Austin part of this project is listed separately under Principal Investigator: John Goodenough.

PROGRAM SCOPE

Electrical energy storage (EES) in rechargeable lithium-ion batteries is the principal power source for portable electronic devices. As pointed out in the BES Workshop on Electrical Energy Storage, batteries are also needed for effective use of clean, renewable wind and solar energies. This proposal focuses on developing a firm fundamental understanding of the electrode and electrolyte materials and the chemistry at their interfaces that will allow improvement of existing battery strategies as well as the development of alternative battery strategies to meet these challenges. To address the design of improved solid electrodes, the choice of active micro- or nano-particles and their low-cost incorporation into composites with optimal architectures of conductive materials, e.g. polymers, graphene sheets, or amorphous carbon, need to be rationalized. Moreover, the solid-electrode interface with the electrolyte needs to be optimized for Li^+ or Na^+ transfer across it, which includes surface modifications as well as understanding the formation chemistries of any passivating solid-electrolyte interphase (SEI) layer. The latter task requires *in situ* characterizations of surface structures and interface chemistries. To develop alternative battery strategies that allow the use of lithium or sodium anodes and air or liquid-flow-through cathodes, the design and characterization of solid and/or composite solid/polymer-gel Li^+ and/or Na^+ electrolytes as mechanically robust membrane separators need to be undertaken. Membrane design must include investigation of oxide-polymer interactions and barriers to Li^+ / Na^+ transfer across oxide-polymer interfaces. To address these fundamental issues, this project brings together an integrated effort between the University of Texas at Austin (UT Austin) and the Oak Ridge National Laboratory (ORNL), involving strong solid-state and polymer science coupled with advanced characterization and synthetic techniques at the two institutions.

FY 2014 HIGHLIGHTS

(a) A new orthochelated salt, lithium bis(monofluoromalonato)borate (LiBFMB), is synthesized and purified. The presence of fluorine in borate anion of LiBFMB increases its oxidation potential and also facilitates ion dissociation. (b) A TiNb_2O_7 nanoporous anode material was prepared by a facile approach. The interconnected nanoporous framework composed of nanocrystals leads to enhanced rate and cycling performance with high coulombic efficiency. (c) The synthesis of mesoporous Prussian blue analogues through a template-free methodology and the application of these mesoporous materials as high-performance cathode materials in sodium-ion batteries were demonstrated. Crystalline mesostructures were produced through a synergistically coupled nanocrystal formation and aggregation mechanism. (d) A unique class of air-stable magnesium electrolytes was developed based on alkoxide magnesium compounds. The crystals obtained from this class of electrolytes exhibit a unique structure of tri-magnesium cluster, $[\text{Mg}_3\text{Cl}_3(\text{OR})_2(\text{THF})_6] [(\text{THF})\text{MgCl}_3]$. (e) A novel ambient Li-SO_2 battery was developed through the introduction of ionic liquid electrolyte with tailored basicities to capture SO_2 via reversible chemical absorption. (f) The phase changes accompanying the second Li^+ insertion into alpha-

LiVOPO_4 and $\beta\text{-LiVOPO}_4$ are presented at various degrees of lithiation, employing both electrochemical and chemical lithiation. The accompanying structural changes are evidenced by X-ray and neutron powder diffraction. (g) The interfacial structure of a Si battery electrode was determined *in situ* using neutron reflectometry. These measurements show the formation of a reaction layer before lithiation. (h) The intrinsic reaction chemistry of Na with a variety of metal anode materials was investigated. This data showed that Na would only diffuse 3 nm within the Cu_6Sn_5 electrode material. This result enabled us to predict particle sizes which would lead to optimal Na storage properties.

Fundamental Charge Transfer Processes in Stable Free-Radical Organic Polymer Systems

Institution: National Renewable Energy Laboratory
Point of Contact: Bill Tumas
Email: Bill.Tumas@nrel.gov
Principal Investigator: Thomas Gennett
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$381,000 (2014)

PROGRAM SCOPE

Polymers with stable pendant radical groups are an emerging class of redox-active materials with potential application within the next generation of hybrid energy storage matrices. These polymeric materials have demonstrated a unique set of remarkably rapid, efficient and reversible charge-transfer processes. However, there is currently not an advanced understanding of the mechanism(s) involved in electron and/or ion transfer for these polymeric materials. This lack of understanding hinders rational design efforts to improve the electroactive properties of radical containing polymers. The focus of this project is to advance the fundamental understanding of the structure-property relationships associated with the mechanism(s) of electron transfer and ion transport, along with the associated interfacial electron- and mass-transfer processes that impact the charge-transfer processes of this class of organic free-radical polymeric redox active materials. Through an integrated research approach that combines chemical synthesis, electrochemistry, spectroscopy and theoretical modeling applied to a series of stable organic radical materials, we have focused our efforts to establish how the morphologies of the polymer films impact the physio-chemical properties of the organic-based radical materials. Subsequently, the directed syntheses of new materials with tailored properties are utilized to test our models and further advance the understanding of charge transfer in both solution phase and solid-state organic redox systems. This work has crosscutting implications within energy applications such as battery systems, organic-based photovoltaic materials, the use of organic membranes in fuel cells, and more broadly in the use of polymeric materials for organic electronics.

FY 2014 HIGHLIGHTS

In FY 2014, we focused on the 2,2,6,6-tetramethylpiperidine-N-oxyl (TEMPO) organic radical moiety incorporated into a complex materials set of poly(4-methacryloyloxy-2,2,6,6-tetramethylpiperidine-N-oxyl) (PTMA) to probe, and establish, the charge-transfer mechanisms for a series of the TEMPO-containing macromolecules with varying radical fractions, chain lengths and side-chain compositions. Our research indicated that the majority of radicals participate in similar intra- and inter-molecular radical-radical interactions regardless of TEMPO moiety fraction and/or solid versus solvated state. It is these stable radical-radical interactions that control molecular packing and are responsible for the rapid self-exchange charge transfer and electron-transfer reactions observed electrochemically. Through

atomistic molecular dynamics simulations of the structure and morphology of polymer films we were able to establish that inter-TEMPO separations are controlled by steric repulsions between methyl groups that dictate the inter- and intra- molecular packing within the various PTMA materials. Electron spin resonance (CW X-band) evaluation of the radical-polymer local environment in both liquid and solid state indicates that the majority of radicals participate in multiple interactions, regardless of TEMPO moiety fraction. Furthermore the approximate radical-radical distances, $\sim 5 \text{ \AA}$, correlates well with our theoretical predictions that show an effective electron transfer length of 5.5 \AA , with a majority of the electron transfer, nearly 85%, occurring between radical sites on different polymer chains in the solid state. In solution, theory predicts the same local environment for the radical-radical separations, although the interactions were intra-molecular rather than inter-molecular. Finally, to investigate the rate of charge transfer during oxidation we exploited the fluorescence quenching properties of the nitroxide radical.

Giant Nanocrystal Quantum Dots

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor

Sr. Investigator(s): Han Htoon; Los Alamos National Laboratory
Richard Schaller; Northwestern University
Anton Malko; Texas-Dallas, University of
Students: 4 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$631,000 (2014)

PROGRAM SCOPE

Science challenges remain as underpinning drivers of fundamental research required for disruptive advances in solid state lighting (SSL). A fundamental understanding of the processes that impact the conversion of electricity into light is still needed. Nanostructures can serve as platforms for understanding such fundamental processes, but also as solutions to realizing control over exciton \rightarrow photon conversion pathways. In the past year, remarkable progress has been made in the commercial introduction of colloidal nanocrystal quantum dots (NQDs) as unique down-conversion phosphors in small and large display technologies. However, despite this clear advance, applying NQDs to SSL remains challenged by the more rigorous demands of lighting platforms compared to displays, where, e.g., high photon flux and high temperatures must be simultaneously tolerated. In our work, we study and develop a new class of optical nanomaterial – the “giant” NQD (g-NQD) – and its structural variations. g-NQDs exhibit unique properties (non-blinking, non-photobleaching, suppressed Auger recombination, large Stokes shift, surface-independent emission) ideal for SSL. Through three Research Goals, we aim to establish g-NQDs as optimally functional “building blocks” for lighting, with an unprecedented combination of stability/ solid-state performance, high efficiency, low-cost and color tunability: (1) Establish design principles for existing and new g-NQDs (non-rare, non-toxic): (a) Determine process-structure-function correlations and (b) Exploit quasi-combinatorial synthesis aided by *in situ* diagnostics, (2) Understand exciton and multiexciton \rightarrow photon conversion pathways as realized through: (a) Designed manipulation of intrinsic nanoscale heterostructures and (b) Extrinsic field control, especially plasmonic manipulation of recombination processes, and (3) Develop and validate g-NQD device constructs informed by (1) & (2).

FY 2014 HIGHLIGHTS

(1) New 'plasmonic g-NQDs' elucidated/demonstrated: Novel hybrid nano-structures show that we can combine ultrastability of g-NQD quantum emitters with plasmonic field effects provided by an external gold shell, including manipulation of emitter decay processes. (2) Employing project-developed "design principles" for optimal exciton-to-photon conversion: (a) Completed studies of new g-NQDs based on ZnSe/CdS and CdSe/ZnSe, where syntheses complicated by instability against cation exchange and alloying during growth, respectively. Systems used to validate impact of electronic structure on g-NQD properties. (b) Optimized new InP/CdSe/CdS g-NQDs for first dual non-blinking photoluminescence in the visible and near-IR regimes. (3) "Extrinsic-control" studies: Shell-thickness-dependent single-dot spectroscopy investigation of NQD/ graphene couples completed; showed enhanced biexciton quantum yields (BE-QYs) at thick shells with implications for novel lasing devices and entangled-photon generation. We further revealed that collective oscillations of local excess electron/hole density formed at the g-NQD/graphene interface yield a novel "plasmon mode," with important implications for extending graphene plasmonics to visible/near-IR regime and new plasmonic cavity/waveguide design approaches. (4) Facilitating extrinsic control via precision nanoscale integration: (a) Developed two-step e-beam lithography to place single g-NQDs at center of gap-bar nano-antennas; revealed plasmon-assisted energy transfer and plasmonic field's influence on multi-exciton Auger recombination. (b) Optimized dip-pen nanolithography approach for precisely placing <10 NQDs onto sub-micron 3-D structures?

Rational Synthesis of Superconductors

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Mercuri Kanatzidis
Sr. Investigator(s): Duck Young Chung; Argonne National Laboratory
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$631,000 (2014)

PROGRAM SCOPE

This project is a material synthesis program using a multi-faceted approach that combines the rational design of novel materials with structural and electronic characterization probes. We hypothesize that the conception of homologous series of phases with tunable building blocks enables the generation of specific and desirable compositions with predictable structures. This strategy is coherent and can yield novel compounds with specific characteristics desirable for achieving the goals of this program. We focus on materials with a high degree of structural and compositional freedom and chemical/electronic complexity with which to investigate (a) density-wave instabilities (spin and charge), and their suppression through chemical doping in order to generate superconductivity that may emerge from phase competition, and (b) how narrow energy band gaps and facile doping properties could lead to a superconducting state. In the former we investigate low-dimensional intermetallics exhibiting magnetic interactions and spin density waves. In the latter we investigate narrow band ternary and quaternary chalcogenide phases comprising heavy elements such as lead, bismuth, selenium and tellurium. We use a conceptually robust tool in designing, predicting and creating sequences of structurally related materials. The project focuses on relationships between structure, composition, electronic structure and physical properties. In the long term, we expect to clarify the influence of various building blocks on the physical properties and enhance our ability to further design members exhibiting superconductivity.

FY 2014 HIGHLIGHTS

Experimental procedures for synthesis and crystal growth were optimally refined to generate high quality polycrystalline and single crystals of $\text{Ba}_{1-x}\text{K}_x\text{Fe}_2\text{As}_2$ and $\text{Ba}_{1-x}\text{Na}_x\text{Fe}_2\text{As}_2$ across the entire phase diagram. The results also enabled us for the first time to observe re-entrant magnetic order coincident with superconductivity at low temperatures in the $\text{Ba}_{1-x}\text{Na}_x\text{Fe}_2\text{As}_2$ series. For a very narrow Na composition range ($0.24 \leq x \leq 0.28$), the orthorhombic superconducting phase is accompanied by a re-entrant tetragonal antiferromagnetic phase. This finding is a crucial step toward the understanding of the mechanism of superconductivity in the iron pnictides (and perhaps by extension, all high-temperature superconductors in general). $\text{LaPd}_{1-x}\text{Bi}_2$ featuring Bi-square nets and PbO-type PdBi layers was also studied. By creating Pd vacancies the Fermi surface nesting is avoided which suppresses any potential charge density wave (CDW) on the Bi net, apparently allowing the emergence of bulk superconductivity. A strong scattering effect presumably induced by Pd vacancies suggests an s-wave pairing symmetry in $\text{LaPd}_{1-x}\text{Bi}_2$. Hall effect measurements reveal dominantly electron-like charge carriers and single-band transport behavior and the magnetization and broadening of the resistivity transition was measured under different magnetic fields demonstrating a high upper critical field of 3 T. The $\text{CePd}_{1-x}\text{Bi}_2$ analog is non-superconducting but shows antiferromagnetic order below 6 K. On the opposite side of the property spectrum are semiconductors which do not exhibit spin density wave states and historically have not been a source of superconductor materials. Recent results, however, are helping to change this view and promise to open up vast new phase space for investigations. The narrow band gap semiconductor CsBi_4Te_6 were doped to become a new superconductor with T_c around 4 K. Also, noticeable in this CsBi_4Te_6 superconductor is an exceptionally high upper critical field (H_{c2}) up to 10 T observed.

Energy and Fuels from Multifunctional Electrochemical Interfaces

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Nenad Markovic
Sr. Investigator(s): Vojislav Stamenkovic; Argonne National Laboratory
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,125,000 (2014)

PROGRAM SCOPE

We propose an interdisciplinary, atomic/molecular level approach, integrating both experimental- and computational-based methodologies to design, synthesize, and characterize electrochemical (EC) interfaces with tailored properties, with a specific focus on addressing closed-loop energy/chemical/environmental cycles based on water, carbon, and lithium. Two fold strategies will be used: (i) first is based on a materials-by-design strategy, involving transferring the knowledge gained from the single crystalline materials and thin metal films to nanoscale materials; and (ii) the second relies on the double-layer-by-design strategy, bearing precise organization of multiple functionalities of the electrolyte components at the sub-nano-scale regime that is operating in the double layer. These two strategies form a closed-loop material/electrolyte design approach wherein the knowledge gained from the model systems is used to tailor the more complex, real-world systems. The range of materials and electrolytes that will be explored by these two strategies is broad, involving metals, metal/metal-oxides, pure oxides, sulfur-based and carbon-based materials as well as aqueous electrolytes with a

wide pH range and organic solvents that are traditionally used in the battery systems. The methods for unraveling complexities that is controlling interfacial properties is diverse, ranging from *ex situ* and *in situ* optical methods to microscopy-based structural probes to synchrotron-based techniques and classical electrochemical methods. Advancing in fundamental understanding of the reaction mechanisms and kinetics involved on well-characterized metal, oxide, and metal/metal-oxide materials in both aqueous-based and organic-based environments will be critical in our quest to learn how to design efficient, stable and selective electrochemical systems that are needed by our society.

FY 2014 HIGHLIGHTS

- Established functional links between conductivity, stability and activity of SrRuO₃ single crystal thin metal films in the oxygen evolution reaction.
- Designed new generation of active and stable Ru-Ir based catalysts for the water splitting reaction and oxygen production in acidic-based electrolyzers.
- Based on electrocatalytic trends for the hydrogen oxidation reaction in alkaline solutions, developed cost-effective catalysts with the highest activity ever observed in alkaline environments (two orders of magnitude more active than the state-of-the-art Pt-based materials).
- Established new guiding principles for the development of bi-functional catalysts for efficient transformation of hydrogen energy into electricity in fuel cells and electrolyzers.
- Based on fundamental knowledge established on single crystal surfaces, designed mesostructured thin films catalysts, with adjustable structure and composition, for the oxygen reduction reaction in PEM based fuel cells.
- Developed surface science approach for studying electrochemical interfaces in organic solvents.

Diamondoid Science and Applications

Institution: SLAC National Accelerator Laboratory
Point of Contact: Thomas Devereaux
Email: tpd@stanford.edu
Principal Investigator: Nicholas Melosh
Sr. Investigator(s): Peter Schreiner; Justus-Liebig University
Zhi-Xun Shen; Stanford University
Jeremy Dahl; Stanford University
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$768,000 (2014)

PROGRAM SCOPE

This program explores the synthetic, electronic, and self-assembly aspects of diamondoids, a new class of hydrogen-terminated molecular diamonds. These materials bridges the gap between small molecules and nanoparticles, having some of the benefits of small molecule chemistry, such as atomically defined structures, site selective functionalization, and facile organization, and some of the benefits of nanoparticles, such as excellent electronic properties, robustness, and strong interaction forces. These materials have demonstrated an amazing ability to regulate the energy of electrons flowing through single monolayer films, form 'extreme' carbon-carbon bonding structures, and dramatically enhanced electron emission processes. We study these systems through a set of interrelated synthetic modifications, self-assembly, X-ray scattering, templating, and electron transfer studies. We seek to understand how the unique combination of the rigid lattice and sp³ hybridization lead to the unique properties compared to related alkane or sp²-based carbon systems.

FY 2014 HIGHLIGHTS

(1) Developing new methods for selective C-C bond modification. Diamondoids are an ideal system to explore the limits of synthetic control due to the remarkably similar molecular reaction sites, requiring subtle manipulation of chemical reactivity for site-selective modifications. We have developed several significant modification schemes to provide broad functionality to the diamondoids. In particular, vinyl adducts are a well known functional group that can incorporate diamondoids into a wide variety of systems, ranging from diamondoid based polymers to surface modifications (2) Diamondoid-C₆₀ molecular rectifiers. We reported a novel all-hydrocarbon molecular rectifier consisting of a diamantane-C₆₀ conjugate. By linking both sp³ (diamondoid) and sp² (fullerene) carbon allotropes, this hybrid molecule opposingly pairs negative and positive electron affinity moieties. The morphology and single-molecule conductances of self-assembled diamantane-C₆₀ domains on Au(111), probed by low-temperature scanning tunneling microscopy and spectroscopy, reveal a large rectifying response of the molecular constructs. This specific electronic behavior is postulated to originate from the electrostatic repulsion of diamantane-C₆₀ molecules due to positively-charged terminal hydrogen atoms on the diamondoid interacting with the top electrode (scanning tip) at various bias voltages.

Innovative and Complex Metal-Rich Materials

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov
Principal Investigator: Gordon Miller
Sr. Investigator(s): Qisheng Lin; Ames Laboratory
Srinivasa Thimmaiah; Ames Laboratory
Students: 1 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$737,000 (2014)

PROGRAM SCOPE

This project strives (i) to uncover and ultimately design new families of intermetallic phases; (ii) to understand the factors that stabilize both new and known metal-rich phases by combining exploratory synthesis and temperature-dependent structure determinations with electronic structure theory; and (iii) to establish structure-property relationships for complex metal-rich materials as related to both practical as well as fundamental issues, e.g., thermoelectric, magnetocaloric, catalytic, and magnetic behavior. Targeted compound classes include, but are not limited to, Hume-Rothery types, polar intermetallics, quasicrystalline and approximant phases, and complex metallic alloys of transition metals. Significant focus includes (i) compounds involving reduced environments for elements of the late 5th and 6th period transition elements (Pd, Pt, Ag, Au), which offer filled d-bands and relativistic enhancements of chemical bonding; (ii) Li-rich intermetallics, taking advantage of Li's dual role of both an active as well as an electronegative metal in chemically reduced environments; and (iii) 3d metal systems grown in reactive and eutectic fluxes.

FY 2014 HIGHLIGHTS

Discovery of new compounds with unusual metal-metal bonds and thorough studies of certain phase spaces were accomplished during the past year. Achievements include the discovery all three ordered BaAl₄-type variants in the Ba-Au-Sn system, which allows, for the first time, the development of a unified view on the interplay between valence electron counts and phase stabilities of these three prolific,

ordered derivatives of the $BaAl_4$ -type. Following up on the lessons learned, a systematic study of the Sr-Au-Sn system was accomplished. Toward a search for new anode materials, we discovered three new Ca-Li-Zn compounds. The understanding of Li-induced Zn clustering in these phases may help to understand the formation of Zn dendrites on electrodes during charge-discharge cycles for Zn batteries. Interpretation of these structures challenges the current Zintl-Klemm concepts of chemical bonding in polar intermetallics. We discovered and characterized new reduced gold and platinum metal-rich compounds with unusual bonding modes and noncollinear magnetic ordering, demonstrating how electronegative gold atoms can serve as ligands (“pseudo-halides”) to transition metals like manganese and provide exchange pathways between magnetically-active 3d metals with rare earth metals. Moreover, new bonding motifs involving the electronegative metals are broadening our understanding of metal-metal bonding within intermetallics. Additionally, the team discovered new ferromagnetic gamma-brasses, re-examined the compositions, structures, and atomic distributions in Fe-Zn and Co-Zn gamma brasses, and discovered two large unit cell structures built of icosahedra using a Zn/Sn flux with 3d transition metals like chromium and vanadium. In collaboration with other groups, we discovered various new phases and a new ferromagnetic Mn-doped (5-15 at.%) rhombohedral-boron with Curie temperature of 500 K and a magnetic moment of $2.4 \mu_B/\text{Mn}$ at 300 K.

Nuclear Magnetic Resonance

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Xiang Zhang
Email: XZhang4@lbl.gov
Principal Investigator: Alex Pines
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$970,000 (2014)

PROGRAM SCOPE

With the support of the DOE BES, our group develops new methods and technologies based on nuclear magnetic resonance and magnetic resonance imaging for the non-invasive investigation of materials structure, function, chemistry, and organization at all length scales. We seek to decrease the dependence of magnetic resonance on expensive infrastructure and lengthy experiments and to enable new applications with enhanced portability and sensitivity. We collaborate with other MSD core programs both to develop new materials and structures used in our own experiments and to pursue exemplary applications of the technology we develop.

FY 2014 HIGHLIGHTS

We harnessed nitrogen vacancy (NV-) centers in diamond as a means of detecting nearby spins. By monitoring the fluorescence of these defect centers, we are able to probe their spin state and extract information about their environment. This enabled the development of “cross relaxation spectroscopy” where spectroscopic information of surrounding electron spins is obtained. We identified long-lived nuclear spin states at zero magnetic field, which take advantage of the inherent symmetry of the zero-field environment to protect the nuclear spin state from a fluctuating environment. These states may be used, in conjunction with nuclear hyperpolarization techniques, to store nuclear spin order for extended time periods. We made significant progress towards miniaturization of xenon-based NMR systems with the development of on-chip xenon hyperpolarization, encoding and detection. This advance opens up the possibility for sensitive, portable sensors that bring NMR outside of the lab and into new fields. Our

work continues on improving the fundamental sensitivity of xenon-based NMR on multiple fronts including: shift enhancement via paramagnetic sensors; microfluidic-based assays with remote detection, and relaxation based sensors that work in the absence of strong magnetic fields.

Hydroxide Conductors for Energy Conversion Devices

Institution: National Renewable Energy Laboratory
Point of Contact: Bill Tumas

Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$288,000 (2014)

PROGRAM SCOPE

Stable, hydroxide conducting anion exchange membranes can act as enabling elements of several energy conversion and storage technologies. The primary goal of this project is to understand and improve the hydroxide stability of covalently tetherable cations for their incorporation into anion exchange membranes. We have investigated hydroxide stability of cations using a combined computational and experimental approach. Our work initially focused on ammonium based cations that have been the standard materials employed in anion exchange membranes. We have used computational modeling to validate experimental results and to lead our efforts to develop more robust cations. We have investigated the impact of chemical substitution on the stability of cations. BTMA is the cation that has been the most studied for polymer incorporation and currently dominates anion exchange media. For practical purposes, BTMA is small, compact, relatively basic, and cheap/easy to synthesis, so if it was displaced from this application it would have to be due to other factors. Our most recent efforts have focused on cation chemistries of imidazolium, phosphonium, and (substituted) benzyl trimethyl ammonium (BTMA). Results have shown that imidazolium and phosphonium moieties exhibit large changes in degradation energy barriers while BTMA shows relatively small changes. Our experimental studies have focused on coordination with our computational studies, as well as method development for more reproducible and reliable measurements of durability. BTMA has been used as a model molecule and its durability (in the first comprehensive and reproducible studies presented in the literature) was found to be significantly more durable than previously reported. This increase in durability was determined by isolating specific accelerants that were common in the experimentally difficult approach for studying high temperature, high pH degradation.

FY 2014 HIGHLIGHTS

FY 2014 resulted in detailed studies of degradation reactions of benzyl trimethylammonium (BTMA). Through literature review and experience with hydroxide based degradation studies, we had noticed a trend of inconsistent experimental findings for reported degradation rates of cations. Unfortunately, performing repeatable and accurate measurements under high pH, high temperature conditions is exceptionally challenging. We have developed advanced degradation techniques involving hermetically sealed Teflon reactors, known thermal responses, avoided the use of deuterium, and determined acceptable (low) concentration of cations that avoid phase separation. Through these studies we have accurately quantified the degradation rate of BTMA and shown that BTMA is much more stable than previously assumed with approximately 10% degradation over 5000 hours at 80C. Conditions which suggest its ability to be used in specific applications may already be acceptable. We also looked at the

influence of systematic substitution to impact the stability of BTMA. Computationally we investigated methyl, methoxy, nitro, hydroxyl, primary amine and complex amine substitution (both single substitutions and multiple substitutions). Experimentally we have investigated methoxy and nitro substitutions. We have found that modest gains can be realized by specific substitution groups and patterns, but these stability improvements result in less than an order of magnitude increase in stability, which is far less than what we have observed for either imidazolium based cations or phosphonium based cations (two advanced cation families that we have also investigated). We have significantly increased our interactions with other research groups who have begun to recognize our specific methods and tools as novel and advanced including Dan Knauss (Colorado School of Mines), Yusan Yan (Delaware), Mike Hickner (Penn State), and Chulsung Bae (RPI).

Chemical and Mechanical Properties of Surfaces, Interfaces and Nanostructures

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Xiang Zhang
Email: XZhang4@lbl.gov
Principal Investigator: Miquel B. Salmeron
Sr. Investigator(s): Gabor A Somorjai; Lawrence Berkeley National Laboratory
Peidong Yang; Lawrence Berkeley National Laboratory
Students: 3 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$1,601,000 (2014)

PROGRAM SCOPE

In this program we carry out atomic and molecular level studies of surfaces and interfaces, focusing on structure, adsorption, reactions, energy transfer across interfaces, and nanoparticle growth, to obtain a fundamental understanding of the mechanisms that govern the physical, chemical, catalytic and tribological properties of materials. We study how the structure of surfaces determines these properties, and how energy is transferred by vibrational, electronic and photonic excitations of surface atoms and molecules. Single crystals and nanoparticles are key materials investigated. An important activity is the development of techniques and methods that make possible surface sensitive microscopy and spectroscopy studies of surfaces in different environments, expanding the ultrahigh vacuum environment of traditional surface science to ambient gas pressures and to solid-liquid interfaces. The basic science of the solid-liquid interface is a new frontier that has been opened by the recent development of new instruments and techniques. It is a central piece of our strategy for the future that we plan to develop.

FY 2014 HIGHLIGHTS

Atoms at step edges are the most reactive and are active in catalyzing many reactions. The critical influence of their geometric arrangement on Pt(111) surfaces towards their reactivity under ethylene and CO was revealed using Scanning Tunneling Microscopy *in situ*. While CO molecules reconstruct the steps at pressures of 1 Torr, causing the formation of clusters of atoms, ethylene can reverse this reconstruction. This occurs only on steps with atoms arranged in triangular motifs. Ethylene can't restore the initial steps when atoms are arranged in square motifs, due to the fact that ethynylidyne, the adsorption product of ethylene, adsorbs only on triangular motifs of atoms. This shows that even small changes in atomic geometry of the catalyst atoms leads to important changes in reactivity. We synthesized highly active and durable electrocatalysts by exploiting the structural evolution of platinum-nickel (Pt-Ni) bimetallic nanocrystals. The starting material, crystalline PtNi₃, transforms in solution by

interior erosion of Ni atoms into Pt₃Ni nanoframes, with three-dimensional molecular accessibility. Both interior and exterior catalytic surfaces of this open-framework structure are composed of a segregated Pt-skin structure exhibiting enhanced oxygen reduction reaction activity. The Pt₃Ni nanoframe catalysts achieved a factor of 36 enhancement in mass activity and a factor of 22 enhancement in specific activity during prolonged exposure to reaction conditions. The structure of H₂O in the double layer on biased gold electrodes was determined for the first time with a combination of x-ray absorption spectroscopy and first principles calculations. At zero or positive bias, about 50% of the molecules lie flat on the surface with all H bonds saturated, and 30% with broken H bonds that do not contribute to the x-ray spectrum. At negative bias, the population of flat-lying molecules with broken H bonds increases, producing a spectrum similar to that of bulk H₂O.

Directed Energy Interactions with Surfaces

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Mike Savina
Sr. Investigator(s): Alexander Zinovev; Argonne National Laboratory
Michael Pellin; Argonne National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$504,000 (2014)

PROGRAM SCOPE

The Directed Energy Interactions with Surfaces program focuses on fundamental studies of the interaction of directed energy sources such as energetic ions with materials, which provides the basis for characterizing and modifying materials. Fundamental understanding of energy-material interactions drives the development of world-class instruments and methods for materials characterization, which in turn enables us to answer questions about new or previously unobservable phenomena and develop new materials. The long-term goal is to understand the interaction of directed energy sources with materials, both in model systems in which basic interactions can be studied in great detail, and in complex systems relevant to DOE missions in which multiple interactions occur and evolve over varying length and time scales.

FY 2014 HIGHLIGHTS

Ion sputtering as a means of generating clusters of various compositions remains one of the least understood phenomena in particle-solid interactions. During sputtering, three distinct processes, i.e. cluster formation, ionization, and fragmentation, occur quasi-simultaneously; the challenge is to distinguish between them and learn basic laws driving the cluster formation process. Secondary Neutral Mass Spectrometry (SNMS) with Single Photon Ionization (SPI) minimizes fragmentation while separating cluster formation and ionization. Recently we applied SMNS-SPI to cluster emission from the ternary alloy Au₇Cu₅Al₄, with a focus on the effect of surface modification via ion irradiation. The cluster yield after pretreatment with Ar⁺ ions shows a large energy-dependent change. High-energy pretreatment significantly enhances Al-containing clusters, while low-energy pretreatment significantly enhances Au-containing clusters. We have previously shown that the cluster yield depends strongly on the first layer composition of the alloy. Preferential sputtering is well known and could account for changes in the relative cluster yields for low ion doses, but this is not the case here. Furthermore, the effect persists for large clusters, which are relatively insensitive to the surface composition. The Ar⁺

penetration depth decreases with ion energy, with a maximum in the first 2-5 monolayers. XPS measurements indicate that some Ar is implanted, though amounts are not expected to remain at such shallow depths. This must be quantified since implanted Ar atoms near the surface would have an effect on sputtering yields. Cluster compositions and yields are clearly affected by chemical and morphological changes due to irradiation, and represent a sensitive measure of the surface state, one that gives different and perhaps richer information than simply surface concentration.

Materials Chemistry - Solid State NMR

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov
Principal Investigator: Klaus Schmidt-Rohr
Sr. Investigator(s): Viatches Dobrovitski; Ames Laboratory
Mei Hong; Ames Laboratory
Evgenii Levin; Ames Laboratory
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$703,000 (2014)

PROGRAM SCOPE

It is the purpose of this program to develop and apply advanced solid-state nuclear magnetic resonance (NMR) techniques for elucidating the structure and dynamics of complex organic, nanocomposite, and semiconductor materials with interesting properties. Modern multinuclear NMR can provide detailed information on the composition and supramolecular structure of complex materials, even in the presence of disorder, and guide the rational design of novel materials. The research in this FWP can be grouped into the following focus areas: (1) Nanocomposites, in particular biological (e.g., bone) and related bioinspired materials, by ^{31}P , ^1H , and ^{13}C NMR. (2) Polysaccharide-rich plant cell walls, elucidating how the energy-rich cellulose and hemicellulose are bound to other biopolymers in the cell wall, using 2D and 3D ^{13}C NMR. (3) Proton conductors, such as the Nafion fuel-cell membrane, by ^{19}F and ^{13}C NMR. (4) Thermoelectric tellurides, characterizing by ^{125}Te NMR the distribution of dopants, charge-carrier concentrations, and local symmetry, and correlate with electronic and thermal transport properties measured in-house. (5) NMR of carbon materials as used in supercapacitor electrodes, and nanodiamond, by ^{13}C NMR. (6) General NMR pulse-sequence development to provide new structural information. (7) Simulations of NMR parameters and scattering curves for extracting the maximum information content from the available data.

FY 2014 HIGHLIGHTS

We discovered an unusual inverse relation between the Seebeck coefficient and carrier concentration in $\text{Ag}_x\text{Sb}_x\text{Ge}_{50-2x}\text{Te}_{50}$ materials, which can be explained by strong energy filtering of charge carriers. We demonstrated that ^{125}Te NMR can be used for determination of carrier concentration in multiphase materials, which is not possible to obtain from Hall effect measurements. This year we also showed the effect of replacement of Ge in GeTe by Ag, Sb, and Dy on ^{125}Te NMR spectra, carrier concentration obtained from spin-lattice relaxation and thermoelectric properties measurements. Using dynamic nuclear polarization enhanced solid-state NMR, the Hong group discovered the long-elusive carbohydrate-binding target of the glycoprotein, expansin, in the plant cell wall. Expansin binds hemicellulose-enriched regions of cellulose to loosen the cell wall for growth.

Polymer-Based Multicomponent Materials

Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$1,925,000 (2014)

PROGRAM SCOPE

Multicomponent polymeric materials are widely used in various modern technologies and will have even broader applications in future technologies, from lightweight materials, to solar cells and electrical energy storage to biomedical technologies. Yet, our fundamental understanding of the processes and interactions that control macroscopic properties in these materials remains limited. The overarching goal of the research proposed herein is to develop a fundamental understanding of how interfacial properties and interactions affect structure, morphology, dynamics, and macroscopic properties of multicomponent polymeric systems. The proposed research focuses on two research themes. The first seeks to correlate properties of polymer-nanoparticle mixtures to the nanoparticle structure and interfacial interactions, while the second involves the correlation of molecular architecture, electrostatic interactions and external fields to the morphology of multiblock copolymer materials. To fully understand the underlying processes and mechanisms, we pursue a comprehensive interdisciplinary approach lead by advanced theory and simulations, precise synthesis with nano-scale control and state-of-the-art characterization (with special emphasis on neutron scattering). The fundamental knowledge developed in this program will contribute to the scientific foundation for the rational design of multicomponent polymer based materials with superior properties and function that can address many DOE challenges such as organic photovoltaics, electrical energy storage and fuel cell membranes, and stronger light-weight materials that result in energy savings.

FY 2014 HIGHLIGHTS

By combining theory, computations and experiment we elucidated the physical mechanisms that determine effective nanoparticle interactions controlling dispersion in polymer nanocomposites (PNC). A theoretical basis has been developed for designing random copolymers to optimize fullerene miscibility. The developed approach predicts a remarkably rich phase behavior and can help guide the development of PNC for photovoltaic applications. The first predictive statistical mechanical theory for activated relaxation in thermal liquids has been formulated. The theory captures the key features of the alpha-relaxation time as a function of temperature and pressure from picoseconds to hundreds of seconds. The approach has been extended to polymers and the role of chain length and stiffness on T_g and fragility elucidated. This advance sets the stage for addressing how confinement and surface/interface effects modify the alpha-relaxation and elasticity in PNCs. Synthesis of soft polystyrene nanoparticles with the size ~ 10 nm has been developed. SANS identified three distinct nanoparticles morphologies that can be well controlled by varying the crosslinking density: (i) fuzzy soft gels; (ii) smooth soft gels; and (iii) dendritic glassy gels. Combining dielectric spectroscopy (DS), DSC and SAXS,

we unraveled the role of nanoparticles on the structure and dynamics of PNC. A thin interfacial polymer layer that has very different density and dynamics than the bulk polymer was deduced. The thickness of the interfacial layer of P₂VP on SiO₂ nanoparticles is ~5 nm in both static (SAXS) and dynamic (DS and DSC) measurements. The layer is not “dead” or “glassy”, but its dynamics are slowed by ~100 times relative to the bulk polymer. These results explain many controversies in the PNC field, provided new insight into the structurally and dynamically heterogeneous nature of PNCs, and demonstrated the need to explicitly consider the interfacial layer to construct predictive models.

Inorganic/Organic Nanocomposites

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Xiang Zhang
Email: XZhang4@lbl.gov
Principal Investigator: Ting Xu
Sr. Investigator(s): Paul Alivisatos; Lawrence Berkeley National Laboratory
Miquel B. Salmeron; Lawrence Berkeley National Laboratory

Tanja Cuk; Lawrence Berkeley National Laboratory
Yi Liu; Lawrence Berkeley National Laboratory
Students: 2 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$1,215,000 (2014)

PROGRAM SCOPE

The Inorganic/Organic Nanocomposite program aims to design and synthesize organic and inorganic building blocks, and guide their assemblies into functional nanocomposite materials by developing a thorough understanding of interfacial electronic properties with an ultimate goal to generate functional hybrid materials with tailored electrical and optical properties.

FY 2014 HIGHLIGHTS

We systematically (1) investigated the phase behavior of supramolecular nanocomposites in thin films to achieve structural control over nanocomposites containing spherical particles and nanorods as well as particle mixtures; (2) performed detailed analysis of assembly process and kinetic pathway that led to optimized solvent annealing process to obtain hierarchically structured nanocomposites in one minute; (3) developed molecular level understanding of surface of PbS nanoparticle both theoretically and experimentally; (4) designed organic conductive ligand to achieve energy level alignment for efficient carrier transport in thin films of nanoparticle solids; and (4) correlated Kelvin probe force microscopy (KPFM) microscopy & spectroscopy with scanning tunneling microscopy/spectroscopy (STM/STS) to study the impurity conduction mechanisms of PbS quantum dots. In addition, we established a new direction to use tetrapod nanocrystals as fluorescent stress probes to investigate the mechanical properties of nanocomposites at nanoscale.

Mechanical Behavior and Radiation Effects

Institutions Receiving Grants

Software Center for Predictive Theory and Modeling

Students: 4 Postdoctoral Fellow(s), 12 Graduate(s), 0 Undergraduate(s)
Funding: \$2,000,000 (2014)

PROGRAM SCOPE

The overarching goal is to establish a unique scientific platform that will enable accelerated predictive materials science. This will be accomplished by completing the following objectives: 1. Develop and establish PRISMS (PRedictive Integrated Structural Materials Science), a suite of integrated multi-scale computational tools for predicting the microstructural evolution and mechanical behavior of structural metals. This software suite will be open-source extensible, user friendly and efficient. 2. Develop advanced, open source computational methods for metallic materials. 3. Tightly couple the computational methods with advanced experimental methods for determining model inputs, filling gaps in theory and for validation. 4. Demonstrate this integrated capability by making major advances in the quantitative and predictive understanding of magnesium alloys, in particular the phenomena of: (i) complex, microstructure-dependent deformation processes of magnesium alloys; (ii) fatigue, ductility, and stress-strain response of structural metals; (iii) theory of microstructure evolution and its effect on fatigue and ductility. 5. Develop and deploy "The Materials Commons," a knowledge repository and virtual collaboration space for curating, archiving and disseminating information from experiments and computations as well as providing a collaborative platform for development of open-source code with active involvement of a broader PRISMS open source community. The center will establish systematic protocols for extension of this integrated multi-scale computational capability to the development of predictive capabilities for other structural materials and to incorporate emerging modeling and experimental methods.

FY 2014 HIGHLIGHTS

To ensure effective integration of PRISMS Center activities, our science objectives are organized around 'use cases'. These use cases provide a means to establish collaborative communities, advance science

and demonstrate linkages and capabilities. The primary use cases are prediction of precipitate evolution, recrystallization and grain growth, tensile properties and cyclic/fatigue properties of Mg and Mg alloys. Highlights of our technical progress include: • Using the advanced PRISMS statistical mechanics software (CASM), a free energy description was developed for ordering precipitation within hcp Mg-rare earth alloys and structural transitions from ordered hcp to ordered bcc. • Used the massively parallel PRISMS phase field code with the CASM-determined energetics to predict growth of β' precipitates in Mg-Nd alloys. • Through high resolution imaging and quantification of chemistry and morphology of precipitates, identified key phenomena in the sequence of phase transformations. • Completed real space DFT calculations that estimated that core-size of edge dislocation in aluminum are three times larger than indicated by conventional estimates. • Completed the first use of PARADIS dislocation dynamics simulations to calculate strengthening from precipitates in Mg (hcp) alloy (with LLNL). • Established methodology for modeling mechano-chemical driven phase transformations. • Used phase field crystal model to calculate grain boundary structures and energies in 2D and compared with molecular dynamics simulations. • Developed novel in-situ ultrasonic fatigue instrumentation to examine fatigue crack initiation and small crack growth in Mg alloys. • Demonstrated capability of digital image correlation for quantifying heterogeneous strain distributions within grains, at grain boundaries and adjacent to twins. • Demonstrated capability of crystal plasticity code to simulate tensile cracking at grain boundaries and fatigue crack propagation in polycrystals.

Structure/Property Relationships in Two-Phase f.c.c./B2 FeNiMnAl Alloys

Institution: Dartmouth College
Point of Contact: Ian Baker
Email: ian.baker@dartmouth.edu
Principal Investigator: Ian Baker
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 4 Undergraduate(s)
Funding: \$169,000 (2014)

PROGRAM SCOPE

The aim of this work is to develop an understanding of the microstructural stability and deformation mechanisms that control the strength of potentially-useful fcc/B2 FeNiMnAl alloys over a range of temperatures and strain rates. In addition, we are determining the origin of three particularly intriguing phenomena that we have found in FeNiMnAl alloys, i.e. 1. While $\text{Fe}_{25}\text{Ni}_{25}\text{Mn}_{30}\text{Al}_{20}$ shows no change in RT hardness upon annealing at 823 K for times up to 100 h, the related alloy $\text{Fe}_{30}\text{Ni}_{20}\text{Mn}_{30}\text{Al}_{20}$ shows a 45% increase in hardness when annealed over the same period with all of the increase occurring within the first 10 h. 2. $\text{Fe}_{28}\text{Ni}_{18}\text{Mn}_{33}\text{Al}_{21}$ fractures before yield under tension in the as-cast state, but exhibits increasing failure strains (up to 7%) as the microstructure coarsens (sic) and loses its blocky character upon annealing. 3. The elongation to fracture of the coarse, two-phase fcc/B2 alloy $\text{Fe}_{30}\text{Ni}_{20}\text{Mn}_{35}\text{Al}_{15}$ increases from 7% to 19% with increasing chromium additions (up to 6 at. %), with a concomitant decrease in the yield strength. The work involves: (1) Microstructural characterization of several two-phase fcc/B2 FeNiMnAl (with up to 6 at. % Cr) both after various heat treatments and after elevated temperature mechanical testing using a combination of state-of-the-art techniques and instruments. (2) Measuring the strength and ductility under tension as a function of temperature and strain rate after different heat treatments and for various Cr additions (up to ~6 at. %). (3) Determining the deformation mechanisms using a combination of post-mortem TEM dislocation analysis, post-mortem SEM fractography, TEM in-situ straining studies, and SEM in-situ straining studies. (4) Using the above results

to evaluate existing models of strength and ductility of similar microstructures and/or develop new models based on the experimentally-observed deformation mechanisms.

FY 2014 HIGHLIGHTS

The microstructure and mechanical properties of $\text{Fe}_{28}\text{Ni}_{18}\text{Mn}_{33}\text{Al}_{21}$, which consists of fine (50 nm phase width) B2 and fcc phases, have been studied in both the as-cast and annealed states. Upon annealing the fine aligned microstructure is replaced by a coarser microstructure, in which the phase size increased with increasing annealing time, up to ~2500 nm for a 250 h anneal. The as-cast alloy showed brittle fracture at room temperature, while the annealed materials all showed yielding before fracture, the elongation to failure increasing with increasing phase width. Tensile tests performed on $\text{Fe}_{30}\text{Ni}_{20}\text{Mn}_{35}\text{Al}_{15}$ with various Cr additions at a strain rate of $5 \times 10^{-6} \text{ s}^{-1}$ showed that even with a chromium additions as low as 0.5 at. %, the environmental embrittlement suffered by this alloy can be ameliorated: increasing Cr additions lead to a slow decline in room temperature yield strength but increasing elongation to values of 674 MPa and 18% elongation, respectively, at 6 at. % Cr. XPS showed that both Cr and Al form protective oxides at the surface and provide rapid passivation, thereby reducing hydrogen liberation rates on the surface and minimizing the environmental embrittlement. As-cast $\text{Fe}_{36}\text{Ni}_{18}\text{Mn}_{33}\text{Al}_{13}$ was cold-rolled to a thickness reduction of ~65% and then annealed at various temperatures from 1000-1273K for one hour. The hardness of the as-cast alloy is 193 HV, while that for the cold-rolled alloy followed by annealing at 1000K or 1273K was 412 HV and 250 HV, respectively. In room temperature tensile tests, the 1273K annealed material had an elongation of 21% (comparable to the as-cast material) but a 25% increase in yield stress to ~575 MPa. TEM examination shows this processing produced a fine-grained structure due to recrystallization. Oxidation tests performed on $\text{Fe}_{30}\text{Ni}_{20}\text{Mn}_{35}\text{Al}_{15}$ with and without 6 at. % Cr at 1073 K and 1273K showed that while all alloys showed excellent oxidation resistance, the Cr-modified alloy showed the better oxidation resistance.

Materials for Extreme Irradiation Environments

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Pascal Bellon
Email: bellon@illinois.edu
Principal Investigator: Pascal Bellon
Sr. Investigator(s): Robert Averback; Illinois-Urbana Champaign, University of
Shen Dillon; Illinois-Urbana Champaign, University of
William King; Illinois-Urbana Champaign, University of
Dallas Trinkle; Illinois-Urbana Champaign, University of
Students: 1 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

A common roadblock to the future-generation energy technologies proposed for high-efficiency energy production is the lack of materials that could function safely and economically in the envisioned harsh and aggressive in-service environments. This materials challenge is a daunting one, as required in-service conditions represent major departures from current systems, pushing materials into new domains, in particular, high levels of irradiation damage and high temperatures. In each of the DOE BES workshops on Basic Research Needs for Future Energy Technologies, it was recognized that current technologies could not be modified to provide the required order(s) of magnitude improvements in materials properties, and that a new paradigm was needed for designing, assessing and certifying new

materials. We proposed a new approach to design materials that are intrinsically resistant to irradiation and other extreme environments by utilizing nanostructuring and self-organization in these nonequilibrium systems. While we focus on nuclear applications, we expect that the scientific advancements achieved in this Cluster will have broad based significance for materials needs in a number of other advanced energy technologies. Our work will be directly related to the following two DOE-BESAC Grand Challenges: Characterizing and controlling matter away from equilibrium; Learning how remarkable properties emerge from complex correlations of atomic or electronic constituents and how we can control these properties. Our Cluster investigates the fundamental processes controlling the formation of novel, self-organized, nanostructured materials, their long-term structural and dimensional stability, and the relationships between the nanoscale features and the macroscopic properties. The research combines irradiation experiments, *in situ* and *ex situ* characterization of microstructure and properties, and atomistic simulations and continuum modeling.

FY 2014 HIGHLIGHTS

In FY 2014, we confirmed by atom probe tomography the stabilization by ion irradiation of compositional patterns and unique “cherry-pit” structures in the immiscible Cu-Fe and Cu-V alloys. We also demonstrated that irradiation-induced nanostructuring can take place in ternary alloy systems that form compounds, such as Cu-Si-Mo and Ni-W-C, thus greatly extending the range of alloy systems of interest. Interfaces play an essential role as point defect sinks for controlling the stability of these self-organized structures, but sink strengths are very rarely, and often only indirectly, measured. We overcame this issue by employing a novel marker broadening technique, which was applied to determine the sink strength of various Cu-X interfaces, X= Ni, V, Nb. We also investigated the mechanical properties of nanostructured alloys, using in-situ techniques. In particular we designed and validated a novel apparatus to measure the creep response of miniaturized metal pillars during high temperature irradiation. This apparatus made it possible to measure and compare the creep compliance of diverse materials, including CuTiAg metallic glass, Si, SiO₂, and Si₃N₄, and to isolate the contributions of electronic and nuclear excitations to irradiation creep. Furthermore, we used in-situ nanocompression tests in a transmission electron microscope to determine the strength of distinct Cu-Nb interfaces, revealing the contribution of interface crystallography and of irradiation-induced mixing on interface shear strength. On the modeling side, we investigated quantitatively the effect of lattice structure and strain fields on irradiation-induced segregation in alloys. These results were achieved by new and key extension to the so-called self-consistent mean-field model. This allowed us to couple first-principle calculations to phase field-type modeling of solute redistribution, for instance around dislocation cores, in specific alloy systems, including Ni-Si.

Characterization and Modeling of Deformation Induced Damage in Titanium Alloys

Institution: Michigan State University
Point of Contact: Carl Boehlert
Email: boehlert@egr.msu.edu
Principal Investigator: Carl Boehlert
Sr. Investigator(s): Thomas Bieler; Michigan State University
Martin Crimp; Michigan State University
Students: 0 Postdoctoral Fellow(s), 5 Graduate(s), 1 Undergraduate(s)
Funding: \$195,000 (2014)

PROGRAM SCOPE

We are using a synergistic experimental and computational approach to identify and examine processes that cause damage nucleation at interfaces in two-phase $\alpha+\beta$ titanium (Ti) alloys. We have systematically studied two near α phase Ti alloys: $\text{Ti}_5\text{Al}_{2.5}\text{Sn}$ (wt.%), referred to as Ti525, and $\text{Ti}_8\text{Al}_1\text{Mo}_1\text{V}$ (wt%), referred to as Ti-811, and two two-phase $\alpha+\beta$ alloys: $\text{Ti}_3\text{Al}_{2.5}\text{V}$, referred to as Ti325, and $\text{Ti}_6\text{Al}_4\text{V}$ (wt.%), referred to as Ti-64, and compared the results with work on commercially pure (CP) Ti in order to determine how differences in composition and microstructure affect the processes that cause damage nucleation at interfaces at ambient and elevated temperature. We have characterized the deformation behavior and the preferential slip systems, as well as instances of slip transfer and grain boundary deformation behavior of this alloy, under a variety of loading rates and temperature and compared the results to single-phase α CP Ti. Using this knowledge to examine the deformation behavior in more complex and commercially important two-phase $\alpha+\beta$ Ti-alloy systems is the next objective. Future work will accomplish this objective using our unique combination of experimental techniques that allow the details of the deformation and fracture initiation mechanisms to be characterized in the context of the larger microstructure. Deformation in selected microstructure patches that are large enough to identify how neighboring grains influence stress shielding and strain incompatibilities will also be simulated using state-of-the-art polycrystalline plasticity-based finite element models. Successful completion of this research program will establish a paradigm by which the fundamental processes responsible for damage nucleation in polycrystals can be identified. The Ti alloys that will be examined are currently used in a wide range of aerospace structural applications, as well as within the energy generation, automotive, and biomedical industries.

FY 2014 HIGHLIGHTS

The momentum of this research program has continued in order to have sufficient data for statistical confidence in identification of deformation mechanism interactions with grain boundaries. The items listed below summarize important research accomplishments. (i.) Rules for slip transfer and damage nucleation across α/β boundaries have been investigated and a methodology for determining the CRSS ratios of different deformation modes has been developed based on in-situ observation of surface deformation traces made in a scanning electron microscope. (ii.) The relative activity of the different deformation systems changes as a function of alloying composition and deformation temperature was quantified. With increasing plastic deformation, the critical resolved shear stress (CRSS) variation at low and high strains has been observed, which may be the result of differently evolving hardening behavior in different slip systems, or other sources of uncertainty, which point toward valuable new areas for research related to statistical errors, rotations of grains during deformation, local stress state variation. (iii.) Effects of chemistry, temperature, and strain rate on slip heterogeneity have been identified (some quantitatively) from novel in-situ experimental methods. (iv.) Crystal Plasticity Finite Element Modeling (CPFEM) simulation show very good correlations with observed complex strain features in a real sample, making the local stress tensor, which is not experimentally measurable, available to evaluate local shear activity, which will lead to accelerated understanding of the driving forces for observed slip. (v.) The ability to image and characterize the dislocations at grain boundaries has been developed. The local dislocation density has been measured, which is related to the resistance of the grain boundary to strain transfer. (vi.) One PhD graduate student has finished his degree program. We have published two articles in peer reviewed journals and submitted two.

Granular Constraints and Size Effects in Polycrystalline Shape Memory Alloys

Institution: Northwestern University
Point of Contact: Catherine Brinson
Email: cbrinson@northwestern.edu
Principal Investigator: Catherine Brinson
Sr. Investigator(s): David Dunand; Northwestern University
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The primary objective is to study the granular and surface constraints on shape memory alloys in the transformation and elastic regimes. Experiments are carried out at the grain scale to see the effect of constraints imposed by neighboring grains on the grain of interest and how this affects the behavior of that grain under stress. Difference between bulk and surface constraints imposed by neighboring grains is also studied by using chemical etching to expose grains that were previously in the bulk to surface grains. The chief experimental technique for the same is High Energy X-Ray Diffraction Microscopy (HEDM). Separate surface studies are performed using Digital Image Correlation (DIC), which allows analyzing the surface of the material at a larger length scale. All samples analyzed have two holes drilled perpendicular to the axial loading direction of the sample, to model the “anti-micro pillar” experiments and also act as seed points for transformation of the material resulting from localized concentration of the stress field. These experimental results are then compared with Finite Element Analysis (FEA) to study the level at which continuum mechanics breaks down by confining different numbers of grains between the two micro holes. The sample is modeled using a continuum based polycrystalline constitutive model and the amount of deviation from experimental results shows where a micro-mechanical constitutive model is more relevant.

FY 2014 HIGHLIGHTS

Presented at SMST (Shape Memory and Superelastic Technology) Conference organized by ASM International in May 2014 at Pacific Grove, CA with a specific workshop on Shape Memory Alloy behavior. Conduction of experiments at Cornell High Energy Synchrotron Source, Cornell University and Argonne National Laboratory where monolithic (dogbone samples without machined microholes) as well as samples with two holes were analyzed using HEDM. This technique allows for 3D grain reconstruction to give individual spatial position and orientation of every grain, following which the effects of granular and surface constraints can be studied. Conduction of DIC experiments at Northwestern University and Colorado School of Mines for studying the transformation on the sample surface for three and two dimensional samples respectively. The two dimensional DIC is supported by Electron Back Scattering Detection (EBSD) results, which indexes individual grains with their orientation for planar surfaces. FEA analysis (both two and three dimensional) using the Stebner-Brinson continuum based model for comparison with experimental data to reach the breakdown of continuum assumptions, normalized to number of grains between constraining features (micro holes machined into the sample in this case).

Thermal Activation in Dislocation Dynamics of Face-Centered Cubic Metals

Institution: Stanford University
Point of Contact: Wei Cai
Email: cai.wei@stanford.edu
Principal Investigator: Wei Cai

Sr. Investigator(s):

Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)

Funding: \$228,500 (2014)

PROGRAM SCOPE

Dislocation dynamics controls plastic deformation, mechanical strength, and failure of crystalline materials. To date, thermally activated dislocation processes are still not well understood. The two most prominent thermally activated processes in pure Face-Centered Cubic (FCC) metals are: cross slip and forest cutting. Many fundamental questions regarding these two processes still remain open, and our proposed research seeks to provide answers. This project will use atomistic simulations with advanced sampling techniques, complemented by dislocation dynamics simulations, to determine the fundamental mechanisms of cross slip and forest cutting processes and their consequence on strain hardening. We will focus on the following four scientific questions. (1) How does the mechanism of homogeneous cross slip of an isolated screw dislocation depend on the various stress components? (2) What is the dominant mechanism of cross slip in a realistic dislocation microstructure? (3) What is the mechanism of forest cutting at finite temperature? (4) Is dynamic recovery controlled by cross slip or by thermally assisted removal of Lomer-Cottrell locks? The answers to these questions will represent a significant advance in our understanding of thermally activated dislocation processes fundamental to the deformation and microstructural evolution of metals, alloys and semiconductors. The knowledge gained in this research will be an essential component in the design and manufacturing of stronger, tougher and more damage-resistant materials for a wide range of future energy systems.

FY 2014 HIGHLIGHTS

(1) We successfully computed the energy barrier for cross slip of screw dislocations in FCC Ni as a function of three different stress components, using both the continuum line tension model and the discrete atomistic model. This is the first time the effect three relevant stress components on cross slip energy barrier are examined with atomistic detail. This work has been published in *JMPS* 62, 181, 2014. (2) We have developed more efficient time integrators for dislocation dynamics (DD) simulations, combining implicit integrators with subcycling algorithm. This leads to order-of-magnitude increase in the amount of strain that can be reached in DD simulations within a given computational time. This work has been published in *MSMSE* 24, 025003, 2014. (3) In an effort to understand the interaction between dislocations and solute atoms (a fundamental problem in controlling the strength of metals), we discovered a widespread error in the contemporary literature regarding the equilibrium concentration of point defects surrounding a dislocation (i.e. the Cottrell atmosphere). We show that the compressive self-stress inside existing inclusions must be excluded from the stress dependence of the equilibrium concentration of the point defects, because it does no work when a new inclusion is introduced. On the other hand, a tensile image stress field must be included to satisfy the boundary conditions in a finite solid. This work has been published in *JMPS* 66, 154, 2014. (4) PI Cai collaborated with colleagues in Universidad Campinus, Brazil, in the calculation of ideal shear strength (ISS) on the basal plane of HCP ^4He , a prototypical quantum solid, using path-integral Monte Carlo (PIMC) simulations. The failure mode upon reaching the ISS limit is characterized by the homogeneous nucleation of a stacking fault and it is found to be anisotropic, consistent with Schmid's law of resolved shear stress. This work has been published in *PRL* 122, 155303, 2014.

EARLY CAREER: Energetics of Radiation Tolerant Nanoceramics

Institution: California-Davis, University of
Point of Contact: Ricardo Castro
Email: rhrcastro@ucdavis.edu
Principal Investigator: Ricardo Castro
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$152,587 (2014)

PROGRAM SCOPE

Nanostructured materials are likely to play a large role in future nuclear reactors and radioactive waste storage due to their strength and potential resistance to structural damage from radiation. However, this potential is hindered by significant gaps in the understanding of interfaces' properties and their role in the overall performance of the nanocrystalline structures. The lack of reliable thermodynamical data of nanomaterials makes it extremely difficult to predict and fully exploit nanomaterials' properties in high-radiation environments, being one of the major reasons why the stability of the nanomaterials is still a big unresolved question. The goal of this project is to investigate nanomaterials with potential interest for nuclear components [the aluminate based spinels (MgAl_2O_4 , $M = \text{Mg, Ni, or Zn}$), and zirconia based materials (ZrO_2 doped with Y or Ca), and establish the link between composition, interface thermodynamics, and radiation resistance, aiming to enable a better understanding of the nature of enhanced performance in nanocrystalline ceramics. Nanoceramics (typically below ~ 100 nm) can show enhanced radiation resistance as compared to their bulk counterpart. This is hypothetically attributed to the increased interface areas in the form of grain boundaries that could act as effective sinks for radiation-induced defects, significantly hindering the accumulation of point defects. In this project, the mechanisms behind this phenomenon as well as its limitations considering the thermodynamics of nanomaterials are being unveiled by combining a series of sophisticated approaches, i.e.: (a) highly sensitive calorimetric techniques to provide a detailed thermodynamic description of the nanosystem; (b) advanced techniques for obtaining unprecedented nanocrystalline samples with grain sizes below 10 nm, (c) high energy ion irradiation studies, and (d) high resolution electron microscopy to study the defect profile.

FY 2014 HIGHLIGHTS

Development of novel synthetic processing and calorimetric techniques have been the initial outcomes of this project. This is because the project requires manufacturing of high quality nanocrystalline samples and techniques of high sensitivity to enable a comprehensive description of the system (that allows more reliable data analysis). Because those techniques were not available in the literature, the developments from this grant resulted in a large number of high-impact publications. The methods have consequences in diverse fields other than radiation tolerance, as they enable controlled fabrication and thermodynamic analysis of nanoceramics. The novel techniques culminated in a very important paper recently published in Scientific Reports (Nature Publishing Group). In that, the high-quality sample enabled an unprecedented solid description of radiation effect in nanocrystalline zirconia, with detailed correlation between kinetics and thermodynamics of radiation-induced defects. The paper is a landmark in the field that will set the stage for better understanding of radiation on nanomaterials.

EARLY CAREER: Deformation and Failure Mechanisms of Shape Memory Alloys

Institution: Michigan, University of
Point of Contact: Samantha Daly
Email: samdaly@umich.edu
Principal Investigator: Samantha Daly
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal of this research is to understand the fundamental mechanics driving the deformation and failure of shape memory alloys (SMAs). SMAs are difficult materials to characterize because of the complex solid-to-solid phase transformations that give rise to their unique properties. These phase transformations occur across multiple length scales and result in a large hysteresis loop, which allows these materials to store or dissipate substantial amounts of energy. In order to optimize the use of this hysteretic behavior in energy storage and damping applications, we must first have a quantitative understanding of the transformation behavior. New methodologies have been used to provide the first quantitative, full-field characterization of phase transformation across multiple length scales, with a focus on the relationship between microstructure and transformation. The proposed research is important from both a fundamental and a practical standpoint. SMAs are an excellent example of the fact that nearly all materials are dependent on multi-scale interactions, and the lessons to be learned from these experiments are representative of a wide class of materials. Here, atomic interactions, sub-granular transformation, intra-granular interactions, localized strain banding, and macroscopic behavior are all closely linked. The quantitative, spatially resolved information resulting from this research is especially useful to the numerous theoretical and computational studies of SMAs that are currently underway. In addition, the new experimental methodologies that have been developed as part of this research are applicable to a wide range of future investigations into the mechanics of strain localization. Finally, these experiments have produced results that significantly elucidate the change in the underlying mechanisms of phase transformation at small length scales.

FY 2014 HIGHLIGHTS

In the past year, work has focused on the statistical analysis of small-scale experimental results. This analysis has produced new findings that are directly applicable towards the modeling and prediction of shape memory alloy behavior. We have determined that contrary to a common assumption in mean-field theories, grains of similar orientation (a) do not necessarily transform similarly; and (b) that a single preferred variant does not nucleate and subsume entire grains. Rather, we quantified large degrees of transformation heterogeneity and extent in similarly oriented grains, including the identification of specific and distinct martensite laths. These findings have recently been submitted for journal publication. Another journal publication in progress details the quantitative interactions between plasticity and transformation on a grain-by-grain basis, and their dependence on cycling and microstructural neighborhood. Interestingly, a certain degree of residual strain (locked in martensite and plasticity) can in fact assist subsequent phase transformation, likely through the action of dislocation networks. At larger length scales, macroscopic fracture studies have been performed to examine the dependence of crack tip shielding (by phase transformation) on strain rate and crystallographic texture, aiming to address a lack in both dynamic and local data on superelastic shape memory alloys. A custom J-integral code that utilizes both line integral and area integral calculations of digital image correlation

data was successfully used to examine dependence on strain rate. These studies are currently being extended to a wider range of strain rates and to include microstructural factors.

Mechanical and Fracture Behavior of Molecular-Reinforced and Hybrid Glasses

Institution: Stanford University
Point of Contact: Reinhold Dauskardt
Email: dauskardt@stanford.edu
Principal Investigator: Reinhold Dauskardt
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$220,000 (2014)

PROGRAM SCOPE

Our research is focused on fundamental studies related to the molecular design, synthesis, characterization and modeling of molecular-reinforced hybrid glass films for superior mechanical and fracture properties in hostile chemical and UV radiation environments. Molecular-reinforced hybrid glass films exhibit unique electro-optical properties while maintaining excellent thermal stability. They have important technological application for emerging nanoscience and energy technologies including anti-reflective and ultra-barrier layers in photovoltaics and display technologies, microelectronic interlayer dielectrics, optical waveguides, and high-performance coupling layers in structural laminates. However, they are often inherently brittle in nature, do not adhere well to adjacent substrates, and exhibit poor mechanical properties. Our research brings together a unique combination of internationally recognized thin-film processing and mechanical characterization capabilities coupled with computational modeling that we have pioneered to study hybrid films. We have developed high-productivity capabilities for sol-gel fabrication together with newly developed atmospheric plasma deposition to inexpensively synthesize hybrid films. Composition and molecular structure is characterized using high resolution X-ray, electron, optical and nuclear spectroscopies. Mechanical properties are studied using acoustic, nanoindentation, force modulated AFM, and thin-film adhesion and cohesion techniques we have pioneered for thin-film structures. Furthermore, we leveraged computational modeling capabilities that have allowed us to understand the complex elastic properties of hybrid molecular materials. This has enabled the molecular design, synthesis, characterization and modeling of hybrid films for superior mechanical and fracture properties in hostile chemical and UV radiation environments.

FY 2014 HIGHLIGHTS

Highlights of our research include developing an atmospheric plasma technique to deposit hard, adhesive, and highly transparent dense hybrid bilayer coatings on plastic substrates in ambient air, at room temperature, in a one-step process, using a single precursor. The adhesion of the hybrid films to the polymer substrates was significantly improved by forming a hybrid glass film with carbon-bridges that provide a molecular reinforcement of the film, and strong bonding to the underlying polymer. A hard dense hybrid layer was subsequently deposited on top of the underlying film. The bilayer structure exhibited ~100% visible transmittance, twice the adhesion energy and three times the Young's modulus of commercial polysiloxane sol-gel coatings. Hybrid molecular materials containing both organic and inorganic components and synthesized via sol-gel chemistry exhibit unique and superior mechanical properties. In our research we recently unraveled the underlying hydrolysis and condensation reactions of an epoxy-silane and metal alkoxide precursor to deposit moisture-insensitive hybrid organic/inorganic

films via dip coating. We have now also demonstrated a new spray sol-gel processing technique to deposit hybrid organic/inorganic films with a compositionally-graded structure with excellent adhesive properties. Finally, we leverage computational models to demonstrate the existence of asymmetrical elastic behavior of hybrid organic-inorganic glasses. The existence of asymmetrical elastic behavior has significant effects on thermomechanical stresses and reliability but has never been demonstrated. We have developed computational tools to generate a highly accurate molecular model of an organosilicate glass and report the first indication that they display asymmetric elastic behavior, a rare property for any material. Initial results indicate that a difference in free volume under compressive and tensile states underlies the asymmetry for the partially connected networks.

Inferring Grain Boundary Properties from Measurements on Grain Boundary Networks

Institution: Massachusetts Institute of Technology
Point of Contact: Michael Demkowicz
Email: mikejd@MIT.edu
Principal Investigator: Michael Demkowicz
Sr. Investigator(s): Youssef Marzouk; Massachusetts Institute of Technology
Christopher Schuh; Massachusetts Institute of Technology
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014)

PROGRAM SCOPE

The goal of this project is to build analysis tools that infer accurate and general grain boundary (GB) crystallography-property relations with quantified uncertainty by assembling partial but complementary data readily obtainable with existing experimental and modeling methods. These tools will markedly enhance our ability to predict and control—through computational design—materials properties governed by GB networks, such as intergranular fracture, diffusion, and embrittlement. We have adopted gallium permeation through GB networks in Al as a model problem on which to develop and validate these tools. The crux of this project is integration of information obtainable from easy-to-perform experiments and simulations. GB properties depend, at minimum, on five crystallographic variables. Conventional approaches, such as investigation of individual GBs using electron microscopy or atomistic modeling, provide incomplete information concerning GB crystallography-property relations. However, the information provided by many of these techniques is complementary. This project integrates information available from multiple sources using analytical techniques such as Bayesian inference and GB network analysis to obtain a more complete understanding of GB crystallography-property relations in a resource-efficient way.

FY 2014 HIGHLIGHTS

We developed methods to track Ga permeation *in situ* in a scanning electron microscope and to relate it to the full five-parameter GB character, obtained through two correlated electron backscatter diffraction measurements. Within a single permeation experiment, we can distinguish between high diffusivity paths as well as clusters of GBs that are either not permeated at all or at a much slower rate. These experiments give qualitative insights into GB crystallography-property relations for Ga permeation into Al, e.g. that Ga permeation velocity does not scale with GB misorientation angle for high angle, general GBs. To infer quantitative GB crystallography-property relations, we have made theoretical advances in the complementary tasks of homogenization (calculating aggregate properties from GB behavior) and localization (calculating GB properties from aggregate behavior). We demonstrated that

the Generalized Effective Medium homogenization scheme provides quantitatively accurate predictions of aggregate diffusivity, D_{eff} , in GB networks with diffusivity contrast ratios from 10 to 10^8 . We then solved the inverse problem of localization by deducing the local diffusivity of each boundary with given microstructure data and measurements of D_{eff} from simulations. Finally, we are using Bayesian inference to integrate macro-scale measurements on GB networks with atomistic and mesoscale simulations as well as data available in the literature. This approach requires a “likelihood model” that predicts the probability of observing a specific Ga permeation rate given a specific permeation mechanism. We formulate this likelihood model using the phase field method. GBs are modeled as surfaces with non-uniform energy and Ga concentration in a GB is described using an order parameter that obeys the Cahn-Hilliard equation. By modifying the gradient energy penalty parameter in this equation, we describe permeation mechanism ranging from Fickian diffusion to front propagation.

Designing Nanoscale Precipitates in Novel Cobalt-based Superalloys to Improve Creep Resistance and Operating Temperature

Institution: Northwestern University
Point of Contact: David Dunand
Email: dunand@northwestern.edu
Principal Investigator: David Dunand
Sr. Investigator(s): David Seidman; Northwestern University
Christopher Wolverton; Northwestern University
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$50,000 (2014)

PROGRAM SCOPE

This ongoing research program focuses on the investigation of a novel family of Co-Al-W-base alloys for use in high-temperature structural applications. These alloys contain a high volume fraction of coherent $\gamma'(L1_2)$ -precipitates with the composition $Co_3(Al,W)$ that obstruct the motion of dislocations, providing high strength at both ambient and elevated temperatures. This is analogous to the Al-Sc-X system (with strength provided by α' - $Al_3(Sc,X)$ precipitates) and the Ni-Al-Cr-based systems (with γ' - $Ni_3(Al,Cr)$ precipitates). We will expand upon our fundamental studies of several representative Co-based superalloys (ternary Co-Al-W, quaternary Co-Al-W-Ni, and higher alloyed specimens containing Ti, B, and/or Zr to enhance the γ' -solvus temperature and grain-boundary strength), focusing on the stability of the strengthening γ' -precipitates and their contribution to strength at ambient and elevated temperatures. The improved creep- and coarsening-resistance of the Co-Al-W system is anticipated to enhance the operating temperature of land-based turbines and jet engine components by 100-150 K compared to those of contemporary Ni-based superalloys, resulting in improvements in engine efficiency and a reduction in fuel consumption, operating costs, and emissions. Our overarching goal is to achieve, on a fundamental level, an understanding of and predictive capability for the $\gamma'(L1_2)$ - $Co_3(Al, W)$ phase stability, morphology, and how these and other factors contribute to mechanical strength of the alloy. We will investigate the stability and microstructural evolution of the γ' -phase during nucleation, growth, and coarsening of precipitates, and their effect on strength at both ambient and elevated temperatures.

FY 2014 HIGHLIGHTS

During this fiscal year, our efforts have been focused on expanding upon our initial work regarding alloying effects on the microstructure and mechanical behavior of these alloys. Specifically, the addition

of sufficient quantities of boron to the ternary alloy leads to the formation of large W-rich borides, whose composition has been measured via atom probe tomography (APT). The presence of these borides has a strong effect on the creep strength of the alloy, decreasing the minimum steady-state strain rate by two orders of magnitude compared to the boron-free alloy, but results in a precipitate denuded zone along the grain boundary that decreases the yield stress at room temperature. We have also built upon our current understanding of quaternary alloying effects, investigating the impact of Ru and Ti additions on the morphological and compositional evolution of the $\gamma + \gamma'$ microstructure during isothermal aging. Ru, an important alloying element for recent-generation Ni-base superalloys, destabilizes the $\gamma + \gamma'$ microstructure during extended isothermal aging due to the onset of discontinuous transformation initiated at the grain boundaries. Alloys containing both Ti and B exhibit improved creep properties compared to ternary Co-Al-W, but the improvement is limited by the dearth of strengthening borides observed during our concurrent investigation of the Co-Al-W-B and Co-Al-W-B-Zr systems; investigation via APT has revealed that in the case of the Ti and B containing alloy, boron partitions to the γ' phase limiting segregation to the grain boundaries. DFT calculations on a ternary Co-Al-W system predicted that the anti-phase boundary (APB) energetics for g' (100, 111, and 111/100 anisotropy) are comparable to that of Ni_3Al . In addition, it was found that $\text{Co}_3\text{Al}_{0.5}\text{W}_{0.5}$ solid solution APB energies are not merely an average of the Co_3Al and Co_3W energies, and negative APB energies calculated for Co_3Al reflect thermodynamic metastability of the Co_3Al $L1_2$ structure.

Response of Simple, Model Systems to Extreme Conditions

Institution: Michigan, University of
Point of Contact: Rodney C. Ewing
Email: rewing1@standford.edu
Principal Investigator: Rodney C. Ewing
Sr. Investigator(s): Maik Lang; Tennessee, University of
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The emphasis of the proposed research is on the application of high-pressure/high-temperature techniques, together with intense energetic ion beams, to the study of the behavior of simple oxide systems (e.g., SiO_2 , GeO_2 , and Ln_2O_3) under extreme conditions. These simple stoichiometries provide unique model systems for the analysis of structural responses to pressure up to and above 1 Mbar, temperatures of up to several thousand Kelvin, and the extreme energy density generated by energetic heavy ions (tens of keV/atom). The investigations will include systematic studies of radiation- and pressure-induced amorphization of high P-T polymorphs. We will apply state-of-the-art *in situ* synchrotron diffraction techniques together with advanced transmission electron microscopy to characterize the different structural modification, which includes crystal-amorphous and crystal-crystal phase transformations. Through an extensive network of collaborations, we have access to a wide variety of experimental facilities including large ion accelerators and synchrotron beamlines. By studying the response of simple stoichiometries that have multiple structural “outcomes”, we will establish the basic knowledge required for the prediction of the response of more complex structures to extreme conditions.

FY 2014 HIGHLIGHTS

The temperature dependence of track formation was studied in natural SiO₂ samples up to 913 K. SAXS revealed an increase in the ion track radius of approximately 0.1 nm per 100 K increase in irradiation temperature. MD simulations and thermal spike calculations are in good agreement with these values and indicate that the increase in track radii at elevated temperatures is due to a lower energy required to reach melting of the material. The shape of single ion tracks was estimated by a combination of SAXS measurements on track radii in apatite and SRIM calculations of the dE/dx. The apparent cigar-like shape with the cross-section reaching its maximum at the last quarter and decreasing rapidly towards the end of the track results from a combination of the varying dE/dx as well as energy density (velocity effect) when the ion penetrates the material. Irradiation-induced modifications were systematically investigated for Ln₂O₃ materials in the cubic bixbyite phase as a function of ion fluence using synchrotron x-ray micro-diffraction. In response to irradiation with 185 MeV Xe ions, the light lanthanide sesquioxides (Sm₂O₃, Gd₂O₃, and Ho₂O₃) were amorphized, while irradiation with 2.2 GeV Au ions induced a transformation to the monoclinic high temperature polymorph. In contrast, the heavy compounds (Tm₂O₃, and Lu₂O₃) underwent a transformation to a nonequilibrium cubic phase under both irradiation conditions. This phase was found to be isostructural with the high temperature cubic polymorph of La₂O₃, which is known to be a fast ion conductor and has not previously been observed for these compounds. The response of coupled extreme conditions was studied by irradiating dense 6-fold coordinated GeO₂ glass *in situ*, i.e., at a pressure of 45 GPa, with swift heavy ions that were injected into a diamond-anvil cell. The application of pressure and high-energy deposition from ions in tandem induced an amorphous-to-crystalline phase transition.

Grain Boundary - Dislocation Interactions in Polycrystals: Characterization and Simulation for the Effective Design of High-Strength, High-Ductility Structural Alloys

Institution: Brigham Young University
Point of Contact: David Fullwood
Email: dfullwood@byu.edu
Principal Investigator: David Fullwood
Sr. Investigator(s): Eric Homer; Brigham Young University
Robert Wagoner; Ohio State University
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$616,999 (2014-2016)

PROGRAM SCOPE

A breakthrough capability to mathematically treat trillions of line defects in crystals, called dislocations, will be developed and verified. Novel experiments, analysis, and simulation of dislocations interacting with crystal plane defects, called grain boundaries, in copper and tantalum will be carried out. The results will be incorporated in a super-dislocation (SD) model, thus introducing a dimension of materials design heretofore unavailable. Success will allow development of new polycrystalline alloys with improved strength and ductility. More broadly, the techniques established will be suitable for treating many types of dislocation interactions in a wide variety of metallic materials. Three enabling technologies will be created and used to accomplish the objectives: 1. At the meso, or middle, scale, new “meso-dislocation microscopy” will measure critical meso-scale quantities. 2. At the atomic scale, “high-throughput molecular dynamics” will be constructed to simulate large numbers of defect interactions. 3. At the macro scale, a “super-dislocation model” will analyze evolving populations of

dislocations. Careful comparative analysis of the three sets of results will reveal the fundamental mechanisms and linkages among the scales that control the properties of polycrystalline alloys.

FY 2014 HIGHLIGHTS

This financial year covers a single month of the new project. However, some progress has been achieved in all three enabling technologies: 1. Dislocation microscopy has been performed on a large-grained aluminum alloy as a proof of concept for the planned experimental work. The expected build-up of dislocation density at grain boundaries was observed. 2. Initial atomistic simulations have been undertaken to demonstrate the capability of simulating the nucleation of dislocations close to grain boundaries. This capacity will be fundamental to all future atomistic modeling tasks. The majority of effort has been spent on determining the ideal methods by which to measure the critical metrics that accurately describe dislocation-defect interactions. 3. Collaboration has begun with Sandia National Laboratory to co-develop the super-dislocation model. Furthermore, an ideal candidate for the post-doctoral position at Ohio State University has been identified; he will begin work on the model in 2015. A project meeting with collaborators at Sandia National Laboratory was scheduled, and occurred after the end of the fiscal year.

Atomic Scale Computational and Experimental Investigation of Twinning Mechanisms in HCP Systems

Institution: Ohio State University
Point of Contact: Maryam Ghazisaeidi

Principal Investigator: Maryam Ghazisaeidi
Sr. Investigator(s): Michael Mills; Ohio State University
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$434,980 (2014-2016)

PROGRAM SCOPE

Increasing both strength and ductility is the ultimate achievement for most structural materials. Traditional methods for strengthening rely on controlled generation of internal defects, and thereby increase strength at the cost of reducing ductility and toughness. Various levels of ductility are observed in hcp metals and their alloys: from extensive ductility in Ti and Zr to poor ductility in Mg, Zn and Be. Understanding the mechanisms behind this divergent behavior is important from both theoretical and industrial application points of view. Low temperature ductility of hcp metals is linked to twinning – an important deformation mode where the number of active slip systems is limited. In extensively ductile Ti and Zr, more than one twin system is operative in both tension and compression while less ductile metals, such as Mg, twin mainly in one mode (the most common being the (10-12) system). Our goal is to understand the fundamental reasons underlying the different twinning behavior of various hcp metals by comparing twin nucleation and growth mechanisms in Ti and Mg and their alloys. Of particular interest is the effect of alloying on twin nucleation and growth which, until now, has not been rigorously quantified. To achieve this goal, we will use a combined computational and experimental approach; deformation mechanisms at individual-defect-scale are best captured through computational methods. Experimental studies have been able to determine characteristic features of twins such as their crystallography, twin shear as well as the strain rate, stress or temperature under which twins form. However, observed twins are usually several nanometers to micrometers thick based on optical or SEM-level analysis, making it impossible to capture atomic scale processes responsible for their nucleation.

FY 2014 HIGHLIGHTS

The project start date is August 2014. The graduate student sponsored by this project has joined OSU and started to work on this project in September 2014.

EARLY CAREER: Modulating Thermal Transport Phenomena in Nanostructure via Elastic Strain at Extreme Limits of Strength

Institution: Pennsylvania, University of
Point of Contact: Daniel Gianola
Email: gianola@seas.upenn.edu
Principal Investigator: Daniel Gianola
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

Nanoscale materials fabricated with nearly pristine crystal structure are often endowed with ultra-strength behavior, where material failure occurs at a significant fraction of its ideal limit. The thermal conductivity exhibited by such materials is also uniquely affected by the high surface-to-volume ratio at the nanoscale. The juxtaposition of the vastly increased dynamic range of elastic strain available in ultra-strength nanomaterials and altered thermal transport shows promise for tunable thermal properties. This project aims to exploit these properties of high-strength nanostructures to elucidate the coupling between large mechanical strains and thermal conductivity (both electron and phonon) leading to better understanding and control of the thermal performance in these materials. Unique fabrication methods to produce nanosized quasi-defect free single crystals and modern nanomechanical testing will be used to identify the size-dependent dynamic range of elastic strain and understand deformation mechanisms near the ideal limit. Identifying and quantifying thermal transport phenomena as a function of mechanical strain in these nanostructures will open the door to using elastic strain engineering in high-strength nanomaterials to tune thermal transport. The results of these investigations will be used to improve the performance, efficiency, and versatility of advanced thermal management and energy conversion devices with tunable response.

FY 2014 HIGHLIGHTS

Supported by this DOE program, we recently developed a novel *in situ* approach and reported on the first experimental measurements demonstrating the effect of both spatially uniform strain and nonuniform strain resulting from defects on thermal conductivity of an individual Si nanowire using a method that we term *in situ* Raman piezothermography. Our results show that, whereas phononic transport in undoped Si nanowires is largely unaffected by uniform elastic tensile strain, a nonuniform strain field introduced via ion bombardment reduces the thermal conductivity by over 70%. In addition to discerning surface- and core-governed pathways for controlling thermal transport in phonon-dominated insulators and semiconductors, we expect our novel approach to have broad applicability to a wide class of functional 1D and 2D nanomaterials. Motivated by our results on Si nanowires and the strong observed role of strain heterogeneity, we have also developed a novel and generic strategy for tunable thermal and electronic transport in Si nanomeshes (thin films with patterned pore arrays). We exploit nanoscale patterning of a periodic mesh structure and spatially varying elastic strain gradients to locally modify electronic band structure and phononic behavior in a manner beneficial to electron and

thermal transport. In analogy to periodic artificial structures and atomic-level defects that introduce elastic strain gradients owing to perturbations of the otherwise perfect crystalline lattice, we term these structures metadefects. Experimental realization of these effects has also been pursued, with guidance and optimization from full-field modeling. We have developed and implemented a micro- and nanofabrication process flow to prototype Si nanomeshes based on silicon on insulator wafers. Mechanical, electronic, and thermal characterization of these samples is currently underway.

EARLY CAREER: Investigation of Radiation Damage Tolerance in Interface-Containing Metallic Nano Structures

Institution: California Institute of Technology
Point of Contact: Julia Greer
Email: jrgreer@caltech.edu
Principal Investigator: Julia Greer
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The project seeks to conduct a basic study by applying experimental and computational methods to obtain quantitative influence of helium sink strength and proximity on He bubble nucleation and growth in He-irradiated nano-scale metallic structures, and the ensuing deformation mechanisms and mechanical properties. The proposed work utilizes a combination of nano-scale in-situ tension and compression experiments on low-energy He-irradiated samples combined with site-specific microstructural characterization and modeling efforts. This systematic approach will provide us with critical information for identifying key factors that govern He bubble nucleation and growth upon irradiation as a function of both sink strength and sink proximity through an experimentally-confirmed physical understanding. So far, the attention has been focused on studying individual bcc/fcc interfaces within a single nano structure: a single Fe (bcc)-Cu (fcc) boundary per pillar oriented perpendicular to the pillar axes, as well as pure bcc and fcc nano structures. Additional interfaces of interest include bcc/bcc and metal/metallic glass all within a single nano-structure volume. The model material systems are: (1) pure single crystalline Fe and Cu, (2) a single Fe (bcc)-Cu (fcc) boundary per nano structure (3) a single metal-metallic glass, all oriented non-parallel to the loading direction so that their fracture strength can be tested. A nano-fabrication approach, which involves e-beam lithography and templated electroplating, is utilized, which enables precise control of the initial microstructure control. Experimentally determined stress-strain relationships are enhanced by in-situ SEM observations coupled with TEM microstructural characterization of the same samples before and after deformation (irradiated and as-fabricated) and atomistic (MD) modeling.

FY 2014 HIGHLIGHTS

Tensile specimens shaped as cylinders with "hats" for gripping have been fabricated from the following material systems: (1) Amorphous Ni-P metallic glass, (2) Amorphous Fe-W metallic glass, and (3) Single crystalline Fe. The diameters of these specimens are between 50nm and 100nm have been fabricated, irradiated, and mechanically tested. In addition multiple free-standing "nano-walls" were produced to extend the perimeter and area between the two adjoining material and to help understand the interfacial topology and its effect on radiation damage. Monolithic Ni-P Fe (irradiated and as-fabricated) nano structures with diameters of ~75-100nm were tested in uniaxial tension (in-situ). This diameter

was chosen intentionally to achieve electron transparency during TEM analysis so that He bubbles could be readily observed.

Nanoscale Characterization of Intragranular and Intergranular Deformation Mechanisms

Institution: Johns Hopkins University
Point of Contact: Kevin Hemker
Email: hemker@jhu.edu
Principal Investigator: Kevin Hemker
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014-2016)

PROGRAM SCOPE

Having developed the tools necessary to characterize stress-assisted room temperature grain growth in nanocrystalline metals, we are now expanding our study to quantify, locally and at the nanoscale, the influence that stress concentrations and microstructural details have on the deformation behavior of microcrystalline metals and alloys. To be truly predictive, multi-scale models and descriptions of deformation processes must be based on experimentally identified physical mechanisms and benchmarked at salient length scales. Our work offers unique opportunities to advance both nanoscale characterization and benchmarking. Two new experimental techniques, TEM-based precession-assisted crystal orientation mapping (PACOM) with Topspin AutoSTRAIN acquisition & analysis and SEM-based transmission Kikuchi diffraction (TKD), offer unprecedented spatial resolution and the opportunity to map, with 2-3nm step sizes, lattice distortions, stress concentrations, and dislocation populations. These techniques are being employed to identify active deformation mechanisms and collect local measures of structure, orientation, and stress that can be used to elucidate nanoscale details such as: the role of local stress concentrations in nascent twin formation in polycrystalline Mg and Zr; the redistribution of local stress during grain boundary migration, twinning, and dislocation pileups; and the storage of geometrically necessary dislocations during plasticity.

FY 2014 HIGHLIGHTS

In 2014 our research focused on *in situ* experiments conducted on nanocrystalline copper. Freestanding films were deposited and annealed at 400°C to produce an equiaxed microstructure (average grain size ~70nm) with extensive growth twins; these films were strained and characterized using precession-assisted crystal orientation mapping (PACOM). The goal of these tests was to observe stress-assisted grain boundary migration (GBM). Indeed, GBM was observed in these films, but it was not the dominant deformation mechanism as has been observed in other materials. We found that GBM and corresponding grain growth occurs by the movement of random boundaries by small amounts, which results in the growth of some grains and the annihilation of others. The mechanism does not rely on a subset of boundaries with a specific character that allows them to have high mobility. There is also no correlation between the out-of-plane texture of the grains and their propensity to grow at the expense of their neighbors. In addition to GBM we were also able to observe extensive deformation twinning and dislocation activity. Among grains near the crack tip where stresses are high there are many instances of coherent $\Sigma 3$ twin boundaries nucleating at a grain boundary, propagating across a grain, and then increasing in width. Both bright-field TEM imaging and intragranular misorientations determined with PACOM suggest that dislocations are active in larger grains and are responsible for plastic deformation. While the angular resolution for the PACOM setup used in the last round of experiments was not

sufficient to measure local variations in strain (and, as a result, dislocation density) within grains, we now have installed software that will allow us to do so. This will enable us to observe how dislocation populations can enable or inhibit other mechanisms such as twinning as well as measuring how dislocation structures evolve throughout deformation.

Stability of High-Strength Nanocrystalline Structures

Institution: Purdue University
Point of Contact: Marisol Koslowski
Email: marisol@purdue.edu
Principal Investigator: Marisol Koslowski
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$17,017 (2014)

PROGRAM SCOPE

Numerical simulations at nanometer scale have advanced the understanding of plastic deformation. Unfortunately, simulations that resolve these length scales constrain the deformation regime to high strain rates. Extrapolating numerical predictions to experimental conditions remains an unresolved challenge. The goal of this program is to study deformation mechanisms in nanocrystalline and ultrafine crystalline materials over a wide range of strain rates. In particular, we study plastic strain recovery upon unloading, reverse plastic strain during cyclic loading and the strain rate sensitivity of the collective behavior of partial and extended full dislocations.

FY 2014 HIGHLIGHTS

We find that the strain rate has a significant impact on the nucleation of leading and trailing partial dislocations. At high strain rates the density of leading partials and consequently, the density of stacking faults, grows initially and later decreases as the deformation proceeds. At the same time the density of extended full dislocations shows a monotonic increase with the applied strain. Finally, the density of extended full dislocations grows beyond the density of partial dislocations as the deformation accumulates. We have studied reverse plastic strain during cyclic loading and plastic strain recovery upon unloading with dislocation dynamics simulations. We vary the average grain size, the grain size distribution and the loading conditions to understand the effect of the microstructure and the loading history. To simulate thermally activated plastic strain recovery upon unloading we coupled dislocation dynamics simulations to a kinetic Monte Carlo algorithm. Our simulations give further evidence that reverse plastic strain during cyclic loading occurs as a consequence of the formation of dislocation structures due to the interaction of dislocation with grain boundaries in agreement with experiments. During re-loading a reverse motion of dislocations is observed in the simulations. Dislocations are annihilated during reverse motion reducing the dislocation density and the plastic strain. Increasing the heterogeneity of the microstructure increases the amount of reverse plastic strain until it reaches a plateau. This shows that reverse plastic strain is driven by stress inhomogeneity due to distributions of grain sizes but also by stresses due to the formation of dislocation structures in larger grains that are able to store dislocations that are annihilated during unloading.

Understanding Microplasticity Processes Related to Fatigue Damage Using High Energy X-Rays and a Crystal-Based Modeling Formulation

Institution: Cornell University
Point of Contact: Matthew Miller
Email: mpm4@cornell.edu
Principal Investigator: Matthew Miller
Sr. Investigator(s): Paul Dawson; Cornell University
Jim Williams; Ohio State University
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2016)

PROGRAM SCOPE

Predicting fatigue crack initiation in ductile polycrystalline materials remains one of the materials science's most important unsolved problems. Generations of researchers have agreed that during low cycle fatigue conditions, spatially heterogeneous cyclic plasticity lies at the core of microcrack initiation. Understanding the conditions that cause plastic deformation to transform to microcracks in a polycrystal remains elusive. During the first three years of this grant, our team has built a hybrid experimental / computational capability to “watch” cyclic plasticity at the scale of each individual grain within a deforming polycrystal. Diffraction patterns from crystals within a deforming polycrystal are used to inform micromechanics-based finite element simulations. X-rays are projected through the model and its performance is examined by comparing the diffracted intensities measured on the virtual and real detectors. During the current project, we are implementing the new methodology to examine the formation of persistent slip networks (PSNs) – polycrystalline analogs to persistent slip bands formed in single crystals. We believe that PSN becomes configured to fully accommodate the macroscopic plastic strain amplitude applied to a specimen or engineering component. The formation of the PSN occurs over many cycles, but eventually this highly localized region is transmitting such an enormous flux of reversed plasticity, that fissures and voids eventually form and microcracks initiate. The objectives of this project are to explore the hypothesis that PSNs exist within polycrystals subjected to low cycle fatigue conditions and that there exists a threshold plastic strain amplitude beyond which PSN formation and eventual microcrack initiation is inevitable.

FY 2014 HIGHLIGHTS

Our new project began in February, 2014. During these first several months we examined the structure of the polycrystal model relative to the cyclic response observed in the diffraction data from. In particular, a latent hardening constitutive model was implemented to capture the tension-compression asymmetry observed in the full width at half maximum (FWHM) diffraction data. We also investigated the effect of crystallographic neighborhood on the diffraction results. In order to be consistent with legacy fatigue data, we also transitioned from a copper alloy (OMC copper) to “pure” OFHC copper. Preliminary experiments were conducted on the OFHC material. Finally, we constructed a more sophisticated mosaic diffraction model to better understand the relationship between heterogeneous slip and FWHM.

Transformation and Deformation Mechanisms in High Temperature Shape Memory Alloys with Nanoprecipitates

Institution: Ohio State University
Point of Contact: Michael Mills
Email: mills.108@osu.edu
Principal Investigator: Michael Mills
Sr. Investigator(s): Peter Anderson; Ohio State University
Yunzhi Wang; Ohio State University
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$203,994 (2014)

PROGRAM SCOPE

The focus of this program is on an emerging class of high temperature shape memory alloys (HTSMAs) that are exciting candidates for actuators and adaptive components in a wide range of energy and transportation applications. These HTSMAs offer the possibility of high reliability, lighter weight and increased capability while lowering space and power consumption. However, at present there is only elementary understanding of the important microstructure-property relationships. The goals of this effort therefore are to (1) develop a fundamental understanding of the inherent microstructure-property behavior of high temperature shape memory alloys and (2) develop computational models that capture these structure-property relationships and provide novel insights into the important transformation and plasticity mechanisms that govern their behavior. Two “Ni-rich” HTSMA alloy systems are at the core of the effort: Ni(Ti,Hf) and (Ni,Au)Ti alloys can exhibit high transformation temperatures, large transformation strain and small permanent strain. These beneficial properties can be strongly influenced by the formation of nanoscale precipitates. Spearheaded by advanced characterization techniques, and aided by insights from first principles modeling, the unusual and novel atomic structure and composition of these precipitates is being determined, along with their coherency with the matrix. Interaction of precipitates with martensite at lower temperature and dislocation activity at higher temperature are key mechanistic insights being sought through *in situ* electron microscopy studies, and being understood through new phase field modeling approaches to particle/defect interactions. These insights are being incorporated into a microstructural finite element framework in order to capture how phase transformations, crystal plasticity, and time-dependent creep interact to determine the response of single crystal micropillar experiments.

FY 2014 HIGHLIGHTS

Research in the past year has focused on understanding and modeling the effect of aging and formation of H-phase precipitates on the martensite transformation and plasticity in the Ni-Ti-Hf system. Mechanical testing has revealed the dramatic effect of aging on the critical stress for transformation/plastic flow as a function of deformation temperature in several near-stoichiometric compositions. At short aging times, a distinct precursor to the H-phase (H') has been determined. The nature of H' and H-phase precipitates, as well as the interface between and the high temperature austenite and lower temperature martensite matrix has been further studied using HAADF imaging. The effects of H-phase precipitation on martensitic transformation and shape memory properties has been modeled through a new, coupled phase field/finite element method (FEM) model that is capable of simulating transformation and plasticity as a function of precipitate structure. The results of the modeling are helping to rationalize the complex effects of aging on transformation and mechanical behavior. A new thrust on the Ni-Ti-Au system has also begun and preliminary microstructure analysis

has been completed. This system is remarkable since it has the highest transformation temperature while providing attractive actuation work output under load-bias, thermal cycling conditions. However, it is also very unusual since its mechanical behavior is only modestly affected by deviation from stoichiometry or aging condition. The microstructure origins for this behavior, which is in such sharp contrast to that seen in Ni-Ti-Hf, are presently under investigation. A final thrust has involved initial study of an extraordinary grain refinement that occurs under load-bias thermal cycling conditions in binary NiTi. The grain refinement has been identified for the first time through a combination of *in situ* TEM heating experiments and ASTAR grain mapping measurements.

Fracture Mechanisms and Fatigue of Magnetic Shape-Memory Alloys

Institution: Boise State University
Point of Contact: Peter Mullner
Email: petermullner@boisestate.edu
Principal Investigator: Peter Mullner
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 7 Undergraduate(s)
Funding: \$30,000 (2014)

PROGRAM SCOPE

Fracture resistance and long fatigue life are required to commercialize Ni-Mn-Ga ferromagnetic shape memory alloys. While Ni-Mn-Ga achieves high fatigue life at low strains, there is little data on the fatigue life of samples that are actuated near the theoretical strain limit. Furthermore, constraints imposed by clamping samples impact their magneto-mechanical and fatigue properties. Here, 10M Ni-Mn-Ga single crystals were exposed to a rotating magnetic field while holding them with rubber O-rings so they were not constrained. Prior to testing, sample surfaces were prepared to various levels of surface roughness. Fatigue life varied with some samples reaching more than 800,000 cyclic loads before fracturing and some samples failing after only 4,000 cyclic loads. Long fatigue life and fracture resistance are achieved when avoiding crystal defects and surface imperfections. Short fatigue life was caused by high surface roughness and stress concentration at defects and notches. A single crystal of Ni-Mn-Ga was pre-strained in compression from 0 to 6% and then the shape was recovered with a magnetic field perpendicular to the loading direction while working against a pair of springs. The magnetic was raised from 0 to 0.64 MA/m and then reduced back to 0. Eight pairs of springs with combined spring constants ranging from 14.3 to 269.4 N/mm were used. When the magnetic field was on, the sample expanded against the springs due to magnetic field induce strain (MFIS). When the magnetic field was turned off, the springs compressed the sample back to the initial size before the next cycle. During each cycle, force and displacement were measured and the specific work was computed. Specific work increased with the applied magnetic field and the pre-strain. The maximum specific work was 14 kJ/m³ at a pre-strain of 4.5 % strain and a magnetic field of 0.64 MA/m.

FY 2014 HIGHLIGHTS

As demonstrated in previous studies, MSMA can sustain very large numbers of loading cycles. This study shows that stress concentrations associated with surface roughness, notches, SAGBs, and other defects substantially reduces fatigue life. Such defects represent obstacles to twin boundary motion. The interplay of moving twin boundaries with these defects leads to the accumulation of twinning dislocations which increase the local stresses and eventually cause crack nucleation. Cracks propagate preferentially along planes of high shear stress. The macroscopic fracture plans are typically close to

{111}. To achieve a long fatigue life, Ni-Mn-Ga crystals must be free of defects such as notches, small angle grain boundaries, and other sources of stress concentration. We showed that for an actuator with a spring-recovery, the maximum useful work output is only a small fraction of the theoretic limit given by the difference of work done by deforming the magnetic shape memory alloy with and without a magnetic field.

Mechanical Properties of Materials with Nanometer Scale Dimensions and Microstructures

Institution: Stanford University
Point of Contact: William Nix
Email: nix@stanford.edu
Principal Investigator: William Nix
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

We are engaged in a program of research on the mechanical properties of materials with micrometer and nanometer scale dimensions and microstructures. This includes work on both the mechanical properties of crystalline materials in small volumes and the emerging problem of mechanical properties of lithiated silicon for lithium-ion batteries. The research on small-scale plasticity focuses on understanding the dislocation processes responsible for the well known “smaller is stronger” effect on strength, which we, and others, discovered a few years ago, using the micropillar compression technique that we also introduced. Our work has included both experiments, using the micropillar compression technique, as well as computational modeling, using dislocation dynamics codes based on the ParaDis code developed at LLNL. The overall aim of the work is to determine the role that dislocations play in controlling the strength of crystals at small scales. Our experimental work has focused on determining the role of initial dislocation density on the mechanical properties in small-scale crystals through pre-straining experiments. Silicon has attracted great attention as a promising negative electrode material for lithium ion batteries due to its exceptional theoretical specific capacity of 3578 mAh/g. But the huge volume changes associated with lithiation and delithiation usually cause mechanical failure of the electrode to occur after just one charging/discharging cycle, unless silicon nanostructures are used. Our work on lithiated silicon has involved studies of the robustness of amorphous silicon nanostructures to resist fracture during lithiation and delithiation. We do this by studying the behavior of amorphous silicon micropillars after lithiation and delithiation and modeling the deformation and fracture behavior using finite element method (FEM) techniques. The aim of the work is to understand the factors that determine the critical size for failure of these nanostructures.

FY 2014 HIGHLIGHTS

We have developed a three-dimensional dislocation dynamics (DD) model to study the collective dislocation behavior in metal micropillars under compression, focusing on the role of dislocation sources at surfaces for both BCC and FCC metals. A few years ago Weinberger and Cai using molecular dynamics showed that dislocations in BCC micropillars can multiply by a surface-controlled cross-slip process involving image forces and non-planar core structures. We have created a DD model of that mechanism and used it to study the effects of micropillar size and microstructure on the strength of BCC micropillars. We have also used 3D DD simulations to study plastic deformation of submicron FCC micropillars with particular focus on the role of surface sources for these crystals. Based on atomistic

simulations, we have introduced an algorithm for dislocation nucleation at free surfaces as a function of stress and temperature in the DD code. Research on amorphous silicon nanoparticles shows that amorphous silicon is more fracture resistant than crystalline silicon during lithiation. But to fully exploit the potential of using amorphous silicon it is important to determine if larger, micron-sized, amorphous silicon structures can be lithiated without fracture. We have studied the morphologies of initially amorphous silicon micropillars up to several microns in diameter both before and after lithiation and have found no cohesive fracture, unlike crystalline Si nanopillars that fail for diameters greater than 300nm. Finite element modeling is used to understand the increased fracture resistance. Knowledge of the mechanical properties of electrochemically lithiated Si, needed for the FEM modeling, has been obtained using nanoindentation. We have studied both time-independent and time-dependent indentation of lithiated silicon and found that elastic modulus and hardness of lithiated silicon both decline markedly with increasing lithium content.

The Coupling Between Interfacial Charge and Mechanical Deformation at High Temperatures in Ceramics

Institution: Colorado, University of
Point of Contact: Rishi Raj
Email: rishi.raj@colorado.edu
Principal Investigator: Rishi Raj
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$350,000 (2014-2015)

PROGRAM SCOPE

This BES program has led to the discovery of a new phenomenon, which has been called flash sintering, where oxide ceramics sinter in mere seconds at several hundred degrees below the temperatures for conventional sintering. The search for the underlying mechanism for this unusual effect is quickly leading to further findings. For example sintering is accompanied by a highly non-linear increase in conductivity, as well as intense photoemission. The rise in conductivity and photo-emission are observed in fully dense, pre-sintered specimens as well. Therefore, the flash event is intrinsic to the generation and mobility of charged and uncharged defects in ceramics. The neutral defects promote self-diffusion, while charged defects induce electrical conductivity. This coupling between charged and charge-neutral defects is vexing. We have proposed “nucleation” of Frenkel pairs that ionize into electrons and holes, providing conductivity and photoemission, and neutral defects that promote self-diffusion as a possible mechanism. This rather simple hypothesis has many assumptions and repercussions that are currently being investigated. In-situ experiments at Brookhaven (BNL) and Argonne (APS) Synchrotrons are beginning to provide insights into this phenomenon.

FY 2014 HIGHLIGHTS

There are two principal highlights during this calendar year. (I) Ultrafast sintering of oxides under an electric field, which has come to be known as flash sintering, has a fundamentally different mechanism of mass transport than the classical explanation where matter is transported from the grain boundaries to the pores by grain boundary or by lattice diffusion. We have shown, through experiments that have traditionally recognized the phenomenon of constrained sintering, that flash sintering likely occurs by the generation of Frenkel defects within the grain matrix, and that densification is accomplished by transporting the interstitials to the pores and the vacancies to the grain boundaries. (II) We continue to

make progress in in-situ experiments at the APS at Argonne National Laboratory. In these live experiments we measure the lattice expansion in the “flash state” and also search for new phases that form and vanish when the electrical field is turned on and off. The upper bound in the specimen temperature is measured by assuming that all the change in the lattice constant arises from thermal expansion. These temperatures are too low to account for the sintering rates achieved during flash sintering.

Mechanical Behavior in Ceramics with Unusual Thermal-Mechanical Properties

Institution: Colorado School of Mines
Point of Contact: Ivar Reimanis
Email: ireimani@mines.edu
Principal Investigator: Ivar Reimanis
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

The study of materials with unusual properties offers new insight into structure-property relations as well as promise for the design of novel composites. In this spirit, the PIs seek to (1) understand fundamental mechanical phenomena in ceramics that exhibit pressure-induced phase transitions and negative coefficient of thermal expansion (CTE), and (2) explore the effect of these phenomena on the mechanical behavior of composites designed with such ceramics. The broad and long-term goal is to learn how to utilize these unusual behaviors to obtain extraordinary mechanical responses. While the results are expected to be widely applicable to many ceramics, most of the present focus is on silicates, as they exhibit remarkable diversity in structure and properties. Eucryptite, a lithium aluminum silicate (LiAlSiO_4), is specifically targeted because it exhibits a negative CTE and a pressure-induced phase transition at a sufficiently low pressure to be accessible during conventional materials processing. Thus, composites with eucryptite may be designed to exhibit a novel type of transformation toughening. The PIs perform *in situ* experiments and atomistic modeling to link structure and thermal mechanical behavior.

FY 2014 HIGHLIGHTS

In situ high pressure x-ray diffraction experiments have revealed that the high pressure phase of eucryptite belongs to an orthorhombic crystal system. Atomistic modeling was used to discover the mechanisms by which beta-eucryptite amorphizes under pressure or under irradiation and also the mechanism of radiation tolerance. Briefly, the material response to pressure or irradiation is to form alumina polyhedra along with the significant distortion of certain silica tetrahedra. Radiation tolerance is present because alumina polyhedra satisfy the oxygen coordination of distorted silica tetrahedra, thereby preventing the total collapse of the structure. It was found that tracking the oxygen coordination allows a description of amorphization and recovery.

NanoMechanics: Elasticity and Friction in Nano-Objects

Institution: Georgia Institute of Technology
Point of Contact: Elisa Riedo
Email: elisa.riedo@physics.gatech.edu
Principal Investigator: Elisa Riedo

Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$130,000 (2014)

PROGRAM SCOPE

Carbon is a fascinating element that takes highly diverse morphology and structure, from diamond to graphite, ending with interesting nano-forms like fullerenes, nanotubes and graphene. Nanotubes and graphene-based materials are well known for their exceptional thermal, mechanical and electrical properties, with the promise to become building blocks in integrated nano-electronic and photonic circuits, nano-sensors, electrodes in solar cells, hydrogen storage devices, nano-electro-mechanical systems, and in composite materials to improve the mechanical and electrical properties of ceramics and polymers. Here, we propose a research program to study the frictional properties and the radial deformation mechanisms of supported C- and BN- nanotubes (NTs) as a function of their morphology, e.g. radius, number of layers, and length; structure, e.g. chirality and defects; substrate interaction, and chemical functionalization. Furthermore, we plan to initiate a new research program on the mechanical properties of epitaxial graphene-based films on SiC and other 2D materials. The long-term goal is to understand, predict and manipulate the size, shape, chemistry and structure of C and BN based nanostructures, for producing nano-materials with tailored optimum mechanical, electro-mechanical and thermo-mechanical properties. The research activity will be divided in two parts: I. The frictional properties of individual NTs on a supported substrate will be investigated by atomic force microscopy (AFM). II. The out-of-plane elasticity of thin films of epitaxial graphene (EG) and epitaxial graphene oxide (EGO) grown on SiC, as well as other 2D materials will be investigated by performing Modulated NanoIndentation experiments by AFM as a function of chemistry, intercalates, number of layers, and substrate.

FY 2014 HIGHLIGHTS

1) We have discovered a method to produce exceptionally high quality graphene oxide thin films, based on the mild chemical oxidation of multilayer graphene films grown epitaxially on silicon carbide. By performing XRD and XPS studies, we discovered that multi-layer epitaxial graphene oxide (EGO) thin films have unique characteristics, making them ideal model systems to achieve fundamental understanding and control of both the oxidation process of sp^2 carbon and the relationship between mechanical and chemical properties of functionalized graphene. 2) Two-dimensional (2D) materials, such as graphene and MoS_2 , are a few-atomic-layer thick films with strong in-plane bonds and weak interactions between the layers. While their in-plane elasticity has been widely studied in bending experiments where a suspended film is largely deformed, very little is known about the elastic modulus perpendicular to the planes. Investigations of the out-of-plane elasticity require indenting supported 2D films less than their interlayer distance. Although experimentally challenging, studying the interlayer elastic coupling is critical, since it affects many properties of 2D films. Here, we report on sub-Å-resolution indentation measurements of the perpendicular-to-the-plane elasticity of 2D materials. Experiments, combined with semi-analytical models and density functional theory are then used to study the perpendicular elasticity of a few-layers thick graphene and graphene oxide films. Interestingly, we find that the perpendicular Young's modulus reaches a maximum when one complete water layer is intercalated between the graphitic planes. This non-destructive methodology can map interlayer coupling and intercalation in 2D films.

Using Artificial Microstructures to Measure Fracture Toughness in Metallic Glass and their Cellular Structures and Composites

Institution: Yale University
Point of Contact: Jan Schroers
Email: jan.schroers@yale.edu
Principal Investigator: Jan Schroers
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$133,000 (2014)

PROGRAM SCOPE

For most structural applications the materials' selection criterion is their resistance to fracture rather than its strength. The complex property of fracture toughness and its mechanistic origin is, however, not well understood for bulk metallic glasses (BMGs), which encompass alloys spanning from close to ideal brittle to remarkably tough behavior. The main reason for the limited fundamental understanding of fracture toughness of metallic glasses has been limited access to high and consistent quality test samples. To date, all fracture toughness test samples of BMG have been fabricated through direct casting which makes it challenging to fabricate consistent and high quality samples. To overcome these shortcomings, we propose an alternative fabrication approach based on artificial microstructures, developed during our previous funding period. Artificial microstructures are fabricated through thermoplastic forming, which drastically reduces problems such as porosity and stresses associated with casting of metallic glasses. Thermoplastic forming is unique among metals, and can be carried out for some BMGs with the ease similar to the processing of thermoplastics. Our goal is to use this method to fabricate >500 BMG fracture toughness test samples/year in order to perform a systematic and very broad study of fracture toughness of BMGs and their composites. Our study will provide an unprecedented quantity and quality of fracture toughness data on metallic glasses, which will be used by the metallic glass community to test and develop quantitative theories, and to potentially develop new metallic glasses that resist fracture better. In addition, the further development of the artificial microstructure method, and specifically its extension to 2⁺ materials, will allow the materials science and mechanics community to determine microstructure-property relationships for a broad range of complex microstructures.

FY 2014 HIGHLIGHTS

Flaws are inevitably present in engineering structural materials. In this project, we introduce a novel approach to study the flaw tolerance of bulk metallic glasses. Our approach allows us to systematically manipulate the notch radius which simulates the flaw size and investigate the influence of flaw size on the fracture resistance of BMGs. The accuracy, versatility, and reproducibility of our approach revealed that fracture toughness of BMGs decreases apparently with decreasing flaw size up to a critical value. Below this value fracture toughness is independent of flaw size, suggesting a flaw tolerance behavior of BMGs. Such flaw tolerance is surprising since bulk metallic glasses lack a microstructure which has been associated with flaw tolerance in other material classes. We explain such flaw tolerance by a critical stress controlled fracture where ρ_c is defined by the critical plastic zone. This zone defines a characteristic distance over which stable shear banding plastic process develops prior to fracture instability. The BMGs' specific characteristic distance varies widely which rationalizes the vast variety in their fracture behavior and suggest distinct flaw tolerance. Our finding is encouraging for BMGs'

structural applications since flaws smaller than ρ_c are increasingly difficult to avoid but are “indistinguishable” in their influence to the fracture toughness.

Deformed Materials: Towards a Theory of Materials Morphology Dynamics

Institution: Cornell University
Point of Contact: James Sethna
Email: sethna@ccmr.cornell.edu
Principal Investigator: James Sethna
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 5 Graduate(s), 1 Undergraduate(s)
Funding: \$400,000 (2014-2015)

PROGRAM SCOPE

Practical mechanical materials are complex systems. They have ramified, often self-similar microstructure on a variety of scales, and they respond to mechanical forces and thermal annealing in an intermittent, bursty fashion. The principle investigator is using nonlinear shock-forming partial differential equations and ideas and methods from statistical physics to develop and analyze generic, prototype models for this emergent behavior. His group then uses these model systems to understand and explain the tangible, practical phenomena observed in mechanical materials. The investigator and his group are numerically probing model materials in ways designed to mimic their important experimental probes. They study macroscopic stress-strain measurements under anisotropic loading paths (Bauschinger effects). They study the resulting anisotropic microstructure evolution using correlation functions, scaling of misorientations and cell sizes, and fractal analyses. They study three different X-ray scattering methods: the 3DXRD far-field reconstruction of real-space evolution of the internal structure of microcrystals, Bragg peak-shapes and their analysis, and small-angle X-ray scattering probes of correlation functions. The investigator is expanding his methods to incorporate and explain new physical phenomena and materials properties. He is simulating the analogous evolution of structure in smectic liquid crystals with partial broken translational order (focal conic domains). He is developing new methods for extracting stress distributions in colloidal crystals from imaging analysis. By incorporating vacancies, solutes, and dirt he is studying the complex dynamics of climb and grain evolution, of the bursty Portevin-Le Chatelier (PLC) effect, of dislocation avalanches pinned by impurities, and of the investigator's newly discovered avalanche-oscillator route to criticality.

FY 2014 HIGHLIGHTS

The investigator's group has a spectacular new simulation of the evolution of focal conic domains in smectic liquid crystals. We use an effective theory and numerical simulations to study focal conic domains in smectic-A liquid crystals. In our simulations, focal conic structures spontaneously emerge from random initial configurations, and are characterized by several visualization tools that we developed. We describe the coarsening mechanism, and the scaling behavior of the probability distribution of the layer radii of curvature. We also study the effects of dilative and shear stress in this system, and compare the results with experiments from Itai Cohen's lab. These simulations lend deep insights into crystalline materials. By exploring broken translational symmetry in one dimension, we find new analogues to polycrystalline grains (focal conic domains), explanation of the 'frailty' of crystals (which form defects after tiny deformations compared to other systems), and provide a new testing ground for our simulation methods. The investigator has, in collaboration with Itai Cohen's group, developed a new method, 'Stress Assessment from Local Structural Anisotropy' (SALSA), for extracting

local stress information in colloidal crystals. Purely using the fluctuating positions of the colloidal particles, SALSA has allowed us to visualize the stresses around a dislocation, the nonlinear stresses around vacancies, and the residual stresses in a polycrystal – adding a whole new window into this model material system.

Radiation Response of Low Dimensional Carbon Systems

Institution: Texas A&M University
Point of Contact: Lin Shao
Email: lshao@ne.tamu.edu
Principal Investigator: Lin Shao
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014-2016)

PROGRAM SCOPE

The objective of this project is to understand radiation responses of low dimensional carbon systems and radiation-induced mechanical property changes at atomic scales. The materials to be studied include graphene monolayer, few-layer graphene, and carbon nanotube (CNT) bundles. In addition to studying effects from their different dimensions, sizes and geometries, the project will focus on boundary effects: (1) For graphene monolayer, the project will study defect sink properties of grain boundary, stimulated by modeling supported hypothesis that a grain boundary can trap defects for self repairing under ion/electron irradiation. Ion irradiation and *ex situ* transmission electron microscopy (TEM) characterization, and *in situ* TEM with concurrent electron irradiation, will be used to obtain atomic scale details of boundary-defect interaction on suspended graphene monolayer. (2) The project will study strained graphene monolayer to understand effects of strain on defect developments. Microfabricated tensile and compression test platforms will be used for *in situ* TEM characterization of graphene under stress and irradiation. (3) For few-layer graphene, the project will study the effect of inter-plane defects on graphene sliding. The proposed study will aid in fundamental understanding of the radiation responses of nanoscale materials. The knowledge will impact a wide range of carbon and non-carbon nanomaterials having a high surface to volume ratio, including nanomembranes, nanowires and fibers. Ion irradiation can either improve or degrade certain physical and chemical properties of carbon nanomaterials, and therefore this research is important to design and functionalize a wide range of nanomaterials-based structural components, microelectronics, sensors, and detectors.

FY 2014 HIGHLIGHTS

The major focus of year 2014 was to study boundary effects on radiation tolerance and structural changes of low dimensional carbon systems. We obtained the fundamental understanding on the geometry and quantum size effects on damage creation and defect annealing behaviors of ion irradiated carbon nanotubes and graphene. We reported large differences in carbon displacement creation under different tube configurations, and developed a multi-scale modeling approach to accurately calculate their displacement cross sections under different geometry and boundary conditions. Furthermore, both modeling and experiments suggested that migration energy barriers for defects on graphitic tube planes and for defects trapped between two touching tubes are largely different. Upon annealing, such difference leads to defect removal within tubes but creation of stable linking defects between tubes, which dramatically increase phonon transport in ion irradiated carbon nanotubes. For studies on graphene, we have shown that the energy barrier, which must be overcome to develop self-rolling, can

be lowered or completely eliminated by introducing vacancies. A structural transition diagram was created in which we show how ion irradiation of graphene can control curvatures of formed carbon nanoscrolls. Furthermore, using *in situ* electron irradiation and transmission electron microscopy, we studied the irradiation tolerance of few-layer graphene and reported easier structural collapse of the top and bottom layers of few-layer graphene, which is in good agreements with modeling prediction. Currently, we focused on the defect sink properties of grain boundaries in graphene under particle irradiation.

Understanding and Controlling Toughening Mechanisms in Nanotube Reinforced Ceramic Coatings

Institution: Brown University
Point of Contact: Brian Sheldon
Email: Brian_Sheldon@brown.edu
Principal Investigator: Brian Sheldon
Sr. Investigator(s): Jun Lou; Rice University, William Marsh
Nitin Padture; Brown University
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$207,000 (2014)

PROGRAM SCOPE

The performance of ceramics is inherently limited by low fracture toughness, and it is well known that composite ceramic architectures can lead to significant toughness improvements. While long-fiber reinforcements can provide substantial advantages, basic length-scale effects do not necessarily point to substantial toughness improvements at the nanoscale. The DOE-BES research that we have conducted to date has made important advances in understanding the mechanisms that dictate toughness enhancements in carbon nanotube (CNT) reinforced ceramics. The primary objectives of the current work are to: (1) Understand failure and toughening mechanisms in ceramic matrices, reinforced with multiwall carbon nanotubes (MWCNTs). Much of this work focuses on information obtained from *in situ* mechanical testing – in particular, using nanoindentation of microcantilever beams at Brown and single CNT pull-out experiments at Rice University. (2) Determine the extent to which the critical properties governing toughness are coupled to one another in CNT-based materials - particularly the variations in fiber strength, the fiber-matrix sliding resistance, and the fiber-matrix debond energy (in conventional fiber-reinforced ceramics these quantities are generally viewed as independent properties). (3) Another component of this work is SWNT reinforced ceramics, where interwall sliding is no longer relevant, but where significantly different mechanisms may be able to impart toughness (i.e., initial evidence suggests that SWNTs inside of bundles can unfurl or uncoil).

FY 2014 HIGHLIGHTS

Interface coatings were applied to MWCNTs with atomic layer deposition (ALD), and these were incorporated in a polymer-derived ceramic (PDC) matrix. In general the ALD coatings increased pull-out lengths with high quality MWCNT's, whereas the same coatings reduced pull-out lengths when tubes with much higher defect densities were used. Additional insight into this unexpected behavior was obtained with in-situ single CNT pull-out experiments (carried out using a micro-fabricated device in a scanning electron microscope). This carefully designed study provides detailed information about interfacial interactions between CNTs and PDC matrices. The measurements show that 30 ALD cycles increase the interfacial shear strength (IFSS) of the CNT-PDC by 45%. This higher IFSS is believed to originate from the additional surface roughness, which leads to mechanical interlocking at the interface

during pull-out. The combination of high strength (low defect) CNT's and special surface structures obtained with carefully designed interlayers opens up opportunities for improving the mechanical properties of CNT-reinforced ceramic nanocomposites. Research with SWNT reinforced was also initiated during this period. Dense and homogenous CNTs-Al₂O₃ nanocomposites were successfully prepared through colloidal processing and spark plasma sintering. Indentation experiments show that MWCNTs are stronger in shear resistance than SWCNTs. MWCNTs with prior covalent functionalization are able to provide crack bridging in the corresponding Al₂O₃-matrix composites, while the same acid treatment is detrimental to the SWCNT mechanical properties. In-situ observation during crack propagation provides more direct evidence of the CNT bridging contributions in bearing the remarkable high applied load. The CNTs' sword-in-sheath failure also suggests intimate bonding between Al₂O₃ and CNTs which can provide effective load transfer from the matrix to the CNTs.

Dynamic Fracture in Dealloying Induced Stress Corrosion Cracking

Institution: Arizona State University
Point of Contact: Karl Sieradzki
Email: Karl.Sieradzki@asu.edu
Principal Investigator: Karl Sieradzki
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$131,096 (2014)

PROGRAM SCOPE

This research program examines the role of dynamic fracture processes in dealloying induced stress-corrosion cracking (SCC) of face-centered cubic alloys. This form of SCC is particularly relevant in energy conversion systems as many failures in alloys such as austenitic stainless steel can result directly from dealloying. Corrosion of such alloys often results in the formation of a brittle nanoporous layer, which we hypothesize serves to nucleate a crack that owing to dynamic effects penetrates into the undealloyed parent phase alloy for a distance of several microns. Since there is essentially a purely mechanical component of cracking, stress corrosion crack propagation rates can be significantly larger than that predicted from electrochemical parameters. Silver-gold alloys serve as a model system for this study since hydrogen effects can be neglected on a thermodynamic basis, which allows us to focus on a single cracking mechanism. There are two major types of experiments underway. One series of experiments is centered on dynamic fracture in monolithic nanoporous gold (NPG). High-speed 1,000,000 frame/second digital photography is used to measure crack velocity as a function of the porous length scale and electrochemical potential. The other set of experiments referred to as crack injection involves forming a porous dealloyed layer under controlled electrochemical potential and zero stress, removing the potential and subsequently loading the system. The results of these experiments are interrogated for cracking using the dual-beam focused ion beam/scanning electron microscope and aberration corrected scanning transmission electron microscopy (STEM).

FY 2014 HIGHLIGHTS

(1) Digital Image Correlation (DIC) was used to measure the Young's modulus and Poisson's ratio for monolithic 40 nm NPG. These numbers were used to determine the dilatational, shear and Rayleigh wave velocities. (2) Crack velocities were measured as a function of electrochemical potential and ranged from ~100 m/s at 0.5 V (NHE) to 200 m/s at 1.4 V (NHE). (3) Fracture toughness tests determined that the fracture toughness of 40 nm NPG was ~ 10 J/m². The dynamic fracture toughness was

determined by the elastic strain energy in the system, which was defined by the loading conditions. (4) STEM characterization of crack injection experiments in polycrystalline AgAu alloys revealed grain boundary porosity at the tip of arrested cracks. This porosity could be a result of either grain boundary dealloying or shock wave propagation. (5) Preliminary crack injection experiments performed on AgAu single crystals show injection to distances of order 2-5 microns.

Tunable Hetero-Epitaxial Shape Memory Alloys

Institution: Purdue University
Point of Contact: Alejandro Strachan
Email: strachan@purdue.edu
Principal Investigator: Alejandro Strachan
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Shape memory materials are used for a wide range of applications, from medicine to aerospace, due to the ability to recover their original shape after inelastic deformation and super-elasticity. The ability to engineer desired performance in these materials is of technological and basic-science importance and this project explores a novel avenue to achieve this using large-scale computer simulations. The goal of the team is to explore hetero-epitaxial integration develop composite shape memory meta-materials with improved or tunable properties. A successful project will provide a quantitative assessment of the potential and limitations of hetero-epitaxial integration as an avenue to develop shape memory materials with tailored properties. This may address some of the limitations that currently restrict the use of SMAs as active materials. From the point of view of basic science the effort will shed light into the fundamental phenomena that govern and limit the fabrication and performance of hetero-epitaxial SMAs nanostructures: i) coherency limits in terms of materials and size, and ii) the role of strain, interfaces, and free surfaces in their martensitic transformation and thermo-mechanical response. Shape memory materials have an enormous potential for a wide range of applications from nanoscale switches for communications and low power electronics to microfluidics and this project will contribute to the knowledge base necessary for the development of next-generation materials nanoengineered to achieve specific functionalities.

FY 2014 HIGHLIGHTS

During FY 2014 the team focused on atomistic simulations of temperature and stress-induced martensitic transformations in nano crystalline shape memory materials. They uses multi-million-atom molecular dynamics (MD) simulations with an embedded atom model potential parameterized for NiAl to provide an atomic picture of grain size effects on the martensitic transformation. They found that nucleation of the martensite phase occurs in the grain interiors due to the mechanical constraints of neighboring grains with different orientations. The martensite nuclei grow outwards up to the point that further transformation is hindered by the constraints imposed by neighboring grains. Decreasing grain size hinders the transformation process and the transformation is completely suppressed for samples with average grain sizes of 7.5 nm and less. This is consistent with experimental observations. Interestingly, mechanical loads can induce the martensitic transformation in samples with ultra-fine grains and, quite surprisingly, the sample with 7.5 nm grain size exhibits improved superelasticity as compared with its coarser grain counterparts. The simulations provide a picture of the processes that

govern the performance and fundamental limits of nanocrystalline shape memory alloys with atomistic resolution.

Interfacial Effects in Radiation Phenomena of Ceramics

Institution: Wisconsin-Madison, University of
Point of Contact: Izabela Szlufarska
Email: szlufarska@wisc.edu
Principal Investigator: Izabela Szlufarska
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$590,011 (2014-2016)

PROGRAM SCOPE

The overall goal of this project is to discover fundamental principles that control radiation effects in ceramics, as exemplified by silicon carbide, and to use this understanding to guide design of ceramics with superior radiation resistance. SiC is not only an archetypical covalent ceramic, but also it is a material of large technological interest for a wide range of nuclear energy and electronics applications. The focus of this project is to determine the role of buried interfaces in the recovery of radiation-induced damage. Increasing the volume fraction of surfaces and interfaces provides a highly promising path toward improving radiation resistance of materials, because interfaces act as sinks for radiation-induced defects. For instance, metallic systems with grain sizes refined to the nanometer regime have been shown to lead to significant enhancement of radiation tolerance due to the increased volume fraction of grain boundaries. Surprisingly, in many ceramics seemingly contradictory results have been reported regarding the effect of grain size refinement on radiation damage. These results show that in design of radiation tolerant materials it is critical to consider coupling of grain size to effects of other nano- and microstructural features. Our approach involves a close integration of multi-scale simulation methodologies (from quantum mechanical calculations to rate-theory models) with state-of-the-art experimental characterization techniques (such as high-resolution high-precision scanning transmission electron microscopy). Specific objectives of this project are to: (i) Unravel the effects of grain boundaries on defect evolution during irradiation; (ii) Discover the effects of radiation on grain boundary atomic structure and on grain boundary sink strength; and (iii) Identify stable configurations of complex defect clusters and their quantifiable contribution to radiation-induced phenomena in SiC.

FY 2014 HIGHLIGHTS

We have developed a genetic algorithm for optimization of defect structures embedded in a bulk crystalline material. Using a combination of this new algorithm and *ab initio* calculations, we determined the ground state structures of a number of small interstitial defects in SiC, “invisible” to traditional transmission electron microscopy (TEM). Understanding the structure and energetics of these defects is essential for development of predictive models for radiation-induced damage. We have also investigated mobility of small defect clusters in SiC using accelerated atomistic simulations based on the kinetic activation-relaxation technique and we predicted that defect clusters in SiC are immobile by thermal mechanisms up to 1200K. Surprisingly however, we have further discovered using high resolution scanning TEM that defect clusters can become mobile under electron irradiation. This is the first direct experimental observation of mobility of intrinsic defect clusters in a bulk material. We developed a model for radiation-induced diffusion, which predicts diffusion coefficients in excellent agreement with experimental values. These results fundamentally change how we view defect evolution

and damage annealing in ceramics because up to this point it has been typically assumed that clusters in these materials are immobile due to their high intrinsic energy barriers to migration. Finally, to understand evolution of radiation-induced damage and its dependence on the presence of grain boundaries, we used high resolution TEM to study radiation-induced amorphous domains in SiC. An unusual morphology of crystalline/amorphous boundaries was found, which was then identified as a result of the cascade overlap and reproduced by our multi-scale model. This mechanism of damage evolution is important for understanding grain size effects on irradiation damage as the grain size effects have been shown to depend on damage mechanisms.

EARLY CAREER: Linking the Codependence of Grain Boundary Structure and Density to Defect Evolution Mechanisms During Radiation Damage

Institution: Drexel University
Point of Contact: Mitra Taheri

Principal Investigator: Mitra Taheri
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

The aim of this project is to provide a fundamental understanding of how metallic nanocrystalline alloys can be utilized as radiation tolerant materials in future nuclear reactors. Information about the origin and mechanisms of damage at the nanoscale and how these mechanisms evolve as a function of grain boundary character (GBC) and density (i.e., grain size) is still unclear. Understanding and mitigating radiation damage is of paramount importance in the nuclear industry. Damage of structural materials is a major limitation to extended lifetime of current reactors, and implementation of future reactors. Information about the mechanisms of and evolution of damage at the nanoscale as a function of grain boundary structure and density (i.e., grain size) is still unclear. Further understanding of the kinetics of the following point defect behaviors is needed: the decrease in point defect density near the grain boundary, or denuded zone, and radiation induced segregation (RIS), the preferential diffusion of solute atoms near the grain boundary that result in chemical inhomogeneity at the boundary. *In situ* irradiation and analytical transmission electron microscopy techniques are being used to study both pure and alloy materials dynamically. Combined with analytical techniques such as STEM-EDS, EELS and APT, in-situ and ex-situ irradiation techniques are being used to study the effect of sink strength and density on defect clustering and behavior in relation to grain boundaries. This work is defining a framework for understanding the origin of radiation damage mechanisms in model BCC and FCC nanocrystalline materials, on which a foundation of radiation tolerant material development can be built. Key topics addressed by this work are (1) the influence of GB density and GB character (GBC) on damage accumulation in model nanocrystalline FCC and BCC alloys and (2) the effect of species dependent interstitial diffusion on the GB chemistry.

FY 2014 HIGHLIGHTS

Key findings include: (1) The determination that the role of grain boundary character in radiation induced defect sink strength is consistent from the mesoscale to nanocrystalline microstructures, as long as grain boundaries are equilibrium structures. (2) Precession electron diffraction can be used as a means of measuring dislocation density and emission, and also strain, during microstructural evolution.

(3) Grain boundary plane is a key factor in radiation induced segregation, however grain boundary saturation can and does occur. Since January 1, 2014: 1 paper published, 2 papers in review, 1 patent pending, 8 invited presentations, 7 student presentations at conferences.

Chemomechanics of Far-From-Equilibrium Interfaces (COFFEI)

Institution: Massachusetts Institute of Technology
Point of Contact: Harry Tuller
Email: tuller@MIT.edu
Principal Investigator: Harry Tuller
Sr. Investigator(s):
Students: 4 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$880,000 (2014)

PROGRAM SCOPE

Brittle oxide functional materials, such as those utilized in solid oxide fuel cells and lithium batteries exhibit significant operational stresses induced via chemical and electrochemical diffusion across material interfaces. Virtually all battery storage materials undergo considerable mechanical strain during Li charging and discharging. Likewise, fuel cell components, operating under steep oxygen activity gradients, often suffer from chemically induced strains. The goals of this program are to develop models to predict chemomechanical phenomena in lithium battery and fuel cell electrodes and electrolytes, to characterize the relation between Li or oxygen nonstoichiometry and lattice dilation/contraction, to predict conditions for device failure related to rate dependent charge/discharge rates and develop a detailed understanding of the role of strain on transport within electrodes and electrolytes and on reaction rates related to electrochemical reduction and oxidation reactions occurring at the electrode/gas or electrode/electrolyte interfaces.

FY 2014 HIGHLIGHTS

A mesoscopic fully coupled electro-chemo-mechanical model was developed capable of accounting for the effects of Li diffusion and consequent isotropic or anisotropic volumetric expansion of the host materials. The numerical analysis simulates fracture within the electrode material and delamination at the interface between electrode particles and solid electrolyte. Crack formation and propagation is predicted by means of a cohesive zone model extended to include decreased Li flux across interfaces due to their loss of mechanical integrity. The effects of inelastic strain (i.e. dislocations) in altering the local defect equilibria, and the kinetics of transport and surface exchange in selected solid oxide fuel cell (SOFC) model materials (CeO_2 and SrTiO_3 -based), are now being examined. Static and dynamic atomistic modeling techniques are being employed to study the effects of edge dislocations on the stability and mobility of oxygen defects. At equilibrium, for ceria, trivalent cations and oxygen vacancies are found to simultaneously enrich or deplete either in the compressive or in the tensile strain fields around the dislocation. The associative interactions among the point defects in the enrichment zone, and the lack of oxygen vacancies in the depletion zone slow down oxide ion transport, a finding contrary to fast diffusion of atoms along the dislocations in metals, and should be considered when assessing the effects of strain on oxide ion conductivity. The first chemical and thermal expansion measurements of perovskite $\text{SrTi}_{1-x}\text{Fe}_x\text{O}_{3-\alpha}$ SOFC electrodes were completed, enabling predictions of durability in working energy conversion and storage devices. Demonstrated strong coupling between thermal and chemical expansion behavior: thermal expansion depends on oxygen stoichiometry, and chemical expansion

depends on temperature. We experimentally confirmed our previous theoretical calculations demonstrating the important role of charge localization in controlling chemical expansion behavior.

Atomistic and Mesoscopic Study of Plastic Deformation of Alloys of Body-Centered-Cubic Transition Metals and Magnetic Iron

Institution: Pennsylvania, University of
Point of Contact: Vaclav Vitek
Email: vitek@seas.upenn.edu
Principal Investigator: Vaclav Vitek
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$171,000 (2014)

PROGRAM SCOPE

The goal of this research is to provide a fundamental insight into the deformation and fracture mechanisms in body-centered-cubic (BCC) transition (refractory) metals. This is carried out by employing atomic level computer modeling of dislocations and other crystal defects. These metals and their alloys are the most important materials employed in the broad range of technologies involved in energy production and conversion. From the perspective of fundamental science, these metals have a mixed nearly free electron and covalent bonding, which leads to significant directional bonds. This presents a formidable scientific challenge for atomic level studies of extended defects and thus one of the principal tasks of this research is to take into account in atomistic calculations all the essential aspects of bonding. In transition metals the partially filled d-band invokes the dependence of the energy on bond angles and in the present research we are developing a new version of bond-order potentials (BOPs) that reflect well this bonding together with bonding mediated by nearly free s and p electrons. The BOPs are being developed for all non-magnetic transition BCC metals and further progress involves iron, in which ferromagnetism plays important role. As a further step is the development of these potentials for binary alloys. The link between bonding on atomic scale and the mechanical response of a material to loading is being established via a multiscale modeling. When investigating plastic behavior of BCC metals we concentrate on the structure and glide of 1/2 screw dislocations that control the plasticity of these metals. This is followed by the development of mesoscopic models of dislocation glide at finite temperatures the part of which is determination of the Peierls barrier employing the nudged-elastic band (NEB) method. The important novel concept is that the Peierls potential is a function of the full applied stress tensor.

FY 2014 HIGHLIGHTS

Numerical bond-order potentials (BOPs) were developed for non-magnetic transition metals V, Nb, Ta, Cr, Mo and W. The testing of these potentials has been made via comparison with calculations that were also carried out using a DFT method. These involve investigation of alternative higher energy structures, transformation paths connecting the BCC structure with other structures by continuously distorted configurations, evaluation of the vacancy formation energy and calculation of phonon spectra. In all cases the BOP calculations are in an excellent agreement with DFT calculations. This testing of BOPs clearly demonstrates that they are transferable to structures well outside the regime of the ideal BCC lattice and are suitable for investigating the atomic structure and behavior of extended crystal defects. Two novel aspects were discovered in this study. First, it was found that screening of the bond integrals that describe the covalent bonding mediated by the d electrons by neighboring s electrons is essential.

Only when the screening is included the dislocation studies lead to the dislocation glide that agrees with experimental observations. This demonstrates, for the first time, that the local electronic structure has to be fully accounted for when investigating dislocation behavior in transition metals. The second exciting finding is that when using the constructed BOPs the motion of the screw dislocation in Nb and V loaded in pure shear and/or tension is predicted to take place on the {101} plane with a Schmid factor much lower than that of the primary slip plane. This agrees with experimental observations in which such slip was found to dominate in both Nb and V. It was named anomalous and its origin is still not well understood. Our calculations suggest that it is likely that we are starting to understand its origin on the level of atomic bonding. This dislocation behavior is now studied in all transition metals.

Localized Deformation and Intergranular Fracture of Irradiated Alloys Under Extreme Environmental Conditions

Institution: Michigan, University of
Point of Contact: Gary Was
Email: gsw@umich.edu
Principal Investigator: Gary Was
Sr. Investigator(s): Ian Robertson; Wisconsin-Madison, University of
Diana Farkas; Virginia Polytechnic Inst. and State U.
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$560,000 (2014-2015)

PROGRAM SCOPE

The local conditions for initiation of irradiation assisted stress corrosion cracking (IASCC) are the development of a high normal stress localized at the intersection of the dislocation channel (DC) and the grain boundary (GB), driven by the intense dislocation activity in the channels. By virtue of the strong bond between the oxide and the underlying metal alloy, the high stresses are relieved only by the rupture of the oxide film above the grain boundary, allowing contact between the high temperature water environment and the freshly exposed metal. A key feature of our approach has been the implementation of a mesoscale science approach that provided linkage from atomistic simulations of dislocation responses to the accommodation and emission of dislocations from grain boundaries, through direct observation of dislocations with irradiation defects and grain boundaries, to macroscale experiments. Having isolated these conditions, we are poised to address why this failure does not occur at every grain boundary that is favorably oriented, why it remains isolated at one channel over others along the same grain boundary, and what is the role of environment in inducing the cracking. With these questions in mind, our overall objective is to determine the basic processes by which localized deformation in irradiated materials leads to intergranular (IG) cracking in alloys in aggressive environments at high temperature. The program focuses on the following sub-objectives: (i) Since all DC-GB intersections do not result in cracking, what is the distinguishing factor or condition? If a threshold in stress for initiation of IASCC exists, can it be determined? (ii) Can the variability in cracking propensity between different alloys be explained by specific material properties such as stacking fault energy, grain boundary structure, or constraints imposed by the surrounding grains? (iii) What is the role that the water environment, either separately or in concert with a high localized stress state, in the cracking process?

FY 2014 HIGHLIGHTS

We have identified the various ways in which dislocation channels (DC) interact with grain boundaries and which are most likely to lead to nucleation of IASCC cracks. DC - grain boundary intersections are classified as either continuous in which slip is transferred across the boundary, discontinuous with grain boundary slip in which the slip is confined to the grain boundary plane, and discontinuous in which there is no evidence of transfer of slip to the neighboring grain or the grain boundary. Stress corrosion cracking tests in 288°C simulated boiling water reactor (BWR) water revealed that discontinuous channel-grain boundary intersections are several times more likely to result in IG crack initiation than either discontinuous channel interaction with grain boundary slip or with continuous channel – grain boundary interaction. Atomistic simulation studies of the interaction of dislocations with grain boundaries were performed in samples created with microstructures that mimic those studied in experiments. The simulations revealed that the arrival of a dislocation at the grain boundary is associated with increased stress. If the dislocations are not transferred across the boundary, crack formation is likely to develop as a result of the stress buildup. In the simulations 78% of cracks developed in boundaries with no slip continuity into the neighboring grain. The simulations also showed that slip transmission versus stress buildup at the boundary is affected by the grain boundary geometry, with 84% of the cracks developing in random high angle boundaries. The key finding at the mesoscale level was that the slip systems activated by the grain boundary in response to the accumulation of incident dislocations both at and in the grain boundary is determined by the same condition as in unirradiated materials. A distinct difference between unirradiated and irradiated austenitic stainless steels is that the magnitude of the locally resolved shear stress becomes important in the latter case.

Deformation Mechanisms of Nanotwinned Al

Institution: Texas A&M University
Point of Contact: Xinghang Zhang
Email: zhangx@tamu.edu
Principal Investigator: Xinghang Zhang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of this program is to investigate at a fundamental level, the deformation mechanisms of nanotwinned (nt) Al films with high density growth twins and stacking faults (SFs). Growth twins have been introduced into certain fcc metals with low stacking fault energy (such as Cu, Ag and 330 stainless steels) to achieve high strength, high ductility, superior thermal stability and good electrical conductivity. However it remains a major challenge to produce growth twins and SFs in metals with ultra-high stacking fault energy (SFE), such as Al. Although deformation twins have been observed in nanocrystalline Al powders by low temperature, high strain rate cryomilling or in Al at the edge of crack tip or indentation (with the assistance of high stress intensity factor), these deformation techniques typically introduce twins sporadically and cannot control deformation twin density. This program is built upon our recent success of fabricating high quality epitaxial nt Al and will test the hypothesis that nt Al may have deformation mechanisms drastically different from those of coarse-grained Al and nt Cu. To test this hypothesis, we will perform the following tasks: (i) Investigate the stability of nanotwins and SFs in Al, (ii) examine if single crystal like nt Al has pop-in events during deformation, (iii) the interaction of dislocations with twin boundaries (TBs) in nt Al, (iv) mechanical stability of TBs and SFs in Al under

stress, and work hardening of nt Al. *In situ* nanoindentation will be used extensively to probe deformation mechanisms in nt Al.

FY 2014 HIGHLIGHTS

In this fiscal year, we have performed in-depth studies on three projects. (1) Investigate an intriguing twin formation mechanism in high stacking faulty energy metals We examined several sputter-deposited, {111} textured Ag/Al, Cu/Ni and Cu/Fe multilayers, wherein growth twins were observed in Al, Ni, and face-centered cubic (fcc) Fe. We derived two important criteria that enable the formation of twins in high SFE metals: (i) a low SFE buffer layer that readily forms twin seeds, and (ii) global coherency between coherent similar interfaces (between constituents with identical planar indices) or local coherency between coherent dissimilar interfaces (between constituents of different planar indices) that permits twins to propagate across layer interfaces. The formation of twin boundaries across layer interface could be a natural consequence of strain relaxation, in competition to the formation of misfit dislocations. (2) Establish a novel technique to reliably determine strain rate sensitivity of nanotwinned and nanocrystalline metal films. Nanoindentation is increasingly used to determine the strain rate sensitivity (SRS) of materials with small volumes. However traditional data analysis yields large scattering and uncertainty due to thermal drift at low strain rates. Here we use a new method that renders hardness insensitive to thermal drift. The method involves (a) directly measuring contact stiffness by means of a small dynamic oscillation and (b) calculating contact area from the measured contact stiffness and the elastic modulus, which is insensitive to strain rate. The new technique is validated on nanocrystalline Ni and nanotwinned Cu films and returns expected values of SRS. (3) We (Beyerlein, Zhang, Misra) wrote an review article (Ann. Rev. Mater. Res.) on growth twins and deformation twins. We anticipate that, by providing a broad perspective on the latest advances in twinning, this review will help set the stage for designing new metallic materials.

Khalid Hattar; Sandia National Laboratories-Albuquerque
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$713,000 (2014)

PROGRAM SCOPE

Nanostructured metallic alloys have revealed intriguing scientific phenomena such as Hall-Petch breakdown and stress-induced grain growth, yet this class of metals is often plagued by grain structure instability, limited ductility, and a lack of available bulk processing routes. In the past 3 years, through 28 publications, this program has fostered a better understanding of grain boundary motion and grain growth as it relates to the unusual mechanical properties of nanostructured metals. While grain instability was once viewed as a detrimental attribute that was difficult to control and predict, our improved understanding of this phenomenon offers the opportunity to tailor stability for particular

thermomechanical environments. In the current year, we continue to explore the thermal, mechanical, and irradiation-induced stability of nanostructured interfaces. For this purpose, we rely on [1] thin film processing methods including pulsed laser deposition and magnetron sputtering to produce pure metals and binary nanostructured alloys of varying degrees of thermodynamically predicted stability, [2] *in situ* deformation, heating, and ion-irradiation of these films in the TEM, and [3] *ex situ* characterization before and after various mechanical environments (tension, shear, indentation, fatigue, wear). Molecular dynamics modeling continues to provide a complementary approach to addressing the questions regarding mechanisms governing boundary stability. The modeling and theory also provides a mechanistic foundation to assist in the interpretation of the experimental observations.

FY 2014 HIGHLIGHTS

In FY 2014, our focus was on quantifying the influence of special grain boundaries or chemically modified grain boundaries in processes associated with mechanically-induced grain growth. In our recent experiments, we have compared the indentation behavior of nanocrystalline and nanotwinned copper and found that sigma-3 (twin) boundaries facilitate extensive grain growth. Moreover, the grain growth is even more pronounced at cryogenic temperatures (4K and 77K) compared to room temperature, suggesting a potentially athermal mechanism. While other researchers have postulated that the twin boundaries facilitate grain growth through a 'de-twinning' process, our own non-local kinematic analysis of molecular dynamics simulations have shown a more complex superposition of several simultaneous mechanisms including twin nucleation and dislocation channeling as well as twin migration. These simulations also suggest that the relative contribution of the various mechanisms is different in tension versus compression. In addition to special boundaries that have unusual kinetic mobility, we have begun to investigate binary alloy combinations where segregation of the alloying element to the boundary provides a thermodynamic barrier to boundary migration. To this end, we have experimentally compared the thermal stability of nanocrystalline Fe-Mg and Fe-Cu alloys – two alloys that were previously predicted by Monte Carlo simulations to have marked differences in thermodynamic stability. Indeed the Fe-Mg alloy was profoundly more resistant to thermally-induced grain growth than the Fe-Cu alloy. Finally, this year we have collaborated with EMPA in Switzerland to perform resonant cantilever fatigue experiments that have provided an independent confirmation of our prior hypothesis suggesting that the grain growth process is a necessary precursor to crack initiation in nanocrystalline alloys.

Crack-Tip Mechanisms Driving Environmental Degradation

Institution: Pacific Northwest National Laboratory
Point of Contact: Louis Terminello

Matthew Olszta; Pacific Northwest National Laboratory
Chongmin Wang; Pacific Northwest National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$631,000 (2014)

PROGRAM SCOPE

First-of-a-kind, discovery-based research is being conducted to explicate environmental degradation mechanisms through atomistic measurement and modeling of interfacial reactions occurring at buried crack tips. Degradation processes in corrosion-resistant alloys involve selective oxidation, vacancy injection and local composition changes along grain boundaries that cannot be adequately explained by existing theories. Revolutionary advancements in site-specific sample preparation, in-situ experimental methods and atomically-resolved 3D analytical tomography will be leveraged to develop a seminal understanding of underpinning mechanisms at the atomic scale that control the cracking response in high-temperature gaseous to lower-temperature aqueous environments. Definitive empirical observations will be correlated with innovative multiscale simulation tools to evaluate specific mechanisms that control degradation phenomena. Observations to date have revealed dramatic compositional and microstructural changes that accompany grain boundary selective oxidation. The rapid development of these features requires accelerated interfacial diffusion that can only be explained by oxidation-induced vacancy injection. Observed compositional redistributions ahead of oxidation fronts are consistent with predicted vacancy-mediated, grain boundary diffusivities for those elements calculated at the quantum mechanical level. Intergranular degradation is found to advance in many corrosion-resistant alloys by selective oxidation even at low temperatures. Observations are generally inconsistent with continuum mechanics and electrochemical model predictions underscoring the critical need for fundamental understanding at the atomic and molecular level. This program will define the mechanisms controlling environmental degradation through cutting-edge empirical observations and original modeling of grain boundary reaction processes that bridge from atomistic to macroscopic length scales.

FY 2014 HIGHLIGHTS

Selective oxidation of Cr in a Ni-Cr binary alloy is discovered to promote vacancy injection and an increase in grain boundary diffusion by more than two orders of magnitude during corrosion in hydrogenated water. Quantum density functional theory-based diffusivities of vacancies, alloying elements and interstitial oxygen in Ni grain boundaries have been determined to help explain vacancy enhanced Cr mobility in comparison to response for Al during selective oxidation. Grain boundary oxidation experiments in high-temperature gaseous environments have been performed on Ni-Cr and Ni-Al binary alloys enabling the first direct comparisons to intergranular (IG) corrosion/oxidation nanostructures produced in hydrogenated water. In-situ, high-resolution transmission electron microscopy (TEM) and energy dispersive x-ray spectroscopy revealed unprecedented nanoscale details of chemical partitioning caused by selective oxidation of Cr in a Ni-Cr alloy. The behavior of injected vacancies during oxidation was directly visualized leading to vacancy supersaturation, nucleation of a single cavity and subsequent sinking of excess vacancies. Quantitative measurements of IG stress corrosion and creep crack growth in high purity Ni alloys established that selective oxidation of Cr, Al and Si promoted environment-assisted cracking in comparison to response for pure Ni, Ni-Cu and Ni-Fe alloys. Unexpected enhancement in intergranular stress corrosion crack growth rates for high purity Ni-Cr alloys as bulk Cr concentration is increased from 5 to 20%, not consistent with observed grain boundary oxidation behavior. Initial development was completed on a multiscale simulation model that combines quantum density functional theory simulations of metal, oxygen, and vacancy diffusivities with an atomistic-to-mesoscale free energy based dynamics simulation of crack tip selective oxidation for comparisons with TEM and atom probe tomography measurements.

Multiscale Mechanical Properties and Alloy Design

Institution: Oak Ridge National Laboratory

Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$969,000 (2014)

PROGRAM SCOPE

The overarching goal of this project is to advance fundamental understanding of mechanisms that control the mechanical behavior of crystalline metals across a broad spectrum of length scales. Of special interest are phenomena that cannot be explained by conventional theories. Examples include size-dependent mechanical properties and certain mechanical responses of compositionally complex (e.g., high-entropy) alloys that defy conventional notions of solid solubility. Our near-term focus continues to be on mechanical behavior at small scales approaching those of the fundamental processes responsible for deformation. We have also recently begun work on the mechanisms responsible for certain interesting mechanical responses of high-entropy alloys such as temperature dependent strength, large elongations, high work hardening rates, and the breakdown of the traditional inverse relationship between strength and ductility. Careful processing techniques are used to synthesize high-quality single- and poly-crystals with controlled microstructures and defect distributions. State-of-the-art microanalytical tools are then used to characterize their microstructure and mechanical behavior over the entire range of lengths scales from the nano/micro to macroscopic. Theory and modeling work aligned closely with the experimental effort are used to interpret the experimental results. The understanding gained as a result of this program will contribute to the development of broad scientific principles for the design of next-generation advanced structural materials.

FY 2014 HIGHLIGHTS

(1) A simple stochastic model to determine the pop-in load and maximum shear stress at pop-in, in nanoindentation experiments. J. Mater. Res. 28, 2728 (2013). The model incorporates pop-in due to nucleation of dislocations in dislocation-free regions, and pop-in by activation of preexisting dislocations. The model correctly predicts the experimentally observed average maximum shear stress at pop-in, and the scatter in pop-in loads and how it varies with indenter radius. (2) A high entropy alloy exhibits exceptional damage tolerance, with mechanical properties that improve at cryogenic temperatures. Science 345, 1153 (2014). High-entropy alloys are equiatomic, multi-element systems that can crystallize as a single phase. We found that the five-element high-entropy alloy, CrMnFeCoNi, has exceptional damage tolerance. Furthermore, its mechanical properties actually improve at cryogenic temperatures. (3) Recovery, recrystallization, grain growth and phase stability of a family of FCC-structured multi-component equiatomic solid solution alloys. Intermetallics 46, 131 (2014). All possible equiatomic subsystems of the high-entropy alloy FeNiCoCrMn were studied by assessing their available phase diagrams and experimentally verifying which of the sub-alloys formed single-phase FCC solid solutions. Neither the ability to form a single-phase solid solution, nor the degree of solid solution

hardening, was determined solely by the number of alloying elements; rather the type of elements present in the alloys needs to be taken into account. (4) Theoretical studies of Ir₅Th and Ir₅Ce nanoscale precipitates in Ir. Phil. Mag. 94, 991 (2014). Very small amounts of thorium or cerium added to iridium metal improve the high-temperature mechanical properties of the resulting alloys. We demonstrate that there are low-energy configurations for nanoscale precipitates in Ir, and that these coherent arrangements may assist in producing improved mechanical properties.

Evolution of Grain Boundary Networks in Extreme Radiation Environments

Institution: Lawrence Livermore National Laboratory
Point of Contact: Eric Schwegler
Email: schwegler@llnl.gov
Principal Investigator: Mukul Kumar
Sr. Investigator(s): Vasily Bulatov; Lawrence Livermore National Laboratory
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$427,000 (2014)

PROGRAM SCOPE

Advanced nuclear energy systems will require materials to perform for long periods in elevated temperatures and high radiation conditions. Conventional materials lack the required microstructural stability in such environments. Grain boundaries (GB) in nanocrystalline materials can substantially mitigate this degradation by acting as highly effective sinks for point defects. Unfortunately, such materials can be thermally unstable, thus reducing their long-term efficacy. Our previous work shows that GB networks consisting of a high fraction of annealing twins and related boundaries can be stabilized against thermal coarsening. We are studying whether such GB networks can also enhance microstructural stability under irradiation. The proposed work aims to address the overarching question: What must a GB network look like if it is to act as an effective point defect sink, not only on initial deployment, but after years of severe irradiation? We envision a network in which high free volume “random” boundaries act as point defect sinks while the more stable special boundaries anchor the network, and the entire ensemble is statistically stable over long periods. We have successfully elucidated the thermal annealing characteristics of nanostructured copper, relating the relative coarsening rates for various microstructural morphologies to the nature of the quadruple nodes in the GB network. We have also elucidated the role of the GB network on radiation-induced GB migration, particularly for nanotwinned copper. These observations are being augmented by 3-D HEDM observations on conventional microstructures, which provide an unprecedented window into the correlated nature of GB networks and its effect on coarsening behavior. These results are also being corroborated through Monte Carlo (MC) simulations of coarsening behavior. These simulations are being informed by a newly constructed function that universally treats GB energy anisotropy for all FCC materials.

FY 2014 HIGHLIGHTS

Conducted a study that resulted in a major modification to how Monte Carlo methods are used to simulate microstructural evolution. Used our newly developed energy function for grain boundaries to document the change in total energy of the system during microstructural evolution. In-situ high energy electron irradiation was used to investigate how grain boundary networks influence radiation-induced boundary migration.

Nanotwinned Materials for Energy Technologies

PROGRAM SCOPE

Nanotwinned metals and alloys are emerging as a particular form of nanoscaled material that can exhibit high strength coupled with improved thermal stability, both of which are yet unexplained. We have developed an integrated experimental, modeling and simulation program to examine the underlying mechanisms of plasticity in nanotwinned samples. We employ a range of methods to create systems with differing twin morphologies and microstructures and characterize their structures using a range of techniques, from electron microscopy to synchrotron scattering to the use of an atom probe. Mechanical testing of these samples is carried out in a novel tensile strain stage that enables accurate measurements of stress-strain behavior with concurrent *in situ* transmission electron microscopy (TEM) observations of evolving microstructures. We will also use a temperature-controlled nanoindenter to characterize the thermal dependence of the mechanical properties. The experiments are coupled with a modeling and simulation program that includes atomistics, dislocation dynamics and polycrystal plasticity simulations. The experiments provide both realistic validation of models and a deeper understanding of fundamental mechanisms, enhancing the development of new understandings of deformation in nanotwinned materials. This program will not only shed new light on plasticity in nanotwinned materials by bridging the current gap between the experiments and modeling, but it will also greatly enhance our overall understanding of many collective and cooperative mechanisms of plasticity in these materials.

FY 2014 HIGHLIGHTS

In FY 2014, experimental and theoretical studies were performed to examine the effects of solute on the strength and thermal stability of nanotwinned materials. Our experimental studies on nanotwinned silver showed a large strengthening effect from copper additions. Molecular dynamics simulations of twin boundary migration in the presence of impurities showed a considerable impurity drag effect that cannot be described by classical solute-drag models.

Stability of Nanoclusters in Metal Matrices under Extreme Environments

Institution: Oak Ridge National Laboratory

Funding: \$928,000 (2014)

PROGRAM SCOPE

The goal of this project is to understand the formation mechanism, energetics, and fundamental hardening behavior associated with stable nanoclusters in metallic alloys and to establish a fundamental understanding of the mechanisms that control their response to intense irradiation and other extremes. The specific aims of the proposed research are to establish the mechanisms for homogenous and heterogeneous nucleation that occur during the earliest stages of formation of nanoclusters and helium bubbles in materials far from equilibrium, to understand the mechanisms that enable radiation tolerant behavior to be achieved in structural steels that are exposed to high doses of irradiation, and to understand the interaction of dislocations with the nanoclusters and other microstructural features in an ultra-fine grain nanostructured ferritic alloy, and hence understand their remarkable mechanical properties. The mechanisms will be elucidated through a synergistic approach of *ab initio* theory, computer simulation and modeling and atomic level experimental characterization of nanostructured materials before and after neutron and ion irradiation by atom probe tomography, analytical and scanning transmission electron microscopy ((S)TEM), weak-beam TEM, novel high-resolution TEM techniques with near atomic resolution of dislocation cores, and neutron scattering. This basic research is ultimately aimed at developing the understanding needed to enable fundamental discoveries regarding nucleation and defect mechanisms in nanostructured materials. The scientific principles developed with this research are expected to have a broad applicability in the synthesis of new-generation nanostructured materials with high-temperature capability for use in advanced energy production and conversion systems under extreme environments.

FY 2014 HIGHLIGHTS

The size and number densities of solute clusters in the ferrite of as-milled mechanically alloyed nanostructured ferritic alloy (NFA) and the stir zone of a friction stir weld were estimated with a prototype high-detection-efficiency LEAP. Solute clusters containing between 2 and 9 Ti, Y and O atoms were detected, providing addition trapping sites for vacancies. Different types of nm-scale precipitates in NFA were identified by combined aberration-corrected electron microscopy and high-efficiency X-ray chemical mapping. By combining advanced STEM hardware with detailed computational datamining of X-ray chemical maps, subtle details of the irradiation effects were identified, such as chemical segregation to grain boundaries blurred by ballistic mixing under cryoirradiation. The distribution of He bubbles at grain boundaries, on nanoclusters, or in the matrix of irradiated NFA has been elucidated by new aberration-corrected electron microscopy methods. Operating the microscope to achieve Fresnel contrast in STEM mode, combined with Z-contrast imaging and elemental mapping, made it possible to detect the smallest ~ 2 nm He bubbles. A thermodynamic DFT-based approach has been developed to estimate the thermodynamic equilibrium by the minimization the free energy of the whole multiphase system with respect to defect production. It uses a limited number of defects and microstructural objects, which properties are calculated from first-principles, allowing the global stability to be studied as a function of composition, internal microstructure, temperature, externally produced defects, etc. Our results confirmed the high temperature stability of Y_2O_3 in Fe. *In situ* neutron diffraction of orientation-dependent lattice strains in ferrite grains reveals a large, temperature-sensitive elastic

anisotropy and a deformation crossover on extensive straining. The novel approach provides a new strategy for characterizing anisotropic elasticity of a variety of complex materials.

PROGRAM SCOPE

The attainment of strength and toughness is a vital requirement for structural materials; unfortunately these properties are generally mutually exclusive. It is the lower strength, and hence tougher, materials that find use for most safety-critical applications where premature, or worse still catastrophic, fracture is unacceptable. Accordingly, the development of strong and tough materials has traditionally been a compromise between hardness vs. ductility. The aim of this program is thus to seek the scientific strategies to solve this “conflict” by defining the basic scientific principles underlying the development of damage-tolerance in lightweight structural materials suitable for the strategic missions of energy and conservation/creation. One approach involves the understanding of the scientific origins of damage-tolerance in new advanced metallic alloys, principally bulk-metallic glasses and high-entropy alloys, where the salient mechanisms involve a balance of intrinsic vs. extrinsic toughening. A second approach involves using concepts of natural hierarchical design to examine the interfaces between the physical and biological sciences in the development of biomimetic hybrid ceramics. Our hypothesis here is that by mimicking natural structural architectures and identifying and incorporating the salient strengthening and toughening mechanisms at multiple length-scales, guided by theoretical modeling at atomistic to continuum levels, and coupled with the use of novel processing techniques, we can develop the scientific foundations for unique lightweight biomimetic structural ceramics materials with unprecedented levels of damage-tolerance. In all cases, our focus is on the scientific interplay between the individual nano/micro-mechanisms that contribute to strength and toughness, that of plasticity and crack-tip shielding, noting that these phenomena originate at very different structural length-scales.

FY 2014 HIGHLIGHTS

A new alloy design concept, high-entropy alloys, has been found to yield a material with exceptional cryogenic fracture toughness properties. Unlike most materials, this alloy shows increasing strength, ductility and toughness with decreasing temperature, associated with the onset of deformation by nanoscale twinning at low temperatures. (Gludovatz *et al.*, Science 2014). Additionally, a novel computational modeling approach has been established to predict the statistical failure of Nature-inspired ceramics at multiple length-scales. Material properties can be created at specific microstructural levels, but must be designed with regard to their macroscopic distribution. Our model permits the physically-based coupling of micro-scale criteria to macroscopic behavior, bridging the micro- and macro-scales. (Genet *et al.*, J. Mech. Phys. Sol., 2014).

Multi-Scale Study of the Role of Microstructure in the Deformation Behavior of Hexagonal Material

PROGRAM SCOPE

Dislocation glide on atomic planes is the most common shear accommodation mechanism in crystals. However, in Hexagonal Close Packed (HCP) materials and some austenitic steels dislocation glide is restricted and shear is simultaneously accommodated by twinning and martensitic transformations, respectively. These transformations require a previous nucleation process governed by stochastic rules, and they propagate by shearing a domain of the grain where a crystal transformation takes place. In this Program we have performed a comprehensive study of the shear mechanisms of twinning in HCP and started studying martensitic transformations in Transformation Induced Plasticity (TRIP) steel. We link these transformations with the macroscopic plastic response of metallic aggregates. The systems studied are the HCP metals Mg, Zr, Be and TRIP steel 304STS and 301LN. This comprehensive research links modeling with experimental studies, at length scales spanning from the atomistic to the continuum. The overarching goals are: a) to improve our understanding of the basic crystallographic mechanisms of shear localization and their role in deformation; b) to develop a predictive multi-scale modeling capability based on such mechanisms. The deliverables of this project are: state-of-the-art material models at atomistic (micro), grain (meso), and polycrystalline (macro) length scales; mechanism-based constitutive laws for HCP and TRIP; new experimental characterization techniques.

FY 2014 HIGHLIGHTS

(1) Used MD, DFT and TEM to further the understanding of Basal-Prismatic (BP) segments in Coherent Twin boundaries (CTB) in HCP. We believe that these segments play a key role in twin mobility. We uncovered atomistic and dislocation mechanisms through which these segments propagate. We performed a comprehensive DFT study of alloying element interaction with BP segments and with CTBs, as preliminary stage to elucidate the role of alloying elements in twin mobility. (2) Uncovered the predominance of atomic shuffle mechanisms (as opposed to twinning dislocations) in the initial stages of twin nucleation and in twin propagation under special boundary conditions. (3) Developed a Crystal Plasticity model for simulating stress induced martensitic transformations in TRIP steel and combined it with measurements of in-situ neutron diffraction to understand the driving forces behind martensitic variant selection during TRIP steel deformation. (4) Developed a stochastic model of stress relaxation, based on distributions of dislocations segments and distributions of internal stress in grains. Implemented this statistical approach in our Elasto-Plastic Polycrystal model (EVPSC). This development provides a way to interpret results of in-situ neutron diffraction experiments. The experiments were done on Mg AZ31 alloy.

The Relationship Between Defect Kinetics and Crystalline Disorder

Funding: \$350,000 (2014)

PROGRAM SCOPE

Mass transport is the defining property for a number of technologically important complex oxides, with numerous applications, from fuel cells to nuclear materials. Thus, there is great incentive for both predicting and controlling mass transport. While there are multiple approaches for controlling diffusion in complex oxides, from doping to microstructure, intrinsic site disorder, in which cation species of different types exchange position, is a key mechanism for controlling transport that has been largely untapped. We argue that there is great untapped potential in both predicting and controlling diffusion as it relates to site disorder in complex oxides. Regarding prediction, given that site disorder greatly influences radiation damage evolution in complex oxides, there is a need for understanding not only anion but also cation transport and how both depend on site disorder in the material and how that site disorder depends on crystal structure and chemistry. Conversely, radiation damage can be used as a tool to control site disorder in complex oxides. We use a combination of state-of-the-art atomistic modeling methods with advanced experimental characterization to determine how the atomic scale mechanisms governing mass transport depend on the local site disorder as a function of the chemistry and structure of the material. In particular, we combine atomistic modeling, both molecular dynamics and accelerated molecular dynamics, with thin film growth and characterization to determine how site disorder controls mass transport, with an initial focus on anion diffusion. We examine both the unit mechanisms responsible for diffusion as well as the aggregate behavior within the sample.

FY 2014 HIGHLIGHTS

(1) Using accelerated molecular dynamics methods, we examined the mobility of oxygen vacancies in a series of complex oxides. We examined the pathways in terms of a layered stacking motif, which provided novel insight into how the structure of the oxide determines the mobility of oxygen vacancies. Finally, a kinetic Monte Carlo model was developed to study the impact of different pathways on the overall diffusion of oxygen. These results provide new insight into how crystal structure and chemistry influence defect mobility, important for both energy applications such as fast ion conductors as well as predicting radiation damage evolution. (2) Using a combination of atomistic simulations (density functional theory and molecular dynamics), we found that the formation energy of antisite defects in pyrochlore, a key quantity for predicting radiation tolerance in pyrochlore, depends on antisite separation. Collision cascade simulations show that the separation depends on irradiation conditions. Together, these results suggest that the radiation tolerance of titanate pyrochlores, as opposed to other pyrochlores, will be very sensitive to irradiation conditions and could be controlled. (3) In collaboration with X. Zhang at Texas A&M, we examined radiation damage evolution in ZnO nanowires. We used rate theory modeling, informed by atomistic calculations, to interpret the experimental results on the size distribution of dislocation loops in the wires as a function of wire diameter. Using the modeling allowed

us to identify the rate-limiting step for interstitial diffusion, which we found to be about 0.3 eV, which allowed us to discriminate between various literature values. (4) In collaboration with C. Jiang at Thermocalc, we have developed a new approach to studying chemically complex materials computationally. It allows for high-throughput calculations for materials with large numbers of species, such as high entropy alloys (HEAs) or chemical complex oxides.

Deformation Physics of Ultrafine Scale Materials

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor
Email: ttaylor@lanl.gov
Principal Investigator: Jian Wang
Sr. Investigator(s): Amit Misra; Los Alamos National Laboratory
Nan Li; Los Alamos National Laboratory
Xiang-yang Liu; Los Alamos National Laboratory
Richard Hoagland; Washington State University
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$916,000 (2014)

PROGRAM SCOPE

This program investigates the deformation physics of ultra-fine scale materials with strengths near the theoretical limits. The descriptions of the mechanisms that determine the strengths and failure limits of such materials lie within new, largely unexplored or unconventional, realms of behavior. Currently, the program is focused on metal-ceramic nanolaminates. The key objectives are to explore: (1) room temperature plasticity, at unusually high strength levels, in nanoscale ceramics afforded by co-deformation with a metal, and (2) mechanisms that enable stable crack growth in nanoscale metal-ceramic nanolaminates. We apply a highly synergistic combination of state-of-the-art atomistic modeling and cutting-edge experimental methods that are able to probe the same nanoscale dimensional features. Specifically, the integrated approach consists of synthesis of nanolayered materials primarily via physical vapor deposition; *in situ* characterization of nanomechanical behavior via scanning and transmission electron microscopy; first principles calculations of interface properties and dislocation-interface interactions; development of empirical interatomic potentials for the metal-ceramic systems to be studied; and molecular dynamics and dislocation dynamics simulations of strain hardening and crack propagation; crystal plasticity modeling of the stress-strain response. This program focuses on developing understanding of the deformation and fracture behavior of materials near their theoretical strength estimates of perfect crystals, and should catalyze new advances in the applications of such materials. The applicability of this knowledge should impact a broad range of engineering materials, such as load-bearing structural components, advanced nuclear energy systems and electro-mechanical systems. It seeks to inspire the development of new materials with attractive combinations of mechanical, electrical, and thermal properties.

FY 2014 HIGHLIGHTS

(1) We proposed and demonstrated “Interface-assisted ductility in “brittle” materials” where materials are brittle and less dislocation activity at room temperature, such as ceramics. Using our developed Three Dimensional Crystal Elastic-Plastic Model (3DCEP), we ascribe the high strain hardening rate to the closely spaced dislocation arrays deposited at interfaces and the load transfer as related to the layer thickness ratio of metal and ceramic layers. We also developed a map that predicts plasticity in nano-

ceramic layers as a function of the ceramic layer thickness and the interfacial dislocation content. (2) We proposed a concept “Interface-enhanced toughening in high-strength nanostructured materials” and performed preliminary study by combining *in situ* SEM bending testing and multi-scale modeling. (3) We explored dislocation activity in ceramics (TiN) using DFT and *in situ* indentation in a TEM. The resistance to glide of lattice dislocations is a fundamental property that determines the deformation and fracture behavior of ceramics. For the first time, using density functional theory (DFT), the lattice resistance to glide (Peierls stress) has been computed for the viable slip systems in TiN. The DFT results will enable the design of metal-ceramic composites where ceramics can plastically co-deform with the metal at unprecedented strength levels. DFT simulations have been carried out to study the preferred slip systems and their respective Peierls barriers in TiN. Using *in situ* indentation in a TEM, we for the first time probed slip systems, critical resolved shear stresses for nucleation and glide of a lattice dislocation in TiN. (4) We further develop the method of interface defect characterization, Atomistically informed Frank-Bilby (AIFB) theory, to characterize interface defect structures and dislocation activity at interfaces. This method can be applied for any crystalline materials.

Electronic and Atomic Response of Ceramic Structures to Irradiation

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris

Sr. Investigator(s): Valentino Cooper; Oak Ridge National Laboratory
Yanwen Zhang; Oak Ridge National Laboratory
Eliot Specht; Oak Ridge National Laboratory
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$400,000 (2014)

PROGRAM SCOPE

The overarching goal of this research is to understand, predictively model, and ultimately control the dynamic response of ceramic structures to irradiation at the level of electrons and atoms. The design of radiation tolerant materials and creation of new functional materials by ion beam modification demand a comprehensive understanding and predictive models of energy transfer and exchange processes at the level of electrons and atoms. To achieve this goal, this research will focus on two specific aims: (1) the dynamic and coupled response of electronic and atomic structures to single ion events; and (2) the collective effects from the coupled dynamics of electronic and atomic processes on damage accumulation, phase transformations and recovery processes for multiple ion events over a broad range of conditions. Novel experimental techniques and multi-scale computational approaches are integrated to investigate the separate and coupled dynamics of electronic and atomic processes over a range of irradiation conditions to elucidate the underlying mechanisms. This research will leverage unique experimental capabilities for measuring *in situ* the response of ceramics to ion irradiation and to individual single ion events, as well as the unique materials synthesis, characterization and modeling resources at Oak Ridge National Laboratory. The scientific advances from the work will not only lead to the design of self-healing and radiation tolerant materials for advance nuclear energy systems, but will provide the foundation for the design and control of material properties that enable broad advances in sustainable energy technologies and national security.

FY 2014 HIGHLIGHTS

We have demonstrated that the energy transferred to electrons by energetic ions via inelastic ionization processes results in a highly localized thermal spike that can effectively heal pre-existing defects and restore the structural order in SiC over a broad range of energies. This self-healing process provides a unique approach for improving SiC based devices, could extend the performance lifetime of SiC in fission and fusion reactor environments, and has significant implications regarding the use of high-energy ion beams and accelerator-based neutron sources for predicting the response of SiC and other materials to fast neutrons. We have discovered that a colossal synergy occurs between inelastic energy loss by ions and pre-existing atomic defects in single crystal SrTiO₃, resulting in the formation of nanometer-sized amorphous tracks. This work identifies a major gap in understanding on the role of defects in electronic energy dissipation and electron-phonon coupling and provides insights for creating novel interfaces and nanostructures to functionalize thin film structures with tunable electronic, ionic, magnetic and optical properties. Density functional theory has been used to predict that the Schottky defect complex is the most stable defect structure in stoichiometric SrTiO₃. Excess SrO leads to the formation of oxygen vacancies and cation antisite defects; excess TiO₂ leads to strontium vacancies, oxygen vacancies and cation antisite defects. These defects play critical roles in controlling the functionality of SrTiO₃. Density functional theory has been used to determine the formation and migration energies of neutral and charged oxygen defects in cubic zirconia. Positively charged oxygen vacancies and negatively charged split-interstitials are the most stable defects. The energy barrier for diffusion of the positively charged oxygen vacancy is significantly less than for the neutral vacancy.

PROGRAM SCOPE

While quantum mechanics is normally associated with electronic motion at the atomic scale, it also finds expression in exotic materials properties. Understanding and controlling “quantum materials” presents one of the grand challenges at the intellectual frontier of the 21st century physical sciences and holds the potential for applications with transformative impact on energy and information technologies. Assembled to advance quantum materials, six PIs with expertise in materials synthesis, neutron and photon spectroscopy and theory form the Institute for Quantum Matter. In a close collaboration coordinated by project director Collin Broholm, they explore quantum materials in the following categories: Frustrated Quantum Magnets where quantum fluctuations supplant conventional static magnetism by a magnetic quantum fluid with exotic particle-like excitations. Examples of quantum magnets to be synthesized in pure crystalline forms and analyzed through spectroscopy and theory include molecule-based magnets, fluoride pyrochlores, and Ising spin chains. Topological Materials where the geometrical character of the bulk stabilizes exotic electronic surface states. IQM shall explore topological Kondo insulators, Weyl-semi metals, and topological superconductors. Correlated Metals: Magnetism near the metal insulator transition will be examined in heavy fermion and organic metals. At the quantum critical point where magnetism collapses, there is a potential for anomalously high temperature superconductivity. Empowered by national facilities such as SNS at ORNL and the NIST center for neutron research, the coordination of key expertise in synthesis, advanced characterization, and theory within IQM seeks to discover and understand quantum materials that can fuel technological progress and meet pressing societal needs.

FY 2014 HIGHLIGHTS

The theory of quantum spin liquids was advanced by identifying quasi-particles in tractable theoretical models of interacting spins with the potential for realization in materials. A new type of frustrated magnets based on fluorine as anion was discovered and synthesized in single crystalline form and subjected to neutron scattering. THz photon spectroscopy was shown to be highly effective for probing anisotropic frustrated systems including quantum spin ice, a quantum spin-orbital liquids, and anisotropic quantum spin chains. A molecular based frustrated magnetic material $\text{LiZn}_2\text{Mo}_3\text{O}_8$ was

developed and subjected to an array of experiments. The material exemplifies entangled magnetism based on static or dynamic singlet formation. Raman experiments that reveal quenched disorder and numerical theoretical work was applied to understand the short range correlated nature of magnetism in the spin-1 triangular lattice antiferromagnet NiGa_2S_4 . Raman scattering was also used to reveal two magnon excitations in the ordered organic magnet $\kappa\text{-(BEDT-TTF)}_2\text{Cu[N(CN)}_2\text{]Cl}$. Neutron scattering and THz photon spectroscopy was carried out on a number of strongly correlated metallic systems to understand the quantum critical point where magnetism collapses. Neutron scattering and theoretical work advanced our understanding of topological Kondo insulators and Weyl semimetals including SbB_6 , CeRu_4Sn_6 , and $\text{Pr}_2\text{Ir}_2\text{O}_7$. Theoretical work was carried out to understand anomalous conductivity by surface modes in Weyl semimetals. A neutron scattering study of magnetic excitations in BaFe_2Se_3 showed the importance of square blocks of four iron atoms in a class of materials that hosts iron superconductivity. A new method for growing crystals from the melt within an optical image furnace was developed and demonstrated in the IQM crystal growth lab. This scientific work at IQM was described in more than 20 publications and more than 50 invited talks.

Application of *In Situ* Neutron Diffraction to Understand the Mechanism of Phase Transitions During Electrochemical Cycling of High Capacity Mg/Si Nanostructured Electrodes

Institution: Utah, University of
Point of Contact: Ravi Chandran
Email: ravi.chandran@utah.edu
Principal Investigator: Ravi Chandran
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$116,592 (2014)

PROGRAM SCOPE

The primary objective of this research is to perform *in situ* neutron diffraction experiments under electrochemical conditions to understand the fundamental nature of phase transitions during Li insertion/extraction in Mg/Si nanostructured high capacity electrodes. A novel electrochemical cell, that enables time-averaged *in situ* observations of bulk phase transitions, will be constructed and optimized for this research. The cell will be used to understand the phase transitions in electrodes made with different nanoparticle sizes and embedded in a conductive medium. The key objective is to discover the particle sizes and compositions at which electrochemically reversible transformations would occur. Mg/Si nanomaterials are the most suited for this study because they (i) can provide very high energy-storage capacity, (ii) offer many phase transition paths representing most anode materials and (iii) present the greatest challenge in anode material science. In particular, the research will investigate (i) how the changes in particle size and composition of the electrodes affect/limit the phase transitions and cell degradation and (ii) how the potential windows and rate of charge/discharge rates affect the kinetics of phase transitions and (iii) the kinetics of formation of the solid electrolyte interface (SEI) layer in the electrode-electrolyte interface. The research will be performed in collaboration with SNS facility at Oak Ridge National Laboratory where the *in situ* neutron diffraction experiments will be conducted. The understanding of phase transitions in Mg/Si electrodes can lead to breakthroughs in electrode chemistry and design for high energy-storage capacity Li-Mg and Li-Si cells. The research can have a large impact in battery materials science. The lack of reversible phase transformations in electrodes based on these materials, over a large number of cycles, has been the bottleneck that is preventing the realization of high capacity battery systems.

FY 2014 HIGHLIGHTS

Our neutron diffraction (ND) work revealed the transient nature of phase transformation in Li-ion batteries; the key finding is that the multiple lithiated phases, for example, Li_xC_6 , LiC_{12} , LiC_6 , co-existed/overlapped in the bulk of the electrode during the major period of charging of the Li-ion cell. Such finding has not been made in X-ray diffraction (XRD) work. Lithiation proceeded by the consumption of the Li-lean phase by the Li-rich phase. This shows that the phenomenon is akin to equilibrium solid-state phase transformation. This also provided indirect evidence that phase transition occurs by planar front movement, raising questions about the porous electrode theory, which is commonly believed. The ND data was obtained in real time and simultaneously on both anode and cathode, which has not been possible with XRD. This way, our work enabled direct one-to-one correlation of phase transitions in anode and cathode and allowed us to directly identify which electrode is limiting the charge capacity of the cell. In particular, we found out that for the LiMnO_2 electrode, the electrode thickness needs to be increased to fully transform C to LiC_6 . Such simultaneous ND diffraction provides a clear illustration of importance of optimizing electrode thickness, especially keeping mind the full phase transformation path. The *in situ* cell ND has simplified lot of conventional XRD experimentation of Li ion cells--ND is one experiment with a real cell as opposed to two separate experiments in XRD with reference electrodes and yet with depth-of-penetration-limitation of XRD. Although the two separate XRD experiments could be combined to provide results similar to ND, there, one can never be certain about one-to-one correlations of phase transitions in anode versus cathode. So this *in situ* electrochemical ND experimentation is a major advancement and realistic with respect to Li-ion cells.

Neutron and X-Ray Scattering Studies of the Liquid-Liquid Transition in Supercooled Confined Water and the Phonon-Like Collective Excitation in Globular Proteins

Institution: Massachusetts Institute of Technology
Point of Contact: Sow-Hsin Chen
Email: sowhsin@MIT.edu
Principal Investigator: Sow-Hsin Chen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$350,000 (2014)

PROGRAM SCOPE

Water, the most common liquid on Earth, is indispensable to all the living systems. The mystery of water is buried in its deeply supercooled region where the bulk pure water cannot enter into because of inevitable freezing into ice, referred to as “no man’s land” in the literature. We have extensively studied, using elastic, quasi-elastic (QENS), and inelastic (INS) neutron scattering techniques, the phase behavior and the dynamics of supercooled water by confining water in hydrophilic nanopores of MCM-41-S so that we can supercool water down to this “no man’s land”. We have also discovered phonon-like excitations in a hydrated protein molecule and the dynamic crossover phenomenon in protein hydration water. An important extension of our research during this period is our studies of microstructure of Ordinary Portland Cement (OPC) and the Green Cement (GC). Why “GC”? With a worldwide production of about 3 billion tons/year, cement is the most important building material used in the modern society. Due to the enormous volumes involved, the CO_2 emission in the production process of cement is responsible for about 5% of the total CO_2 emission of human origin -- 40% of which is due to the energy consumption in the process of using it, while the remaining 60% arises from the calcination of limestone

and clays to obtain the mix of calcium silicates and aluminates that constitutes OPC. The cement paste eventually solidifies into a concrete, in it the major binding phase is a gel called calcium silicate hydrate (C-S-H). We have studied this important C-S-H, using neutron scattering technique at various national labs in the US with samples provided by the University of Florence Group. The GC is made of Magnesium Oxide based material and its production process requires lower temperature that results in much less CO₂ emission. In 2014, we have studied multiscale structure of C-S-H gel and magnesium-silicate-hydrate (M-S-H) gel that is the major binding phase of the GC.

FY 2014 HIGHLIGHTS

In the past year, we have made specific significant progress in the study of the deeply supercooled water confined in MCM-41-S through the direct measurement of density of water in the pore using an ingenious SANS method and have published about a dozen referred articles in high-impact journals. We show evidence of the existence of a first-order phase transition from high-density liquid (HDL) to low-density liquid (LDL), and the resultant phase diagram is suggested in several of our publications. In addition, we found that it is possible to explore the existence of the HDL and LDL by another inelastic neutron scattering method and confirmed that the end-point pressure of the Widom line in the one-phase region of the phase diagram is around 1.6 kbar. As to our studies of microstructure of OPC and the GC, with the continuing enthusiastic collaboration with the Florence Group, we have found that the colloidal particles that make up this C-S-H gel to be multilayer disk-like “globules”, whereas for M-S-H gel the globules are polydispersed spherical particles. These prominent differences in basic structure of the two gels can explain why the concrete that are formed from the OPC and the GC have different mechanical strength. This understanding of the microstructure of C-S-H and M-S-H also gives us a clue to possible methods of improving the GC so that its resultant concrete can have a better mechanical strength by certain kinds of additives in the future. This suggests the great potential for further study on this subject in the coming year. During this reporting period, we added two major publications on this topic, and one of my Ph.D. students on this research also graduated in August 2014.

Improper Ferroelectricity and Frustrated Magnetism in Hexagonal Multiferroics: Neutron and Ellipsometry Studies

Institution: New Jersey-Rutgers, State University of
Point of Contact: Sang Cheong
Email: sangc@physics.rutgers.edu
Principal Investigator: Sang Cheong
Sr. Investigator(s): Valery Kiryukhin; New Jersey-Rutgers, State University of
Andrei Sirenko; New Jersey Institute of Technology
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$270,000 (2014)

PROGRAM SCOPE

Using a complementary combination of neutron scattering and full Muller matrix far IR ellipsometry, we investigate “duality” of improper ferroelectricity and magnetic frustration in hexagonal multiferroics. These systems exhibit an enhanced sensitivity to external fields. We study effects of structural constraints and magnetic geometrical frustration on the ferroelectric, magnetic, and magnetoelectric properties of multiferroics including (RE,In)(Ga,Mn)O₃, REInO₃, and several related systems such as Ca₃CoO₆. Static and dynamic properties of various phases, as well as of structural and magnetic transitions are investigated. The resulting understanding of the microscopic structure, dynamics, and

their relationship to the effects of applied fields should help identify the specific systems with a potential for giant static and dynamic response, and thereby show a prospective approach for discovery of compounds with enhanced properties for future device applications.

FY 2014 HIGHLIGHTS

Multiferroic vortices in the domain patterns of hexagonal manganites have been investigated. Fluctuating vortices were frozen by quenching, imaged, and the obtained patterns analyzed. The obtained results reveal deep theoretical connections between physics of ferroelectrics, superfluids, elementary particles (such as the Higgs boson), and the evolution of the cosmos. In particular, it was found that the dynamics of the phase transitions in the multiferroic manganites follows the predictions of the Kibble–Zurek model for cosmological strings formed in the early Universe. This discovery opens a new avenue for understanding the universal properties of phase transitions in such different subjects are cosmology, high-energy particle physics, and condensed-matter physics. We also studied Mueller matrix spectra of optical phonons in hexagonal multiferroic oxides RMnO_3 , where $R = \text{Ho, Er, Tm, Yb, and Lu}$. Signatures of spin-phonon interaction have been found below the temperature of the antiferromagnetic phase transition T_N due to magnetic ordering of Mn^{3+} spins. A decrease of the ionic radius for R^{3+} ions between Ho^{3+} and Lu^{3+} in the corresponding RMnO_3 compounds resulted in systematic variation of the frequency for several optical phonons.

Using Neutron as a Probe to Study Magnetic Excitations in Strongly Correlated Electron Materials

Institution: Rice University, William Marsh
Point of Contact: Pengcheng Dai
Email: pengcheng.dai@rice.edu
Principal Investigator: Pengcheng Dai
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$720,000 (2014-2016)

PROGRAM SCOPE

Understanding the electronic structure and magnetism in correlated electron materials continues to be at the forefront of modern condensed matter physics. Compounds containing quasilocalized d-electrons and extended f-electrons exhibit a wide range of phenomena, include high transition temperature and unconventional superconductivity. Elucidating the microscopic spin excitations in these systems is central to understand their exotic macroscopic properties, which continue to defy description of the conventional Fermi-liquid theory. Neutron scattering plays an important role in determining the dynamical spin properties in these materials. The normal operation of the spallation neutron source and upgraded high-flux isotope reactor at Oak Ridge National Laboratory has created a unique opportunity for us to establish a strong materials synthesis and neutron scattering program at Rice University. The scope of our present program is to study spin excitations in iron-based superconductors, with the dual purpose of describing magnetic interactions in these materials and, at the same time, training the next generation of neutron scattering scientists. We also establish a materials growth laboratory capable of producing some of the best Fe-based superconductors for the U.S. condensed matter physics community.

Vortex Lattices Studies in Type II Superconductors

Institution: Notre Dame, University of
Point of Contact: Morten Eskildsen
Email: eskildsen@nd.edu
Principal Investigator: Morten Eskildsen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 2 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The program centers on the study of vortices and the vortex lattice (VL) in type-II superconductors and has two main themes. The first is fundamental studies of superconductivity. The formation and condensation of Cooper pairs varies for different materials, and in many cases the exact microscopic mechanism remains elusive. An important step towards a microscopic understanding is detailed knowledge of the order parameter. This is especially important in materials such as UPt_3 and Sr_2RuO_4 where the carriers in the Cooper pairs are believed to form a triplet, but where the detailed order parameter is not well established. We use the vortices to probe the intrinsic nature of the superconducting state in unconventional and/or new materials. The second theme is the study of vortex matter dynamics and in particular the recently discovered metastable VL phases in MgB_2 . Vortex motion will lead to dissipation and is responsible for limitations in the critical electrical current density and of direct importance to the practical use of superconductors. However, the VL metastability is not due to traditional vortex pinning and instead it appears to be due to VL domain effects. This has opened up a new direction in the study of vortex dynamics with analogues to jamming in granular materials.

FY 2014 HIGHLIGHTS

We have used small-angle neutron scattering (SANS) to study the VL in a number of superconductors within the scope of the project. Our earlier measurements of the intrinsic superconducting anisotropy in Sr_2RuO_4 found this to be much larger than the upper critical field anisotropy. This suggests either a subtle coupling between the magnetic field and the triplet order parameter proposed for this material, or Pauli limiting, which is inconsistent with triplet pairing with the Cooper pair zero spin projection along the c -axis. Extending these measurements we found the superconducting anisotropy to be independent of applied field and temperature, lending further support to a Pauli limiting scenario and imposing significant constraints on possible models of (triplet) pairing. In UPt_3 the superconducting phase diagram has three distinct mixed (vortex) phases that can only be explained by unconventional superconductivity. Multiple models for the order parameters in this material have been proposed, all with nodes in the superconducting energy gap and different nodal structure in the three vortex phases. We have measured the temperature dependence of the components of the London penetration depth

that probe the gap nodal structure along the principal directions of the crystal finding a linear behavior in the low temperature limit. Our measurements are consistent with calculations based on an order parameter with E_{2u} symmetry. To investigate the mechanism responsible for the metastability in MgB_2 we have studied the dynamics with which the VL is driven to the ground state by successive applications of small-amplitude AC magnetic field oscillations. We observe a crossover from a slow to a fast power law indicates a two-step process, possibly beginning with a nucleation of ground state VL domains followed by their rapid growth once the VL domain walls reach a critical density. This supports the hypothesis that the metastability may be due to a VL domain jamming.

Vibrational Thermodynamics of Materials at High Temperatures

Institution: California Institute of Technology
Point of Contact: Brent Fultz
Email: btf@caltech.edu
Principal Investigator: Brent Fultz
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$190,001 (2014)

PROGRAM SCOPE

This is a study of entropy, the central issue in thermodynamics. Most of the entropy of materials comes from atom vibrations, and this is a project to understand the origin of vibrational entropy. With accurate assessments of entropy, we assess its effects on the thermodynamic stability of phases in materials and on phase transformations. The work is designed to address cases where vibrational entropy is expected to be large and interesting, especially at high temperatures where there can be significant effects from anharmonicity and electron-phonon interactions. It is primarily an experimental investigation of materials at high temperatures, using inelastic neutron scattering performed at national user facilities such as the Spallation Neutron Source, ORNL. Inelastic neutron scattering, with support from computation, is the most powerful approach today for quantifying the different contributions to vibrational entropy. The experimental measurements give vibrational spectra of the materials, i.e., their phonon densities of states (DOS). With accurate phonon DOS curves, we can obtain the vibrational entropies of different materials, or measure changes in vibrational entropy with temperature or chemical composition. From neutron scattering measurements on single crystals we can obtain a more detailed picture of why phonons undergo changes with temperature. The underlying reasons for differences in DOS curves and entropies are obtained from computational methods such as *ab initio* molecular dynamics simulations, but we still use perturbation theory for useful insights. At high temperatures there is a hierarchy of anharmonic effects, and we have methods for separating them into quasiharmonic entropy, anharmonic entropy, and effects of electron-phonon interactions. Negative thermal expansion associated with highly anharmonic behavior is also of interest in some of the proposed investigations.

FY 2014 HIGHLIGHTS

Ph.D. Thesis completed: Tian Lan, Ph.D. in Applied Physics, May 6, 2014. Hillary L. Smith, Ph.D. in Materials Science, May 29, 2014. Neutron Scattering Studies of Classical and Quantum Fluids in Nanoporous Media

Institution: Delaware, University of
Point of Contact: Henry Glyde
Email: glyde@udel.edu
Principal Investigator: Henry Glyde
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

We conduct unique, world class neutron scattering measurements of Bose-Einstein condensation (BEC), atomic momentum distributions and the collective modes of quantum liquids. This is both in bulk liquid ^4He and in liquid ^4He confined in nanoporous media where superfluidity, BEC and the collective phonon-roton (P-R) modes are substantially modified. Also, liquid ^4He in porous media is an example of nanoscale Bosons in disorder. BEC, superfluidity and sharply defined modes are the three most fascinating properties of liquid ^4He . Interest in BEC and superflow also reaches across condensed matter (e.g. superconductivity, BEC in quantum gases and reduced dimension systems). BEC and P-R modes are uniquely measured using neutrons. We bring unique neutron scattering data on BEC and modes for comparison with superfluidity measurements to reveal the interdependence of BEC and superfluidity. As a recent achievement, we note that there are two renowned theories of superfluidity, quite different and each with specific domains of application. In the first, the Landau theory, superflow follows from the existence of a well-defined P-R mode supported by dense liquid ^4He . In the second, superflow is a manifestation of BEC and phase coherence in the liquid. We present combined measurements of superfluidity, BEC and phonon-roton modes in liquid ^4He confined in the porous medium MCM-41. The results integrate the two theories by showing that well-defined P-R modes exist where there is BEC. In porous media, the critical temperature for superfluidity, T_c , is suppressed below that for BEC. The measurements show that BEC and well-defined P-R modes co-exist. The two are common properties of a Bose condensed liquid and either can be used as a basis of a theory of superfluidity. In addition, the disorder in the porous medium creates a localized BEC 'phase' consisting of islands of BEC and P-R modes.

FY 2014 HIGHLIGHTS

The goal of this program is to reveal the interdependence of Bose-Einstein condensation (BEC), well-defined, collective phonon-roton (P-R) modes and superfluidity in liquid ^4He confined in porous media. It is particularly to determine how BEC and P-R modes create superfluidity. BEC and modes are uniquely observable using neutrons. We have recently made the first ever successful measurements of the Bose-Einstein condensate fraction of liquid ^4He in any porous media at the Spallation Neutron Source (SNS) in collaboration with S. O. Diallo (SNS), R. T. Azuah (NIST Center for Neutron Research) and D. L. Abernathy (SNS). These measurements of BEC show unequivocally that well-defined P-R modes exist where there is BEC (in the same temperature range). This confirms the theory which proposes that well-defined P-R modes exist because there is BEC. We have also measured the P-R modes in porous media, chiefly at the Institut Laue Langevin, in collaboration with J. Bossy, J. Ollivier and H. Schober and made path integral Monte Carlo (PIMC) calculations of the BEC condensate fraction and the superfluid fraction of liquid ^4He in pores to interpret these measurements. There are two competing theories of superfluidity: one based on the existence of well-defined P-R modes proposed by Landau (1941 and 1947) and the other based on BEC and consequent phase coherence in the fluid proposed initially by London (1938). The present measurements show that BEC and P-R are common properties of a Bose condensed fluid so that the two theories are really complementary rather than competing pictures of superfluidity. Fourthly, on a quite different topic, we have shown how the intrinsic motional dynamics in proteins can be obtained from neutron scattering experiments, dynamics that are independent of the instrument energy resolution and the scattering wave vector used.

Crystal Growth and Scattering Studies of Model Cuprate Superconductors

Institution: Minnesota, University of
Point of Contact: Martin Greven
Email: greven@physics.umn.edu
Principal Investigator: Martin Greven
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$750,000 (2014-2016)

PROGRAM SCOPE

The goal of this effort is the crystal growth and comprehensive investigation of the $\text{HgBa}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+2+\delta}$ cuprates, arguably the most desirable unconventional superconductors due to their record transition temperatures (T_c) and their relatively simple crystal structures. The hope is to conclusively identify the minimal model required for a proper theoretical description of the enigmatic cuprates. Our group remains the only one in the world to have mastered the growth of sizable single crystals of $\text{HgBa}_2\text{CuO}_{4+\delta}$ (Hg1201), the simplest ($n=1$) member of this materials family. The proposed work will build on our demonstration, using neutron scattering, of unusual translational-symmetry-preserving ($q=0$) magnetism in the pseudogap phase of Hg1201. These magnetic neutron scattering results will be extended over a wide range in parameter space (energy, momentum, temperature, hole concentration) and, in particular, include the antiferromagnetic response. They will furthermore be complemented by transport and synchrotron X-ray measurements of the charge degrees of freedom. In addition, the growth and study of the $n=2$ member of the Hg-family of cuprates will be explored. Last, but not least, the work will continue to aim to have a far-reaching impact beyond the neutron, X-ray and transport experiments led by the PI through collaborations with experts using complementary experimental tools.

FY 2014 HIGHLIGHTS

A seemingly universal feature of the antiferromagnetic (AF) excitation spectrum of the cuprates is the hourglass dispersion. Using neutron scattering, we discovered that this feature is absent in Hg1201 ($T_c=71\text{K}$), and that the AF fluctuations in Hg1201 can be rather impervious to the onset of superconductivity, with a spectrum that is dominated by a large susceptibility peak at about 50 meV that onsets at the much higher pseudogap temperature ($T^*\approx 300\text{K}$). Furthermore, the onset of substantial AF fluctuations correlates with the appearance of quasistatic $q=0$ order below T^* . These findings constitute a dramatic departure from the notion that an hourglass-shaped spectrum associated with charge-spin stripe fluctuations is a universal feature of the cuprates [preprint]. For nearly three decades, it has often been argued that the cuprates are unconventional metals. One influential experimental result had been the apparent violation of Kohler's rule for the magnetoresistance. In stark contrast, we discovered that the simple tetragonal model compound Hg1201 beautifully obeys Kohler's rule in the pseudogap regime, with a Fermi-liquid scattering rate. We were furthermore able to show that Kohler's rule is in fact hidden in other cuprates [Phys. Rev. Lett. (2014); editor's suggestion]. Our planar resistivity measurements of underdoped Hg1201 in high magnetic fields demonstrated the universality of quantum oscillations, and thus allowed us to rule out that quantum oscillations in Y-based cuprates are a materials-specific property [Nature Physics (2013)]. Using resonant X-ray scattering, we observed subtle short-range charge-density-wave order in the same samples that exhibit quantum oscillations, which allowed us to demonstrate a simple universal connection between the ordering wave vector and Fermi-surface area associated with the oscillations [Nature Commun. (2014)]. Our initial efforts to synthesize Hg1212 ($n=2$) have yielded small crystals.

EARLY CAREER: Neutron Scattering Instrumentation Research and Development for High Spatial and Temporal Resolution Imaging at Oak Ridge National Laboratory

Institution: Tennessee, University of
Point of Contact: Jason Hayward
Email: jhayward@utk.edu
Principal Investigator: Jason Hayward
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Neutron scattering facilities like those available at Oak Ridge National Laboratory are enabling the discovery and development of advanced materials including those to be used for next generation energy storage systems. In spite of all the success that neutron imaging has enjoyed in recent years, even higher-impact research is limited by the current temporal and spatial resolution of neutron detection devices. In particular, the spatial resolution of all neutron imaging methods in use and under development is fundamentally limited by the variance introduced by the charged particles emitted from neutron absorption. Thus, we are investigating, designing and demonstrating an array of $\sim 1\ \mu\text{m}$ -sized glass scintillating fibers arranged via photonic-crystal-fiber patterning techniques— with particle tracking (a must) so that position resolution can be finer than that allowed by the charged particle ranges. The processes, knowledge and algorithms developed will allow for spatially ($1\ \mu\text{m}$) and time resolved ($<100\ \text{ns}$), high throughput neutron transmission imaging in large areas at reasonable costs in the near term.

FY 2014 HIGHLIGHTS

Two microstructured glass scintillator arrays were fabricated, and testing began on a neutron beamline at HFIR. Scintillation of micron-sized scintillator was observed. These arrays were modeled using Monte Carlo methods, and the ideal performance was predicted. Reconstruction algorithm development has begun based upon the results of Monte Carlo simulations.

Neutron Scattering Studies of Cobaltite Crystals and Heterostructures

Institution: Minnesota, University of
Point of Contact: Chris Leighton
Email: leighton@umn.edu
Principal Investigator: Chris Leighton
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,221 (2014)

PROGRAM SCOPE

Complex oxide materials such as perovskite cobaltites provide enormous challenges to our fundamental understanding of electrons in solids, in addition to outstanding potential for applications in a range of technologies. This project is aimed at two of the biggest challenges that have emerged in this area - the need for a fundamental understanding of the electronic and magnetic behavior in complex oxides, and a full appreciation of what we can achieve via an understanding of the physics, materials science, and chemistry, of complex oxide interfaces and heterostructures. We are tackling these questions using a single family of materials (the doped cobaltites) as an illustrative example, trying to understand nanoscopic magneto-electronic phase separation, spin-state transitions, insulator-metal transitions, and the influence of interfaces, defects, and strain on magnetism and transport. The research is thus very broadly relevant, touching upon catalysis, solid oxide fuel cells, data storage devices, oxide spintronics, and the general development of oxide electronics. We are carrying out a collaborative and interdisciplinary approach to understanding magnetism and transport in these materials, bringing to bear a battery of complementary measurement techniques, exploiting the full power of neutron scattering, and capitalizing on expertise in synthesis and characterization of both bulk and thin film oxides.

FY 2014 HIGHLIGHTS

In 2014, progress was made in four main areas: Understanding nanoscale inhomogeneity in lightly doped cobaltites, the physics of narrow electronic bandwidth cobaltites, cobaltite films and heterostructures, and magnetic inhomogeneity in complex alloys. In the first, we focused on lightly doped (La,Sr)CoO₃ to understand how magnetic polarons forming at light doping evolve into ferromagnetic clusters at higher doping. We have developed an understanding of this crossover, emphasizing its statistical nature, and the key role of spin and charge dynamics. In the second area, narrow bandwidth cobaltites, systems such as Pr_{1-x}Ca_xCoO₃ have been studied, in order to understand (a) the interplay between phase separation and spin-state, and (b) the Pr-based compounds recently discovered to undergo first-order transitions where the Pr valence abruptly shifts. In the third area, cobaltite films and heterostructures, a number of findings have come to light, including a full appreciation of how oxygen vacancy ordering serves as a mechanism of lattice mismatch accommodation. This creates a link between strain and stoichiometry, which we exploited to demonstrate strain and orientation manipulation of this defect ordering, and the associated oxygen

depth profile. Most importantly, subsequent tuning of the interfacial magnetic and charge transport properties has been demonstrated. In addition to establishing a new means to tailor interfacial properties of complex oxides, the results point to new phenomena emerging under oxygen vacancy ordering. Finally, the approach used to study nanoscale magnetic inhomogeneity has been extended to other systems exhibiting these effects, including complex metal alloys such as off-stoichiometric Heuslers. Neutron scattering provided detailed insight into the magnetic behavior of these materials, establishing a number of important points of connection with strongly correlated oxides.

Local Complexity and the Mechanics of Phase Transitions in Novel Materials

Institution: Virginia, University of
Point of Contact: Despina Louca
Email: louca@virginia.edu
Principal Investigator: Despina Louca
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$760,000 (2014-2016)

PROGRAM SCOPE

The scope of this program is to investigate novel materials that provide unique opportunities to study emergent exotic states of matter that arise from the intricate coupling of the electronic and lattice degrees of freedom, and of their implications in the mechanics of phase transitions. Central to this project is the exploration of distinct features such as the coexistence of two (or more) order parameters, the nucleation of different phases in the parent matrix, spin/charge density waves, and the formation of structural patterns that break the global symmetry and present even at equilibrium conditions. These are key components to our understanding of the evolution across phase boundaries. However, they cannot be readily characterized with traditional means used for probing single electron behavior. This is because their behavior is a collective effect, in response to strong interactions. The goal of the proposed program is to explore such states of matter that appear to be endemic in oxides, superconductors and intermetallic compounds using scattering techniques.

FY 2014 HIGHLIGHTS

In the 2014 fiscal year, our studies on Mott systems such as LaNiO_3 provided evidence for a continuous cross-over across the quantum critical point in nickelates. Monoclinic droplets dispersed randomly in the lattice tend to be insulating and can explain the presence of a pseudo gap in this metallic system. We have also completed a very detailed study of orbital ordering in magnetic vanadates and evidence has been provided to support the presence of G-type orbital ordering above the transition. With doping the ordering changes to C-type. In the insulating antiferromagnet of SrFeO_2 , we observed the magnetic exchange coupling to be very sensitive to a local mode involving transverse displacements of O and Fe. On the Fe superconductors, we have been investigating the issue of phase separation in $\text{K}_x\text{Fe}_{2-\gamma}\text{Se}_2$. This work is still ongoing with many new single crystals grown and measured using neutrons for further analysis. We have also been making Ba and Ca doped FeSe using the new ammonia synthesis. Frustrated systems such as $\text{Ba}_3\text{CuSb}_2\text{O}_9$ and LuMnO_3 have provided us with a venue to explore the intricate interplay of spin and lattice interactions.

Understanding Functional Lyotropic Liquid Crystal Network Phase Self-Assembly and the Properties of Nanoconfined Water

Institution: Wisconsin-Madison, University of
Point of Contact: Mahesh Mahanthappa
Email: Mahesh@chem.wisc.edu
Principal Investigator: Mahesh Mahanthappa
Sr. Investigator(s): Arun Yethiraj; Wisconsin-Madison, University of
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

Lyotropic liquid crystals (LLCs), a class of nanostructured soft materials comprising structurally periodic aqueous and hydrophobic nanodomains lined with well-defined chemical functionalities, stem from the self-assembly of small molecule amphiphiles in concentrated aqueous media. Potential applications of LLCs include advanced separations membranes, templates for mesoporous inorganic oxide catalysts, and ion transporting membranes for fuel cells and batteries. Network phase LLCs with percolating 3D-networks of monodisperse, water-filled nanopores (~0.5-2 nm in diameter) are particularly desirable in many of these applications. Through a synergistic combination of new amphiphile syntheses, characterization of their aqueous LLC phase behavior using small-angle scattering techniques, and molecular dynamics (MD) simulations of these self-assembled structures, Mahanthappa and Yethiraj are developing guiding principles for rational design of surfactants that preferentially form LLC network phases. Our studies focus on identifying specific molecular attributes of bis(sulfonate) and bis(phosphonate) gemini ("twin tail") surfactants that drive their preferential self-assembly into LLC networks. Since MD simulations suggest that surfactant headgroup-counterion correlations crucially govern LLC phase selection, we are using neutron and X-ray scattering methods to assess the validity and generality of this self-assembly model. We are also using wide-angle and quasielastic neutron scattering to investigate how pore functionality, geometry, and diameter affect the structure and dynamics of water nanoconfined within LLCs. By correlating nanoconfined water properties with the ionic conductivities of bis(sulfonate) and bis(phosphonate) LLCs, we aim to identify new molecular design criteria for next-generation ion transporting membranes for solar fuels generation and utilization.

FY 2014 HIGHLIGHTS

By synthesizing several new bis(sulfonate) gemini surfactants and rigorously characterizing their aqueous LLC phase behaviors, we have demonstrated that the gemini architecture enables the formation of network phase LLCs unavailable from conventional, single-tail sulfonate amphiphiles. Electrochemical impedance spectroscopy measurements demonstrate that gemini bis(sulfonic acid) LLCs, in which sulfonic acid moieties decorate water-filled nanopores with diameters ~1-2 nm, exhibit exceptionally high proton conductivities. Against conventional wisdom, our initial studies suggest that pore wall acidity and proton conductivity are not necessarily correlated. Instead, we hypothesize that pore functionality affects nanoconfined water structure and dynamics in a manner that significantly contributes to the observed high proton conductivities. Comparative molecular dynamics simulations have established that the parity of the length of the hydrophobic linker in gemini dicarboxylate surfactants controls the allowed conformations of the hydrated surfactant, whereby odd carbon linkers disallow the formation of both lamellar and hexagonal LLC phases in favor of the double gyroid network phase. However, preliminary simulations indicate that the effects of linker length parity are much less

significant in bis(sulfonate) surfactants. Ongoing simulations aim to understand the origins of these differences in the LLC self-assembly behaviors of dicarboxylate and bis(sulfonate) surfactants.

Engineering and Doping Profiles in Organic Semiconductor Materials

Institution: California-Davis, University of
Point of Contact: Adam Moule
Email: amoule@ucdavis.edu
Principal Investigator: Adam Moule
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 8 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

We establish p-type doping gradients in conjugated polymers with potential applications towards organic electronic devices. The goal of the proposal is to develop methods to produce thermally persistent non-uniform doping profiles in organic materials. Doped organic semiconductors are currently unsuitable for device applications because organic dopants diffuse and drift at low temperatures, destroying device function. We address this problem by synthesizing chemically tailorable dopants that are designed for processability. The specific aims of this proposal are: (a) to determine the p-type doping effectiveness of neutral dopants in conjugated polymers, (b) to synthesize a family of p-type dopants for organic films with side groups that can be optimized for solubility and doping effectiveness (c) to use the functionalized dopants to generate non-uniform doping profiles and study the thermal persistence of the dopant, and diffusion mechanism. (d) to develop neutron and x-ray methods to measure the dopant distribution profile, dopant diffusion rate, and doping effectiveness. To achieve these aims, we synthesized a family of p-type dopants based on the F4TCNQ molecule. Specifically we exchanged the cyano group on the F4TCNQ for an ester that can be functionalized with side chains to affect solubility. We then used these dopant molecules to fabricate doping gradients with high precision. We found that dopants cause strong reduction in the solubility of the polymer in common non-polar solvents. We used dopant induced solubility control (DISC) to develop a scalable conjugated polymer patterning process that can be optically controlled. We have also used neutron scattering techniques (BASIS, GP-SANS, VISION) to study the interaction of the polymer P3HT with the dopant F4TCNQ. X-ray spectroscopy is being used to determine the electronic structure of the dopant and polymer in order to constrain the structural model needed to fit the VISION data.

FY 2014 HIGHLIGHTS

The Moule group published one article in 2014 titled "Material Profile influences in bulk-heterojunctions" in Journal of Polymer Science B. The article quantifies vertical concentration in organic PV layers comparing results from electron tomography, x-ray reflectometry, and neutron reflectometry. We filed for a provisional U.S. patent for the invention of a conjugated polymer patterning method. Our first article on this method was accepted in ACS-nano in December 2014. We developed separate Materials Transfer Agreements with LBNL Molecular Foundry and Cambridge Display Technology Inc. for high quality conjugated polymers related to the patterning technique. We received measurement time for the BASIS, VISION, and GP-SANS beam lines at SNS. On VISION we acquired enough data for 1-2 publications comparing the vibrational states of doped and undoped polymers. We are now working on modeling of the data in collaboration with Thomas Proffen from CNMS. Our BASIS time was delayed due to beam outage. The GP-SANS sample holder failed in the first measurement and samples will be re-

measured in January with improved solvent seals. We received measurement time at ALS to perform NEXAFS on doped polymer samples. The element specific data is ideal to constrain molecular models of doped states. We studied the vertical diffusion of dopant/polymer and dopant small/molecule systems as a function of temperature, dopant strength, and dopant size. Results of this study are being prepared for publication. We synthesized a series of dopants with side chains designed to alter the diffusion rate and miscibility of the dopants. We found that dopants with side chains are significantly more miscible but have reduced diffusion rate due to increased size. Also di-substituted dopants do not have a -1 state but rather only a 2- state due to symmetry changes to the TCNQ with the addition of two esters. A first publication on new dopants is in preparation.

Thermodynamics of Self-Assembly in Globular Protein-Polymer Conjugates

Institution: Massachusetts Institute of Technology
Point of Contact: Bradley Olsen
Email: bdolsen@MIT.edu
Principal Investigator: Bradley Olsen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$720,000 (2014-2016)

PROGRAM SCOPE

Engineering enzymes and optically active proteins into bioelectronic devices for the production of H₂, the reduction of CO₂, or the production of biofuels allows the evolutionarily optimized performance of the protein to be exploited to produce high-performance biomolecular variants of catalysts. Engineering biocatalytic materials requires achieving a high protein activity and active site density, controlling substrate/product transport through the material, maintaining protein stability, and developing low-cost processes for material fabrication. Analogous to synthetic catalysts or organic electronics, this requires the arrangement and orientation of the protein at an interface between two phases that provide for the transport of each reagent or charge carrier. The self-assembly of block copolymers containing an enzyme or optically active protein block provides a bottom-up method to produce nanostructures that simultaneously achieve control over transport through two phases and yield a high density of oriented protein at an interface. This project investigates the fundamental structure and thermodynamics of block copolymer systems containing a globular protein block, enabling the production of functional nanomaterials. Both the folded protein chain shape and the specific interactions between globular proteins differ significantly from the Gaussian coil block copolymers, adding significant complexity to the phase behavior of these systems. Despite this complexity, we hypothesize that universal rules of self-assembly may be elucidated for these protein-polymer hybrids, and in the past two years we have addressed three fundamental questions: (1) How is the phase behavior for a protein-polymer conjugate different than that of traditional block copolymers? (2) What is the effect of protein shape (steric interactions) on self-assembly? (3) What is the effect of protein-polymer interactions on self-assembly?

FY 2014 HIGHLIGHTS

To explore the effect of protein interactions on self-assembly, a carefully controlled experiment was performed to compare the self-assembly of mCherry and EGFP conjugates. The red and green fluorescent proteins have little primary sequence homology and consequently significantly different electrostatic and hydrophobic surface potential distributions; however, they have similar sizes, shapes, and second virial coefficients. When conjugates with the same molar mass Poly(N-isopropylacrylamide)

(PNIPAM) were prepared for both proteins, self-assembly was largely identical. A further experiment was performed to mutate mCherry, systematically altering its electrostatic surface potential. Again, only minimal effects on the order-disorder transition concentration, symmetry of nanodomain structure, and domain spacing were observed. Comparison of self-assembly for conjugates with different polymer types illustrates that protein-polymer interactions are critical to the self-assembly of these systems. Comparing PNIPAM conjugates to those with poly(hydroxypropylacrylate) (PHPA) and poly(oligoethyleneglycolacrylate) (POEGA) illustrates the ability to form previously unobserved phases, including a cubic phase consistent with a gyroid structure, and the ability to tune the Order-Disorder Transition (ODT) based on protein-polymer interactions. To follow up on this observation, two separate methods are currently under development for quantifying these protein-polymer interactions: form factor analysis of conjugates in dilute solution and partial structure factor decomposition analysis of protein-polymer blends with varied H₂O/D₂O solvent systems, enabling quantitative extraction of the protein-polymer structure factor which can then be modeled as a function of interactions.

From Interfaces to Bulk: Experimental-Computational Studies Across Time and Length Scales of Multi Functional Ionic Polymers

Institution: Clemson University
Point of Contact: Dvora Perahia
Email: dperahi@g.clemson.edu
Principal Investigator: Dvora Perahia
Sr. Investigator(s): Gary Grest; Sandia National Laboratories-Albuquerque
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$182,421 (2014)

PROGRAM SCOPE

Neutron scattering coupled with computational studies have been carried out to resolve the structure and dynamics at the interfacial regions of ionic structured co-polymers. Structured ionic polymers with their large size and complexity offer superb media to tailor multiple desired properties into one molecule to form multifunctional materials. The interfacial regions between segments with different chemical nature, such as hydrophilic and hydrophobic, within structured polymeric complexes often control their properties and their responses to changes in the environment. These potentially responsive multifunctional materials is a key to the development of next generation of smart materials for clean energy generation and storage, self-healing layers and drug delivery media; all in the core of the national needs. A conjunction of experimental and computational studies has been carried out on a series of polymers whose chemical architecture is systematically tailored to target controlled changes at the interfaces. Specifically we investigate a pentablock that consists of t-methyl styrene, bound to randomly sulfonated polystyrene by polyethylene propylene. Dvora Perahia from Clemson has been leading the experimental effort and Gary S. Grest from Sandia co-directs the computational studies. Structural features ranging from 0.1nm to 100 nm have been identified by neutron and x-ray scattering/reflectivity. Dynamics across the time window that incorporates the motion of the polymer, ions and solvents across a length scale of 0.1 to ~30 nm is captured by quasielastic neutron studies including spin echo and quasielastic neutron backscattering probing the time range from ~0.1 to 100 nsec. Molecular dynamic simulations of model polymers identical to those studied experimentally provide molecular understanding of the structure and dynamics and explore length and time scales that can not be probed by the experimental tools.

FY 2014 HIGHLIGHTS

Work had been carried out along several pathways including solutions and thin film using scattering, atomistic and coarse grained computational studies, as well as computational methodology developments. Experimental Neutron studies SANS of dilute solutions of cyclohexane/heptane were completed and are in review at the Journal of Soft Materials. This study defined the structure of the pentablock in dilute solution from that of an individual molecule to that of a micelle. One of the major goals of the work is to resolve the dynamic processes that underlie the transport within complex polymers containing ionic groups. With the ultimate goal of resolving the dynamics of complex ionomers we construct three separate interfaces including poly-styrene-polystyrene sulfonated (Etampawalla *et al*, submitted to J. Chem. Phys.); polystyrene/polyethylene and polyethylene polystyrene sulfonate which will be compared with the pentablock's behavior. The degree of interpenetration as a function of time is resolved for polystyrene/polystyrene sulfonate where only limited interdiffusion is observed. Computational The structure of a single molecule in solvents, parallel to the neutron scattering study was resolved (Aryal *et al*. Communication in Macromolecular Theory and Simulation 2014). We have shown that the overall conformation is solvent depended and where the ionic block remains collapsed under experimental conditions. In Parallel, we have developed a course graining methodology for polystyrene, that is essentially transferable to t-butyle polystyrene, (Macromolecules, Agrawal *et. al*. 2014). In addition we were able to resolve for the first time the structure of the ionic clusters in polystyrene sulfonate (Agrawal *et. al*. In review in PRL). The results were also presented at the American Physics Society meeting 2014, including an Invited (Dvora Perahia) presentation that demonstrated the understanding that coupling between neutron studies and commutations can achieve.

EARLY CAREER: Neutron Scattering Investigation of the Relationship between Molecular Structure, Morphology and Dynamics in Conjugated Polymers

Institution: Washington, University of
Point of Contact: Lilo Pozzo

Principal Investigator: Lilo Pozzo
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 4 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

Conjugated polymers (CP) are enabling technologies including organic photovoltaic cells (OPVs), batteries, thermoelectric energy devices and flexible displays (OLEDs). Unique properties of CPs include simplified processing, synthesis from abundant raw materials, flexibility and a capacity to fine-tune energy levels. Unfortunately, CPs are insoluble and difficult to process. It is common practice to add substitution moieties (e.g. linear, branched and cyclic hydrocarbon groups) to the CP backbone in order to boost solubility without affecting the optoelectronic properties. Yet, little fundamental knowledge has been gained on how these side-groups interfere with self-assembly and/or with charge propagation in nanostructured CP phases and in the solid-state. Currently, there are no mechanisms available to design CP structures from fundamental principles for use in specific applications. We are using a comprehensive suite of neutron scattering techniques coupled with simultaneous (in-situ) property evaluation to develop accurate structure-property relationships to enable effective molecular design. Our four project objectives are: 1) to evaluate the influence of chain architecture on solution conformation, 2) to determine the influence of molecular structure on CP self-assembly, 3) to measure

and correlate dynamic motions of CPs in self-assembled structures (i.e. organogels) and 4) to correlate dynamic molecular relaxations and macroscopic properties of CPs in the solid state. The project is also complemented by advanced molecular simulations to fully understand relationships between chain structure, mesoscale morphology, dynamic relaxations and macroscopic properties. Through the completion of this fundamental investigation we are informing scientists and engineers actively working on the synthesis of novel polymer architectures so that they can achieve simple processing and optimized properties via rational molecular design.

FY 2014 HIGHLIGHTS

Initial quasi-elastic neutron scattering experiments and molecular dynamics simulations were completed to determine the effect of alkyl chain length for poly-alkyl-thiophene derivatives on the solid-state dynamics and electronic properties. New types of high surface area organic-dispersible PEDOT and polypyrrole materials were also developed and their use in cathodes for Li ion batteries has been evaluated. These experiments are ongoing and publication is expected in 2015. Below are the highlights corresponding to 2014 publications. [1] Accurate control over P3AT organogel structure and properties was demonstrated via use of solvent quality to modify self-assembly. It was demonstrated that a clear optimum value in conductivity was achieved, for each material, at specific and unique self-assembly conditions. Newbloom GM, de la Iglesia P, Pozzo LD. *Soft Matter*, 2014, Nov 28; 10 (44), 8945. [2] The internal structure of P3HT/fullerene nanoparticle dispersions was modified by control of composition and synthesis conditions. These dispersions are ink precursors for 'painted' solar cells. Small angle neutron scattering is used to probe internal structure while conductive AFM is used to evaluate photoconductive properties. Richards JR, Whittle CL, Shao G, Pozzo LD. *ACS Nano*, 2014, 8 (5), 4313. [3] The conformation of dilute solutions of poly-3-alkyl-thiophenes is probed with neutron scattering and optical spectroscopy in several solvents and with different alkyl substitution moieties. It is determined that color changes that occur upon dissolution in solvents are controlled by the polarity and structure of solvent molecules and not by conformational changes, which was the more accepted hypothesis. Molecular dynamic simulations are used to validate the neutron scattering results and to probe differences in solvation shells around the polymers. Newbloom GM, Hoffmann SM, West AF, Gile MC, Sista P, Cheung HC, Luscombe CK, Pfaendtner J, Pozzo LD. *Langmuir* DOI: 10.1021/la503666x.

Inelastic Neutron and X-Ray Scattering Investigations of Electron-Phonon Effects in Quantum Materials

Institution: Colorado, University of
Point of Contact: Dmitry Reznik
Email: Dmitry.Reznik@Colorado.edu
Principal Investigator: Dmitry Reznik
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$450,000 (2014-2016)

PROGRAM SCOPE

Many quantum materials, i.e. materials where quantum effects are crucial for key properties, often undergo phase transitions driven by electronic charge and/or spin fluctuations. These fluctuations influence electrical and thermal conductivity, specific heat, thermal expansion, etc. Coulomb/magnetoelastic coupling of charge/spin fluctuations to the atomic lattice can induce competing or mutually reinforcing phenomena such as real or incipient structural phase transitions and superconductivity. My group focuses on inelastic scattering of neutrons (INS) or x-rays (IXS) from atomic

lattice fluctuations coupled to charge/spin fluctuations associated with real and/or incipient phase transitions in quantum materials. These lattice fluctuations are either phonons or incoherent fluctuations. The long-term goal of our research is to learn how use observed features of lattice dynamics spectra as markers of microscopic physics of quantum materials responsible for their macroscopic properties of fundamentals and practical interest. The work proposed for the next 3 years has the following themes that feed off each other: 1. Extending Multizone phonon refinement pioneered by us to a bigger class of materials. 2. Experiments to systematically measure electron-phonon effects in order to understand and eventually control charge order and fluctuations, structural phase transitions, and polarons. 3. General insights into electron-electron and electron-lattice interactions. Item 1 fits into the BES mission to operate major scientific user facilities because it serves to amplify the capabilities of the SNS and items 2,3 fit into the DOE Basic Energy Sciences (BES) program's mission to understand, predict, and ultimately control matter and energy at the electronic, atomic, and molecular levels.

FY 2014 HIGHLIGHTS

During the previous period we 1) directly measured the spectrum of dynamic charge stripes for the first time; 2) found evidence of a novel charge collective mode that correlates with the superconducting T_c in a family of copper oxides; 3) clarified the origin of the kink in electronic dispersions in cuprates, 4) Identified a previously unknown spurious feature that can contaminate neutron scattering spectra near 17meV energy transfer. 5) Developed a new Multizone Phonon Refinement (MPR) time-of-flight data analysis technique that clearly resolves phonon branches separated by as little as 10% of the energy resolution by using data from all measured Brillouin zones. Thanks to MPR an efficient and systematic search for electron-phonon effects in a wide variety of materials is now possible. This work resulted in 6 peer-reviewed publications.

Neutron and X-Ray Studies of Spin and Charge Manipulation in Magnetic Nanostructures

Institution: California-San Diego, University of
Point of Contact: Sunil Sinha

Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014)

PROGRAM SCOPE

Electronic and magnetic materials are some of the most important and highly tunable materials systems with a wide range of new scientific discoveries. Understanding of the dynamics and the fundamental nanoscale physics of these materials is a crucial cornerstone for developing ways in which electronic and magnetic order parameters can be designed, controlled and manipulated. By combining skills in neutron and synchrotron techniques with sample fabrication, magnetic and transport measurements in films, nanostructures and devices we probe fundamental properties of nanoscale magnetic materials. The proposed and ongoing research has two research thrusts: (1) Time-dependent studies of magnetic nanostructures This research probes the physics of magnetic nanostructures by studying the underlying excitations of the system with atomic depth resolution and nm lateral resolution. The time scales, physics to be studied and techniques used are divided into three distinct regimes: (i) Microseconds to seconds cover the time-scales of dynamics of slow magnetic fluctuations in materials, such as thermally-

induced domain wall motion. (ii) Tens of nanoseconds to tens of picoseconds correspond to magnetic precessional frequencies, where we will study the dynamic response of nano-magnetic systems to nanosecond current, temperature and field pulses and (iii) pico-seconds to femto-seconds cover the time scales for energy and angular momentum transfer between orbital, spin and lattice degrees of freedom and can be used to probe the fundamental nature of phase transitions and the ultra-fast magnetization dynamics. (2) Interfacial phenomena in oxides We are studying the fundamental interfacial phenomena in complex oxide interfaces. This includes understanding the role of electric field effects in piezoelectric-ferromagnetic heterostructures and probing electronic reconstruction that occurs at oxide interfaces.

FY 2014 HIGHLIGHTS

(i) Effect of Electric fields on magnetization in Oxide films. Using resonant x-ray magnetic reflectometry, we measured the magnetization depth profile of an LSMO film as a function of electric field applied to the LSMO/PZT heterostructure. The polarization, its magnitude or direction, had no influence on the saturation magnetization of the ferromagnetic ordered film. However, in the absence of a magnetic field, the remnant magnetization and ferromagnetic thickness of the LSMO film decreased when the electric polarization of the PZT film promoted accumulation of hole-charge at the LSMO/PZT interface. These results are consistent with a picture that hole-doping induces weak ($< 6 \times 10^5$ erg/cm³) anti-ferromagnetic exchange between Mn⁴⁺ at the LSMO/PZT interface and nearest neighbor Mn moments. Tuning of Mn valence at an interface with electric potential applied to a ferroelectric may be a new route to control of interface magnetism. (ii) Magnetic vortex dynamics The dynamic annihilation of magnetic vortices was studied on a series of samples consisting from Permalloy (Ni₈₀Fe₂₀) disks with diameters ranging from 250 nm to 2500 nm and thicknesses from 20 nm to 50 nm. Magnetic field pulses were applied to the disks. The magnetization in the disks was imaged by the full-field transmission soft x-ray microscope at the Advanced Light Source in Berkeley, CA. These experiments allowed us to construct a pulse rise time – pulse amplitude phase diagram of successful vortex annihilation. We are able to distinguish three distinct regions: (1) a region of low pulse amplitude and long rise time, where the vortex core was not expelled out of the disk and gyrated freely in the disk with an unchanged polarity (2) a region of intermediate pulse amplitude and intermediate rise time, where the pulse parameters were sufficient to expel the vortex core out of the disk, and finally (3) a region of short rise time and high amplitude where circulation switching was not successful. (iii) Phase transitions in FeRh films: We used a suite of characterization techniques to characterize the nature of the antiferromagnetic-ferromagnetic phase transition in FeRh films and nanostructures including the critical behavior of the domain formation and the role of exchange. (iv) Skyrmion formation in Fe/Gd multilayers: We have mapped the magnetic field-temperature phase diagram of skyrmion lattice formation in Fe/Gd superlattices.

DOE National Laboratories

Impact of Dynamic Instabilities and Microstructure on Energy Materials

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: John Budai
Sr. Investigator(s): Olivier Delaire; Oak Ridge National Laboratory
Michael Manley; Oak Ridge National Laboratory
Eliot Specht; Oak Ridge National Laboratory

Gene Ice; Oak Ridge National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,623,000 (2014)

PROGRAM SCOPE

The goal of this project is to advance our fundamental understanding of how dynamic lattice instabilities interact with local microstructure to control the temperature-dependent physical properties of advanced materials. This knowledge is needed to accelerate the predictive discovery of energy materials under realistic operating conditions such as finite temperature. Issues of nonlinear lattice vibrations, phase competition and broken static symmetry play critical, but often unknown, roles in determining materials properties. This research will integrate state-of-the-art neutron and synchrotron x-ray scattering methods with first-principles computational techniques to obtain new scientific insights. In particular, research thrusts will focus on fundamental studies of technologically-important model materials including: localized dynamic instabilities in relaxor ferroelectrics and frustrated “strain glasses”; the role of anharmonic phonons in controlling phase competition in metal-insulator materials; and the interaction of ferroelectric instabilities with external fields. A common scientific hypothesis in the research is that strong lattice anharmonicity can be intentionally tuned to produce greatly enhanced physical responses. In addition, inhomogeneous nanostructures such as chemical order, precipitates and strains can be fashioned for further synergistic enhancements. Effectively exploiting instabilities and inhomogeneities in complex materials will require both detailed experimental characterization and fundamental understanding of how interactions drive physical properties. This project directly addresses these needs, and thus supports the DOE BES mission to provide the understanding needed to enable discovery breakthroughs in functional energy materials. The research will establish critical connections linking lattice dynamics and microstructure with first-principles theories to enable the prediction of enhanced materials.

FY 2014 HIGHLIGHTS

(1) Determined the origin of anomalous spectral lineshapes of highly-anharmonic ferroelectric soft-modes in PbTe, based on first-principles simulations of the phonon self-energy. This discovery offers new insights into the role of three-phonon scattering in phase-space in enhancing anharmonicity, to improve thermoelectric performance. (2) Established systematics of diffuse scattering from nanoscale self-ordering in AgSbTe₂ thermoelectrics, using a combination of synchrotron x-ray scattering, neutron scattering, and electron microscopy. These results show the importance of short-range ordering in scattering phonons and suppressing thermal conductivity. (3) Investigated the impact of lattice dynamics on the metal-insulator phase transition in vanadium dioxide by combining comprehensive neutron and x-ray scattering studies with large-scale, first-principles molecular dynamics calculations. Studies revealed that soft (low-energy), anharmonic phonons provide the entropy that overcomes the electronic energy to stabilize the metallic phase of VO₂ above room temperature. Research published in Nature, November 2014. (4) Discovered how phonon localization drives the formation of ferro- and anti-ferroelectric polar nanoregions (PNRs) in relaxor ferroelectric materials PMN-PT and PZN-PT. The idea is being extended to related systems to investigate if this phonon localization mechanism is more generic. (5) Discovered a phonon avoided crossing of PNRs in PZN-PT and PMN-PT relaxor-based ferroelectrics that induces a dynamic instability in the structure. We hypothesize that this instability is responsible for the giant electromechanical coupling observed in these materials near the morphotropic phase boundary. (6) Installed Pilatus hybrid pixel 2D array detector on our laboratory x-ray system, developed software for diffuse scattering analysis, and used in studies of Pb(Zr,Nb)O₃-PbTiO₃ relaxor ferroelectrics.

EARLY CAREER: Multiphase Soft Colloids: From Fundamentals to Application of Energy Sustainability

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Wei-Ren Chen
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Multiphase soft colloids are synthetic macromolecules that possess at least two different types of functional groups located at the particle periphery. This class of materials represents a unique microscopic building block for designing bulk materials that perform multiple functions simultaneously. Their structural heterogeneity establishes interactions between colloidal particles that are directional in nature, introducing new functionality. Their complex nature must be understood in order to control the spatial arrangement of these particles to produce optimized macroscopic morphologies for functional devices. Thus, the overarching goal is to develop a fundamental understanding of the physical processes occurring on the nanometer length scale that are critical for the molecular-level design of these systems. Two specific aims form the basis of the proposed research: The first seeks to understand the microscopic interaction mechanisms giving rise to spatial organization on the length scale from that of an individual colloid to collective phase behavior. The second aim focuses the relationship between dynamics and structure that give rise to equilibrium phase behavior. Underpinned by specific tailored synthesis, these two specific aims provide the critical link between the bulk properties and the microscopic features of their precursor solution state. Emphasis is placed on understanding and controlling the anisotropic inter-particle interactions which determine structural organization in the solution and ultimately in their solid functional forms. A combination of the research capabilities of ORNL are employed to study the structure and dynamics of these materials. Isotopically labeled materials highlight the structural and dynamical signatures of neutron scattering, and computer simulations will be performed to provide a unified basis for interpreting the scattering measurements and to give deeper insight into the microscopic behavior of these soft colloids.

FY 2014 HIGHLIGHTS

(1) Structure and Dynamics of Soft Colloids Neutron scattering experiments revealed the existence of the crossover between the two dynamical degrees of freedom well below the overlap concentration. The concentration, at which the inter-molecular collision time is equal to the intra-molecular relaxation time, is defined as the dynamical crossover point. This important discovery discriminates the dilute regime where the inter- and intra-molecular dynamical processes can be fully decoupled. Moreover, we developed two new approaches to analyze the scattering data, and found the continuous desolvation of soft colloids below and beyond the overlap density due to increasing the concentration. Furthermore, to understand the effect of the associated solvent molecules on colloidal structure, we developed the scattering function of star polymers with the excluded volume effect, which shows quantitative agreement with experiment. Based on the same theoretical framework, we also developed a scattering function for polymer-colloid conjugates. (2) Phase Transition and Dynamics of Non-Centrosymmetric Nanoparticles We developed the scattering function for yolk-shell nanoparticles, a category of functional materials with a mobile core in a hollow shell. It facilitates the investigation of these novel materials

using scattering. We further predicted the dynamics of yolk-shell particles using Brownian dynamics simulation and generalized Langevin equation theory. Moreover, we studied the phase transition of another type of non-centrosymmetric particles, shifted charge colloids, using simulation. We discovered a liquid-to-crystal transition at a much lower concentration than centro-charged colloids. We also found that the system undergoes a continuous disorder-to-order transition with respect to the charge orientation. These investigations have provided critical information for the practical applications of these novel materials.

EARLY CAREER: Quasiparticle Couplings in Transport of Heat, Charge, and Spin for Novel Energy Materials

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Olivier Delaire
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Understanding the microscopic processes involved in the transport and conversion of energy from the atomic scale to the mesoscale is critical for the development of next-generation energy materials. The coupling of heat and charge transport is at the heart of thermoelectrics research and thermal engineering, enabling practical devices for “waste-heat harvesting” and heat pumping. At a microscopic level, this coupling results from interactions of phonons with other phonons owing to anharmonicity (phonon-phonon interaction, PPI), or with charge carriers (electron-phonon interaction, EPI). An additional and exciting dimension to these interactions has arisen from the recent discovery of the spin-Seebeck effect (SSE), whereby the interplay of phonons and magnons can link thermal and magnetic transport. Lack of detailed knowledge about quasiparticle couplings is impeding a full microscopic understanding of thermoelectrics and slowing the development of novel SSE devices. However, progress has recently been made, both experimentally and theoretically, in probing and understanding microscopic processes that determine the phonon propagation (scattering rates and mean-free-paths). Neutron and x-ray scattering techniques provide powerful microscopic insights that are key to rationalizing bulk transport measurements. In addition, developments in first-principles simulations enable the computation of phonon scattering rates from anharmonicity, and from electron-phonon coupling. This project uses state-of-the-art scattering experiments, complemented by transport measurements, computer simulations, and sample synthesis, and encompasses a broad range of materials for energy applications, including thermoelectrics and spin-Seebeck systems. Insights gained from this research program will directly impact technological approaches to control microscopic processes for energy harvesting and information processing.

FY 2014 HIGHLIGHTS

[This Early Career Award project was started in Q3 2014] (1) We have elucidated the origins of strongly anisotropic thermal transport in thermoelectric compound $\text{MnSi}_{1.75-x}$ (higher-manganese-silicide HMS). These compounds crystallize in a highly-anisotropic Nowotny chimney-ladder structure which leads to low-lying optical modes and “diffusion” transport, and unusual phonon transport. A manuscript is under review in Nature Communications. (2) Through inelastic neutron scattering (INS) measurements and

first-principles simulations, we have elucidated the origin of anomalous pair-distribution function peak shapes in rocksalt telluride thermoelectrics (SnTe / PbTe), establishing anharmonicity as the root of the effect (manuscript in press in Phys. Rev. B). (3) We investigated the phonon scattering mechanisms in single-crystals of thermoelectric FeSi doped with heavy elements Os, Ir. We predicted and observed the formation of resonance modes of heavy impurities, and showed that they interact strongly with acoustic modes, leading to the suppression in thermal conductivity and improvement in figure-of-merit (a manuscript is under review in Phys. Rev. B). (4) We have performed systematic measurements of the phonon dispersions and linewidths in the novel thermoelectric material SnSe with record-high efficiency. A publication is under preparation. (5) We have designed and built an ultrafast-optical time-domain thermoreflectance (TDTR) apparatus for the measurement of quasiparticle lifetimes and thermal conductivity in the time domain, in collaboration with Y. Ma and B. Doughty (CSD). (6) We have obtained beamtime at the SNS for INS measurements of coupled phonon-magnon heat transport in magnetic oxides of current interest as spin-Seebeck systems. We have also acquired and tested single-crystals for several compositions.

Correlations and Competition Between the Lattice, Electrons, and Magnetism

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov
Principal Investigator: Alan Goldman
Sr. Investigator(s): Bruce Harmon; Ames Laboratory
Yongbin Lee; Ames Laboratory
Andreas Kreyssig; Ames Laboratory
David Vaknin; Ames Laboratory
Students: 3 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$1,264,000 (2014)

PROGRAM SCOPE

The properties of novel materials, such as high-temperature superconductors, charge/orbital ordering systems, and multiferroics, are all sensitively controlled by correlations and competition among the lattice, electronic, and magnetic degrees-of-freedom. A complete understanding of the interrelations between these systems and the necessary conditions for enhancing or tailoring desirable physical properties have been identified as a Grand Challenge to the scientific community. Neutron and x-ray scattering are powerful techniques that directly probe the structural, electronic, and magnetic aspects of complex ground states, phase transitions, and corresponding excitations. Within this FWP, the varied expertise of the PIs in different scattering methods is employed in a synergistic approach and systems are studied using a wide range of neutron and x-ray techniques. The experimental program is supported by a closely coupled effort in *ab initio* band structure calculations, theoretical modeling, and scattering simulations.

FY 2014 HIGHLIGHTS

Our inelastic neutron scattering measurements demonstrated that that the onset of superconductivity in $\text{Ba}(\text{Fe}_{1-x}\text{Co}_x)_2\text{As}_2$ coincides with a crossover from well-defined spin waves to overdamped and diffusive excitations. [Phys. Rev. B 89 180503(R) (2014)] One of the keys to unconventional superconductivity lies in its proximity to an ordered antiferromagnetic (AFM) ground state. In $\text{Ba}(\text{Fe}_{1-x}\text{Co}_x)_2\text{As}_2$ AFM order and superconductivity coexist and compete, permitting investigations of how the normal state spin

fluctuations provide the conditions for superconductivity to emerge. Measurements on the ARCS instrument at the SNS provided unambiguous evidence of the absence of magnetic fluctuations in the collapsed tetragonal (cT) phase of CaFe_2As_2 , demonstrating that the non-superconducting cT phase is also non-magnetic, consistent with the view that spin-fluctuations are a necessary ingredient for superconductivity in the iron pnictides. [Phys. Rev. Lett. 111, 227002 (2013)] The wide view in both Q and E available using TOF inelastic scattering on ARCS clearly demonstrates that all spin fluctuations are absent and, therefore, that the cT phase is non-magnetic. We have discovered that SrCo_2As_2 is close to an instability toward stripe-like AFM order, exhibiting steeply dispersing and quasi-two-dimensional paramagnetic excitations near the wavevector Q_{AFM} . [Phys. Rev. Lett. 111, 157001 (2013)] Dilute substitutions of Co for Fe in the AFe_2As_2 compounds (A = Ca, Ba, Sr) destabilizes the stripe-like AFM ordering and Co substitutions of only a few percent allows a superconducting ground state to emerge. Further Co substitutions (> 12% Co) lead to a complete suppression of both stripe-like spin fluctuations and superconductivity. The surprising re-emergence of stripe-like magnetic fluctuations in SrCo_2As_2 raises new questions regarding the origin of strip-like magnetic order in the iron pnictides.

Center for Accelerating Materials Modeling from SNS Data

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Thomas Proffen
Sr. Investigator(s): Bobby Sumpter; Oak Ridge National Laboratory
Olivier Delaire; Oak Ridge National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$400,000 (2014)

PROGRAM SCOPE

Neutron scattering enables simultaneous measurement of structural and dynamic properties of materials from the atomic scale (0.1 nm, 0.1 ps) to the mesoscale (1 μm , 1 μs). These ranges are remarkably complementary to current capabilities of computational modeling, and the simplicity of the scattering cross section allows the prediction of neutron scattering data straight forwardly from atomic trajectories in a computer model. The Center for Accelerating Materials Modeling (CAMM) from SNS Data is accelerating the rate of scientific discovery by integrating modeling into all aspects of the experimental chain. We have developed a refinement loop using classical molecular dynamics (MD) as the modeling technique, in combination with quasielastic neutron scattering data from the BASIS instrument. We have successfully demonstrated the refinement of MD force-field parameters for LiCl, and the software tools developed have been subsequently used in several projects initiated by SNS users. The software tools developed to enable these studies are now made available to SNS users. Based on the demonstrated ability to perform force-field refinements from neutron data (e.g., experimental validated computational models), moving forward CAMM will focus on developing fundamental understanding of dynamics and transport in non-crystalline materials such as polymers, gels, composites, glasses, and colloids by using our integrated feedback with neutron scattering that has been established for validating and verifying force-fields to enable accurate simulations to explore the structure and dynamics.

FY 2014 HIGHLIGHTS

The goal of the Center of Accelerating Materials Modeling (CAMM) of SNS data is to close the gap between materials modeling and neutron scattering. CAMM teamed up with J. Budai and investigated the nature of the metal-to-insulator transition in VO₂ ultimately showing the metal phase is stabilized by lattice vibrations resulting in a paper appearing in Nature. Another CAMM project unraveled anharmonic lattice dynamics in SnTe and PbTe thermoelectrics using inelastic neutron scattering and finite temperature in the first-principled *ab initio* MD simulations. As part of efforts to integrate modeling and neutron scattering experiments in 'real time', a pilot experiment was carried out, that enabled instant access to high performance computing during an experiment on the HYSPEC instrument at ORNL. This allowed the team to run *ab initio* molecular dynamics simulations and use the results for decision making during the experiment. The results are currently being analyzed. The core tool developed by CAMM is a workflow allowing the refinement of input parameters of materials models based on neutron scattering data. Expanding on the initial demonstration of refining force constants from quasielastic neutron scattering data of LiCl in water, the work progressed to the refinement of nano-diamond RNA (work in progress). As part of outreach to SNS users, the current version of CAMM developed tools and the refinement framework has been made available including documentation, tutorials and the website <http://camm.ornl.gov>.

Neutron and X-Ray Scattering

Sr. Investigator(s): Raymond Osborn; Argonne National Laboratory
Suzanne te Velthuis; Argonne National Laboratory
Daniel Phelan; Argonne National Laboratory
Omar Chmaissem; Northern Illinois University
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$1,966,000 (2014)

PROGRAM SCOPE

The Neutron and X-ray Scattering Group investigates the structure and dynamics of bulk and interfacial strongly correlated systems with a particular focus on the role of phase competition in generating complex phenomena of interest in energy related materials, such as superconductivity, magnetism, thermoelectricity, etc. The latest advances in neutron and x-ray instrumentation at major DOE User facilities, in some cases developed by members of the group, allow us to investigate how materials respond on a range of length and time scales to competing interactions, so that we can learn to control emergent behavior in energy-related materials. Phase competition can generate or enhance material functionality, but it is extremely challenging to characterize fluctuations in the competing order, whether in bulk disordered materials or artificial heterostructures. Our goal is to utilize efficient techniques that we have been developing for measuring nanoscale phase fluctuations, both static and dynamic, to enable the rational design of new materials for energy within the Materials Science Division.

FY 2014 HIGHLIGHTS

A detailed investigation of the phase diagram of hole-doped $\text{Ba}_{1-x}\text{Na}_x\text{Fe}_2\text{As}_2$ by high resolution neutron powder diffraction revealed the existence of a novel state, a magnetic phase that restores tetragonal symmetry. Such a tetragonal, magnetic phase is predicted by spin-nematic theories, showing that nematic order in iron-based superconductors is driven by magnetic, rather than orbital, interactions. High resolution neutron powder diffraction was used to study in detail the structural and magnetic transitions in the hole doped and phosphor substituted $\text{Ba}_{1-x}\text{Na}_x\text{Fe}_2\text{As}_2$ and $\text{BaFe}_2(\text{As}_{1-x}\text{P}_x)_2$. We find that in both cases the structural and magnetic transitions are coincident and weakly first order, but that the lattice anomaly in the P-substituted compounds is different than in the hole doped systems due to different evolution in the lattice component in the electronic ordering as function of doping. Polarized neutron reflectivity studies, combined with X-ray magnetic circular dichroism (XMCD) and theoretical modeling, reveal a strong effect of interface-induced magnetization on the temperature dependent transport properties of magnetic tunnel junctions consisting of ferromagnetic manganite $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$ and insulating cuprate $\text{PrBa}_2\text{Cu}_3\text{O}_7$. These results provide evidence for a novel emergent spin-filter functionality not previously considered, and are of significant interest for both basic research and spintronics applications. Utilizing polarized neutron reflectometry and XMCD we demonstrated a reversible, voltage-driven magnetization switching without assistance from a magnetic field in a heterostructure consisting of an insulating copper oxide and a ferromagnetic manganite oxide and we show that the observed unusual magneto-transport behavior results from a novel form of magnetoelectric coupling arising from orbital reconstruction at the interface between these two strongly correlated oxides.

National School for Neutron and X-ray Scattering

Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$232,000 (2014)

PROGRAM SCOPE

DOE is the leading organization in the United States involved in the design, construction, and operation of large-scale facilities for producing high-intensity neutron and x-ray beams for scientific research. A critical factor for making the most effective use of these facilities is educating the U. S. scientific user community in the potential of the wide array of measurement techniques available at these sources. Providing basic education in how neutron and x-ray scattering techniques can be applied to provide atomic scale information relevant to a variety of scientific disciplines is essential not only to the current users of these facilities, but even more so for graduate students who will form the next generation of scientists conducting experiments at the existing and future sources. The annual National School on Neutron and X-ray Scattering (NXS), jointly hosted by Argonne National Laboratory (ANL) and Oak Ridge National Laboratory (ORNL), has been extremely successful in fulfilling this purpose. This school distinguishes itself from other more topical schools in the United States by providing a broad grounding in the fundamentals of both neutron and x-ray scattering techniques, emphasizing the complementary nature of these structural probes. The NXS School offers, primarily to graduate students from North American Institutions, a comprehensive introduction to the underlying theory and the experimental

techniques that are available at major neutron and x-ray scattering facilities, especially in the United States. The students receive lectures from leading experts in the field. Furthermore, a key component of the school is the hands-on training provided using instruments at the Advanced Photon Source (ANL), the High Flux Isotope Reactor (ORNL) and Spallation Neutron Source (ORNL).

FY 2014 HIGHLIGHTS

The 16th National School on Neutron and X-ray Scattering was held from June 14-28, 2014. Out of 201 applicants, 66 participants were selected to attend, of which 60 were funded by this FWP. The participants spent the first week at Argonne National Laboratory and then transferred to Oak Ridge Laboratory on June 21, 2014 for the remaining period. Besides receiving a comprehensive course in the fundamentals of neutron and x-ray scattering theory and the associated techniques through lectures, in the afternoons, in groups of four, participants performed three or four synchrotron x-ray and four neutron scattering experiments. On the final day, each group of participants gave a 10-minute presentation, describing one of the experiments they had participated in. Overall, the feedback from the participants, as monitored by an extensive survey, is very positive, as has been the case for previous years. Lecture notes and videos have been made available through the school's websites (<http://neutrons.ornl.gov/nxs/2014/> and <http://www1.aps.anl.gov/nx>).

Complex Electronic Materials

Roman Movshovich; Los Alamos National Laboratory
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,746,000 (2014)

PROGRAM SCOPE

Complex electronic behaviors are most pronounced near magnetic/non-magnetic and metal/insulator boundaries in correlated materials and become particularly poorly understood as these boundaries are tuned to absolute zero temperature, i.e., to a quantum-critical point (QCP). With typically small characteristic energy scales, states of strongly correlated intermetallic compounds based principally on Ce, Yb, U and Pu can be tuned to these interesting boundaries with rather modest changes in a control parameter. The goal of this project is to develop an understanding of complex electronic materials and phenomena by discovering new examples of these and related materials that reveal both new states of electronic matter and the essential physics underlying their complex and collective states. Knowledge gained from studying correlated f-electron materials in parallel with technologically important d-electron materials provides a broad perspective necessary to guide the development of a microscopic theory of complex electronic materials. Success in this project of discovering new physics through new materials requires integration of materials preparation, in single crystal form where possible, with a necessarily broad suite of characterization techniques that probe static and dynamic degrees-of-

freedom and their interactions on multiple length and time scales. Our approach is two-fold: one of initial exploratory research on new materials and phenomena and a second of in-depth investigations. At the exploratory stage, structure, transport, magnetic and thermodynamic measurements, often at very low temperatures, high pressures and high magnetic fields, are sufficient to identify new states that deserve more detailed study by various spin and charge spectroscopies, particularly neutron scattering, nuclear quadrupole/magnetic resonance and photoemission.

FY 2014 HIGHLIGHTS

(1) We have studied the case of Cd-doped CeCoIn_5 , where Cd doping suppresses superconductivity and induces magnetic order. Specific heat, electrical resistivity and NMR measurements as a function of pressure find that pressure globally reverses the effect of Cd-doping, suppressing magnetic order and inducing bulk superconductivity with nearly the same T_c as in undoped CeCoIn_5 , but signatures of quantum criticality are absent. An analysis of these experiments reveals the formation of static 'droplets' of magnetism around the Cd-dopants that prevent the reappearance of conventional signatures of quantum criticality but induce a heterogeneous electronic state. (2) CeRhIn_5 , isostructural with CeCoIn_5 , is an antiferromagnet at atmospheric pressure but becomes superconducting under pressure with a maximum T_c at its QCP. We have used high-resolution neutron spectroscopy experiments to determine its complete spin-wave spectrum at ambient pressure. (3) Our inelastic neutron scattering measurements on a crystal of Pd-doped CeNi_2Ge_2 near its magnetic quantum critical point (QCP) demonstrate the role of disorder in assessing a QCP. (4) By growing very high quality crystals of URu_2Si_2 , we have enabled substantial progress on the nature of 'Hidden Order'.

Neutron Scattering

Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$2,388,000 (2014)

PROGRAM SCOPE

This program is organized around the challenge of understanding the antiferromagnetic spin correlations characteristic of high-temperature superconductors, with particular focus on systems such as copper oxides and the iron-based superconductors. The main experimental tools are neutron scattering and high-energy x-ray diffraction, with experiments performed at the best facilities in the U.S. and abroad. Problems addressed include: doping of correlated insulators, self-organized spin and charge inhomogeneities (such as stripes), electron-phonon coupling, spin dynamics, quantum magnetism in low-dimensional systems, and the impact of disorder. Growth of suitable single-crystal samples is an essential part of the program, with complementary characterizations performed in collaboration with other Brookhaven groups, especially at the National Synchrotron Light Source. There are also close interactions with the Center for Emergent Superconductivity, an Energy Frontier Research Center. This program leads the Instrument Development Team for HYSPEC, an inelastic spectrometer with

polarization analysis, now operating at the Spallation Neutron Source; it also participates in the US-Japan Cooperative Program on Neutron Scattering, which has partial access to the cold-neutron triple-axis spectrometer at the High Flux Isotope Reactor. The BNL-NIST Alliance involves collaborative efforts at the National Institute of Standards and Technology's Center for Neutron Research.

FY 2014 HIGHLIGHTS

Progress has been made in characterizing the magnetic correlations associated with superconductivity in the system Fe(Te,Se). In a study of the non-superconducting “parent” material Fe_{1+y}Te , a first-order ferro-orbital ordering transition has been identified and characterized by neutron scattering. In superconducting Fe(Te,Se), we have observed that substitution of Ni or Cu for Fe causes a suppression of the superconductivity but has little impact on the weight of low-energy antiferromagnetic correlations. For copper-oxide superconductors, our focus has been on the role of charge and spin correlations. A surprising time-reversal-symmetry breaking effect has been detected in the charge-stripe phase of $\text{La}_{1.875}\text{Ba}_{0.125}\text{CuO}_4$ through measurements of the polar Kerr effect. Crystals of underdoped $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ were prepared, enabling scanning tunneling microscopy and x-ray scattering studies of charge order. Competing charge, spin, and superconducting orders in $\text{YBa}_2\text{Cu}_3\text{O}_y$ have been characterized with the help of x-ray scattering. In the compound $\text{La}_{2-x}\text{Sr}_x\text{NiO}_4$, which is isostructural with superconductors, the fluctuations of charge stripes have been detected directly for the first time, by inelastic neutron scattering.

Physical Behavior of Materials

Institutions Receiving Grants

Magnetocaloric and Multifunctional Magnetic Materials

Institution: Southern Illinois University
Point of Contact: Naushad Ali
Email: nali@physics.siu.edu
Principal Investigator: Naushad Ali
Sr. Investigator(s): Shane Stadler; Louisiana State University
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$199,999 (2014)

PROGRAM SCOPE

In this collaborative effort between Louisiana State University and Southern Illinois University, a comprehensive study is being conducted on a select group of materials that undergo magnetostructural phase transitions, and exhibit magnetocaloric and multifunctional phenomena. These systems include those based on the Heusler alloys $\text{Ni}_{50}\text{Mn}_{35}\text{In}_{15}$ and $\text{Ni}_{2-x}\text{Co}(\text{Mn}/\text{Al})$, and on the orthorhombic compounds MnT_x ($T=\text{Ni}, \text{Co}, \text{Cu}$ and $X=\text{Si}, \text{Ge}$). Investigations will also be carried out on the properties of magnetocaloric and multifunctional materials in thin film and nanocomposites forms in order to understand scale-size effects; the properties of these systems can vary greatly from those of the bulk. The detailed objectives of this project are the following: (i) To understand the effects of compositional variations and isoelectronic vacancies on the phase transitions and physical properties of $\text{Ni}_{50}\text{Mn}_{50-x}\text{In}_x$ and $\text{Ni}_{2-x}\text{Co}_x(\text{Mn}, \text{Al})$ Heusler alloys; (ii) to develop new metamagnets MnT_x and understand the underlying physics of the phase transitions in these systems; and (iii) to grow Heusler alloy and MnT_x thin films using pulsed laser deposition, and understand the ramifications of size-scale effects on the phase transitions and physical properties (including magnetocaloric effects). The potential scientific outcomes include: (i) the development of new magnetocaloric and multifunctional materials; (ii) a deeper understanding of the physics of the phase transitions responsible for magnetocaloric and multifunctional behaviors; and (iii) the discovery of new physical phenomena in thin films and nanocomposites materials. The discovery of a practical and effective magnetic refrigeration material would eventually lead to more efficient cooling systems. The impact of this could be profound: it would be one step towards energy independence, as this is one of our most energy-demanding technologies.

FY 2014 HIGHLIGHTS

The first highlight is our study on hydrostatic pressure-induced enhancements of the magnetocaloric effect in bulk $(\text{MnNiSi})_{1-x}(\text{MnFeGe})_x$. We observed a remarkable decrease of the structural transition temperature of MnNiSi from 1200 to < 300 K by chemically alloying it with MnFeGe , resulting in the coupling of the magnetic and structural transitions, and leading to a large magnetocaloric effect near room temperature. Application of low hydrostatic pressures (~ 2.4 kbar) led to an extraordinary enhancement of the isothermal entropy change from $-\Delta S = 44$ to 89 J/kg K at ambient and 2.4 kbar applied pressures, respectively, for a field change of $\Delta B = 5$ T. This was associated with a large relative volume change of about 7% with $P = 2.4$ kbar. (Phys. Rev. B 91, 020401(R) (2015) (Editor's Suggestion). The second highlight regards the isostructural alloying of two compounds with extremely different magnetic and thermo-structural properties, resulting in a new system, $(\text{MnNiSi})_{1-x}(\text{FeCoGe})_x$, that

exhibits extraordinary magnetocaloric properties with an acute sensitivity to applied hydrostatic pressure. Application of pressure shifts the first-order phase transition to lower temperature ($\Delta T = -41$ K with $P = 3.43$ kbar) but preserves the giant value of isothermal entropy change ($-\Delta S_{\max} = 143.7$ J/kg K for a field change of $\Delta B = 5$ T). (Submitted to Applied Physics Letters, Patent Application Number 62/062,0901, filed 18 July (2014)). The patent also applies to $(\text{MnNiSi})_{1-x}(\text{MnFeGe})_x$. Finally, we discovered an asymmetric switching behavior in the low-field magnetoresistance of the bulk metamagnetic Heusler alloy, $\text{Ni}_{50}\text{Mn}_{35}\text{In}_{15-x}\text{B}_x$. This novel physical phenomenon resembles a large asymmetric switching-like magnetoresistance at low applied fields. A thermally-activated isothermal forward metamagnetic transition with a signature of a pronounced time-dependent relaxation was observed, whereas the reverse metamagnetic transition exhibited the usual thermal behavior. (Phys. Rev. B 90, 064412 (2014)).

Electrochemical Potential Control of Mesophotonic Structures

Institution: California Institute of Technology
Point of Contact: Harry Atwater
Email: haa@caltech.edu
Principal Investigator: Harry Atwater
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

Our project has two broad objectives: 1) to understand how electrochemical potential modulation gives rise to striking changes in the optical properties of materials in the transition from plasmonic to dielectric behavior and 2) to understand how resonant and nonresonant optical excitation of nanostructures alters the electrochemical potential state of photonic materials. We are investigating electrochemical potential control in nanophotonic structures by external gating in i) composite conducting oxide/metallic resonant nanostructures, ii) graphene nanostructures, and iii) hybrid graphene/metallic nanostructures. Variation of the electrochemical potential enables an extremely large modulation of the refractive index ($\Delta n \sim 1$) in conducting oxides at visible and infrared frequencies, and gives rise to interesting tunable resonant phenomena. We are also investigating electrochemical potential control of resonant plasmon excitation in arrays of graphene nanostructures with critical dimensions in the 10-100 nm range. Tunable resonant mid-infrared absorption features due to transverse and longitudinal plasmonic metamaterial resonances are achievable, as are coupling of plasmons to localized phonon polariton modes in the underlying substrate. While graphene metastructures have relatively low quality factors Q , their extremely small mode volumes V and hence Q/V have potential to enable very large Purcell factors. By applying large potential modulations in ultrasmall (< 10 nm) resonators we will explore the possibility of realizing plasmonic graphene structures at infrared wavelengths that can couple to and dramatically modify spontaneous emission and scattering in quantum dots and atomic emitters.

FY 2014 HIGHLIGHTS

(1) Plasmoelectric Potentials in Metal Nanostructures: We introduced a new method using an all-metal geometry, based on the plasmon resonance in metal nanostructures. In arrays of Au nanoparticles on an indium-tin-oxide substrate and arrays of 100-nm-diameter holes in 20-nm-thick Au films on a glass substrate, we showed negative and positive surface potentials during monochromatic irradiation at wavelengths below or above the plasmon resonance respectively. We observed plasmoelectric surface

potentials as large as 100 mV under 100 mW/cm² illumination. Plasmoelectric devices may enable development of entirely new types of all-metal optoelectronic devices that can convert light into electrical energy. (2) Tunable Large Resonant Absorption in a Midinfrared Graphene Salisbury Screen: The optical absorption properties of periodically patterned graphene plasmonic resonators were studied experimentally as the graphene sheet is placed near a metallic reflector. By varying the size and carrier density of the graphene, the parameters for achieving a surface impedance closely matched to freespace ($Z_0 = 377 \Omega$) are determined and shown to result in 24.5% total optical absorption in the graphene sheet. Theoretical analysis shows that complete absorption is achievable with higher doping or lower loss. This geometry, known as a Salisbury screen, provides an efficient means of light coupling to the highly confined graphene plasmonic modes for future optoelectronic applications. (3) Electronic Modulation of Infrared Radiation in Graphene Plasmonic Resonators: We experimentally demonstrated tunable electronic control of blackbody emission from graphene plasmonic resonators on a silicon nitride substrate. We showed that the graphene resonators produce antenna-coupled blackbody radiation, manifest as narrow spectral emission peaks in the mid-IR. By continuously varying the nanoresonator carrier density, the frequency and intensity of these spectral features can be modulated.

Nanocrystal-Based Diodes for Solar to Electric Energy Conversion

Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)

Funding: \$51,929 (2014)

The University of Pittsburgh part of this project is listed separately under Principal Investigator: David Waldeck

PROGRAM SCOPE

We are exploring charge transfer in nanoparticle-based materials that promise to provide a systematic and modular approach to creating a new generation of solar energy conversion devices. In bulk heterojunction device architectures, sets of semiconductor nanoparticles self-organize at the interface of two photoconductive polymer phases. Such structures have the key beneficial features of being produced by self-assembly processes, in which the surface functional groups direct the nanoparticles and polymer interfaces in a composite material, and they are composed of modular components (nanoparticles, linkers, and conjugated polymers), which can be optimized separately. Our goal is to identify properties of the charge transfer elements and their assemblies that will allow such devices to capture the entire available range of solar irradiance, to efficiently transduce the absorbed energy to separated charges, and to form by self-assembly into a robust structure. While much is known about the properties of nanoparticles (NPs) and conjugated polymers (CPs) as separate entities, much less is known concerning their property evolution as they assemble into functional structures. Indeed, one's ability to predict and control the optical, electronic, and electron transfer characteristics at NP/NP and NP/CP interfaces, from knowledge of their individual electronic properties, is in an early stage of development. For example, the charge transfer efficiency of any photo-electric device depends critically on the energy level alignment of its components, relative to each other and relative to the system's Fermi-level. The project team is working on the design, synthesis, and characterization of linked-nanoparticle and conjugated polymer assemblies, which will act as the charge separation "engines" in new generation solar cells.

FY 2014 HIGHLIGHTS

The through-bond and through-space electronic couplings between two semiconducting nanoparticles (NPs) in a NP-bridge-NP system was analyzed theoretically using tight-binding electronic structure methods. We are exploring how the NP radius, solvent environment and molecular linkage influence the magnitude and distance dependence of the couplings. As the radii of the NPs increase, the through-bond and through-space couplings decrease at distinctive rates. We have identified crossover radius for fixed linker distances at which the strengths of the through-space and through-bond couplings will dominate. As such, we have identified regimes in which linker structure would significantly influence the charge separation rates and their distance dependences, and regimes in which the charge separation kinetics would be weakly structure dependent. We are using the results of these studies, as well as analysis of how surface modifications of NPs may polarize donor/acceptor states to define transport kinetic mechanisms and control strategies for NP-to-NP photoinduced charge separation.

Coherent Control of Spin States in Organic Electronic Devices - Manipulation of Electron-spin Interactions for Organic Electronics and Spintronics

Institution: Utah, University of
Point of Contact: Christoph Boehme
Email: boehme@physics.utah.edu
Principal Investigator: Christoph Boehme
Sr. Investigator(s): John Lupton; Utah, University of
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$185,000 (2014)

PROGRAM SCOPE

This project focuses on using spin-dependent electronic transitions in organic conductors and semiconductors for the study of spin-spin interactions of charge carriers. Spin-spin interactions can profoundly determine the nature of spin-dependent recombination processes which in turn can strongly affect electrical, optical, and magnetic materials properties of organic semiconductors. The research plan of this project encompasses three work areas: (i) the study of spin coupling (spin-dipolar and spin-exchange, spin-orbit, hyperfine interactions) in various organic semiconductor materials including pi-conjugated polymers with various degrees of local hyperfine field strengths such as different polyfluorene- and poly(p-phenylene vinylene)-derivatives (PPV), polystyrene sulfonate doped poly(3,4-ethylenedioxythiophene) (PEDOT:PSS) as well as new, recently synthesized materials; (ii) the exploration of electric field-control schemes of spin-exchange and -dipolar interactions between charge carriers in pi-conjugated polymers. This research activity is motivated by the prospect that an electric field dependence of spin-interactions could offer new routes for spin manipulation and thus new pathways for the control of spin-dependent macroscopic materials properties; (iii) the electrical detection of nuclear spins and hyperfine interactions and thus the question of how the nuclear spin-degree of freedom influences macroscopic magneto-optoelectronic materials properties of organic semiconductors.

FY 2014 HIGHLIGHTS

One important accomplishment of this project during fiscal year 2014 has been to experimentally verify that nuclear spin states of the omnipresent hydrogen in organic semiconductors play an important role

for the electronic and optoelectronic properties of these materials. The idea behind these experiments was to show that if proton spins affect a material's conductivity through influencing electron spins of spin-dependently recombining charge carriers as previously claimed in literature reports, then a nuclear magnetic resonance (NMR) manipulation of proton spins will cause a change in conductivity. The technical challenge of this experiment was to overcome the low polarization of proton ensembles at low magnetic fields and high temperatures. This problem was solved in two ways: First, by electrically measuring the effect of coherent nuclear spin motion on coherent electron spin motion through an electrically detected electron spin-echo envelope modulation (ESEEM) pulse scheme which projected Larmor oscillations of nuclear spins onto the electron-spin state of recombining charge carriers. By repeating these ESEEM experiments with the same polymer material (MEH-PPV) but substituted hydrogen isotopes where deuterium nuclei rather than protons were used on the 2-ethylhexyloxy side groups, it was demonstrated that the characteristic Larmor precession of the proton spins modulates the charge carrier spin echo decay. The second way to test nuclear spin control by electric currents was to directly observe current changes caused by application of nuclear magnetic resonance (NMR) to the hydrogen spins of a polymer. The electrical NMR resonance detection was achieved by using an electron-nuclear double resonance pulse sequence which selectively excited a highly spin-polarized nuclear spin subensemble. The detected NMR lines allowed for the determination of the strength and distribution of hyperfine couplings to charge carriers in the investigated material.

First Principles Prediction of Structure, Structure Selectivity, and Thermodynamics Stability Under Realistic Conditions

Institution: Massachusetts Institute of Technology
Point of Contact: Gerbrand Ceder
Email: gceder@mit.edu
Principal Investigator: Gerbrand Ceder
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$220,000 (2014)

PROGRAM SCOPE

There has been considerable progress in the first principles prediction of materials properties through the development of new and more relevant algorithms, coupled to more accurate and robust quantum mechanical approximations. This has led to the emergence of several success stories in computational materials development and has highlighted the potential for *ab initio* computation as a virtual materials laboratory. More recently, high-throughput computing has shown that predictions can rapidly be scaled to tens of thousands of known and virtual compounds. In this project we tackle three important and interconnected components of computationally driven materials design: The prediction of crystal structure, the effect of particle size and environment on structure, and the rational determination of synthesis paths for metastable structures. The properties of a material derive from its structure; therefore the capability to predict which structures will form in a compound is a central problem of materials design and engineering. The most stable structure of a material is the one with the lowest (free) energy, a mathematically well-defined but difficult to solve optimization problem. Previously, we have combined data mining with density functional theory methods to develop a very efficient structure prediction tool, requiring typically only 10–15 energy evaluations to obtain the lowest energy structure. We now are extending this approach and data-mine the common substructures of crystal structures so that for a novel compound, the likely local atomic environments can be predicted. Coupled with crystal structure construction algorithms, such an approach will allow us to predict completely new structure

prototypes, enable the relation between structural environments, properties, and composition to be expressed more completely, and make it possible to extend our approach to non-periodic and low symmetry situations (such as surfaces).

FY 2014 HIGHLIGHTS

Our accomplishment this year involves the development of a distance semi-metric in compound space. The availability of large amounts of data generated by high-throughput computing or experimenting has generated interest in the application of machine learning techniques to materials science. Machine learning of materials behavior requires the use of feature vectors or descriptors that capture the essential compositional or structural information that is most likely to influence a property. While humans tend to use intuitive –and imprecise – ideas to evaluate whether two chemistries or crystal structures are the same, machine learning requires quantitative metrics to evaluate “similarity”. Rigorous structure descriptions including concepts such as unit cells and symmetry, but chemists and materials scientists often use more intuitive and less well-defined terminology such as local environment, coordination, and polyhedral connectivity, to explain the properties of a compound. Indeed, unit cells and symmetry vary discontinuously with small changes in the atomic coordinates, and therefore do not provide a good set of descriptors in which to understand or expand materials properties. We have developed a mathematical description of structure and chemistry that can be used to create a distance semi-metric between compounds. This allows us to rigorously define similarity between compounds, and we expect this formalism to form the basis for machine learning approaches in materials science. Our novel semi-metric captures both topological and chemical information of the local environment around atoms (i.e. an octahedral site formed by oxygen ions is different from one formed by metal atoms). We combine a distance metric in chemical space (the ionic similarity) and in topological space (the coordination similarity), and coarse-grain the environment observed in known compounds (e.g. as documented in the ICSD database.)

Spectrally-Tunable Far-Field Thermal Radiation Extraction from Micro and Nanostructures

Institution:	Massachusetts Institute of Technology
Point of Contact:	Gang Chen
Email:	gchen2@mit.edu
Principal Investigator:	Gang Chen
Sr. Investigator(s):	Svetlana V. Borisikina; Massachusetts Institute of Technology
Students:	1 Postdoctoral Fellow(s), 5 Graduate(s), 0 Undergraduate(s)
Funding:	\$480,000 (2014-2017)

PROGRAM SCOPE

The overall goal of this project is to explore a new approach towards radiative heat extraction from the near-field regime into the far-field regime that utilizes morphology-mediated thermal emission. Morphology-mediated global and local DOS engineering in photonic structures has already been successfully used to either enhance or inhibit light absorption, fluorescence rates, Raman scattering efficiency, and near-field energy transfer for applications in on-chip communications and sensing. However, the broadband nature of thermal emission and the temperature dependence on the occupancy of available states make engineering the electromagnetic potential for heat extraction much more challenging. To date, there has been no systematic attempt to harness the high LDOS of confined photon states to design cold thermal extractors as well as hot thermal emitters in the far field. Furthermore, the limits of radiative heat extraction via any generalized thermal extraction scheme have

never been estimated. The only exceptions are the far-field extraction through dielectric prisms and known theoretical results from the Mie theory for some low-dimensional emitters/absorbers. Therefore, this project seeks to develop a general understanding and specific design rules for morphology-mediated radiative heat extraction both theoretically and experimentally. In particular, mechanisms of manipulating far-field thermally-emitted photons via engineering of local electromagnetic potentials will be investigated. The limits of thermal radiation from (or via coupling to) micron and nanoscale structures into the far field will also be investigated. We will also explore new possibilities to convert low energy photons into high energy phonons via phonons in low-dimensional thermal absorbers/emitters. The feasibility and efficiency limits of the thermal up-conversion in the low-dimensional structures with spectrally-tailored LDOS characteristics will be assessed.

FY 2014 HIGHLIGHTS

We studied radiative heat transfer between thin films in the near-field and far-field regimes using the Rytov theory. By reducing the thickness of the emitter and the absorber, spectral selectivity for thermal emission and absorption was improved due to the photon confinement in analogy to the electron confinement in quantum wells. We applied this approach to thermophotovoltaic (TPV) systems to improve energy conversion efficiency. Using a realistic electrical model for the PV cell, we predicted a thermal-well TPV efficiency of 38.7% in the near-field regime (100nm gap separation) and 31.5% in the far-field regime for a Ge emitter at 1000K and a GaSb cell at 300K. We also studied via the generalized Mie theory radiative heat extraction using SiO₂ microspheres (acting as thermal dots) to reduce excess heating of illuminated metal nanoparticles. We show that hybrid metal-particle-thermal-dot structures enable two orders of magnitude enhancement of localized electric fields while simultaneously reducing dissipative heating of metal and enhancing thermal emission. These effects result in particles temperature reduction by 100-300K for the irradiance of 106 W/m². We also continued to experimentally characterize near-field radiative transfer using an AFM bilayer cantilever. Experimental configurations so far have been limited to either two parallel plates or a sphere and a plate. We developed and conducted the first experimental measurement of near-field radiative transfer between two spheres. SiO₂ microspheres with a diameter of 46 μm were used. Experimental results showed good agreement with theory for gaps wider than 200nm, and at smaller gaps, deviated from theory due to spheres roughness (RMS surface roughness ~40 nm and peak to peak ~200 nm). We also developed an atomistic approach based on nonequilibrium Green's function and microscopic Maxwell equations to describe the transition from phonon radiation in the far and near field to phonon heat conduction at contacts.

EARLY CAREER: Prediction of Thermal Transport Properties of Materials with Microstructural Complexity

Institution: Florida, University of
Point of Contact: Youping Chen
Email: ypchen2@ufl.edu
Principal Investigator: Youping Chen
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project focuses on overcoming the major obstacle standing in the way of progress in dynamic multiscale simulation, which is the lack of a concurrent atomistic-continuum method that allows elastic

waves, heat and defects to pass through the atomistic-continuum interface. The primary goal of this research is to establish a concurrent multiscale methodology that can overcome this obstacle and that can be used to simulate and optimize materials with microstructural complexity. In pursuit of this goal, we propose to reformulate the classical statistical mechanical theory of transport processes to unify atomistic and continuum descriptions of balance laws and recast the governing equations to facilitate coarse-scale finite element simulation of discontinuous materials behaviors. The proposed methodology will be tested through concurrent atomistic-continuum simulation of thermoelectric materials and comparing the mechanical and thermal transport properties of thermoelectric materials from simulations with those from experimental measurements. It is anticipated that this research will lead to a new mechanical theory of transport processes, a new simulation tool that provides a unified treatment for mechanical and thermal transport behavior, and a fundamental understanding of the effects of microstructure, interfaces, and defects on phonon transport processes in complex thermoelectric materials.

FY 2014 HIGHLIGHTS

Using stroboscopic X-ray topography, Shilo and Zolotoyabko in 2003 explicitly visualized the interactions between dislocations and surface acoustic phonons (~580MHz in frequency and ~6 μ m in wavelength). However, it is not yet possible in experiments to directly observe dislocation interactions with short- to medium-wavelength high-frequency (GHz) phonons. Atomistic simulations, on the other hand, are limited to very short length scales. Using the concurrent atomistic-continuum (CAC) method that we have been developing, we have explored the dynamic dislocation-phonon interaction process and demonstrated that CAC are capable of providing detailed information on dislocation interactions with phonons that have wavelength from nanometers to microns. The mean dislocation velocity is computed and the phonon drag coefficient on dislocation motions is predicted. During dislocation-phonon interaction processes, the energy transferred from the incident phonons has been quantified and local temperature rise is estimated. We have also identified the underlying physical nature associated with the phonon-drag mechanism: an atomic-scale “breathing mode” in which the separation between leading and trailing partial dislocations fluctuates with time in a quasi-periodic fashion.

Electrochemically-Driven Phase Transitions in Battery Storage Compounds

Institution:	Massachusetts Institute of Technology
Point of Contact:	Yet-Ming Chiang
Email:	ychiang@mit.edu
Principal Investigator:	Yet-Ming Chiang
Sr. Investigator(s):	W. Craig Carter; Massachusetts Institute of Technology
Students:	2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$146,000 (2014)

PROGRAM SCOPE

Compounds of interest for ion storage in advanced batteries frequently exhibit phase transformations as the concentration of the working ion varies. Under the large electrochemical driving forces inherent to practical use, systems are often driven far from equilibrium. In this program a combined theoretical-experimental study is developing a predictive understanding of the interaction between materials composition, transformation strain, crystallite size and shape, and the electrochemical conditions driving the phase transition. Behaviors at the nanoscopic to mesoscopic scale under electrical overpotentials that vary in magnitude and with time are of special interest. The systems to be studied have

fundamental and practical interest, and include lithium and sodium transition metal olivines, $AMPO_4$ ($A = Li, Na; M = Fe, Mn, + \text{additives}$) exhibiting a wide range of transformation strains. Phase-field modeling of phase stability and transformation pathways is combined with operando experiments in which electrochemical titration is conducted simultaneously with characterization by synchrotron X-ray diffraction, neutron scattering, or transmission electron microscopy, using DOE facilities. Understanding of phase transformation pathways is expected to lead to new materials design concepts, and electrochemical duty cycles, that improve capacity utilization at high charge/discharge rates, control voltage and capacity hysteresis, and improve life by reducing cycling-induced mechanical fatigue.

FY 2014 HIGHLIGHTS

Nanoparticle olivine cathodes are the basis for large and growing class of high-power, long-life Li-ion batteries. The prototype in this family, $LiFePO_4$, has recently been shown to exist in binary lithiated/delithiated states at intermediate states of charge. Interestingly, the Mn-bearing version, $LiMn_yFe_{1-y}PO_4$, exhibits even higher rate capability as a lithium battery cathode than $LiFePO_4$ of comparable particle size. To gain insight into the cause(s) of this desirable performance, the electrochemically-driven phase transformation during battery charge and discharge of nanoscale $LiMn_{0.4}Fe_{0.6}PO_4$ of three different average particle sizes, 52, 106 and 152 nm, was investigated by operando synchrotron radiation powder X-ray diffraction. In stark contrast to the binary lithiation states of pure $LiFePO_4$ revealed in recent investigations, formation of metastable solid solutions covering a remarkable wide compositional range, including while in two-phase co-existence, are observed. Detailed analysis correlates this behavior with the existence of small elastic misfits between phases compared to either pure $LiFePO_4$ or $LiMnPO_4$. On the basis of time- and state-of-charge dependence of the olivine structure parameters, a coherent transformation mechanism is proposed. These findings illustrate a completely different phase transformation mode for pure well-ordered nanoscale olivines compared to the well-studied case of $LiFePO_4$. The results suggest that surprisingly large deviations from equilibrium under electrochemical driving force are not only possible but common, and inform the design of new battery materials.

Materials, Physics, and Nanostructures for Next Generation Spintronics

Institution: Johns Hopkins University
Point of Contact: Chia-Ling Chien
Email: clc@pha.jhu.edu
Principal Investigator: Chia-Ling Chien
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$190,000 (2014)

PROGRAM SCOPE

The research program focuses on various new spintronic phenomena, in particular pure spin current, its generation, detection, and exploitation. In contrast to a spin-polarized current, a pure spin current delivers the same spin angular momentum with fewer charge carriers thus generating less Joule heat. The situation is even more advantageous in ferromagnetic insulators, where there are no charge carriers, the magnons transmit the pure spin current with practically no heat dissipation. The few mechanisms that can generate a pure spin include spin Hall effect (SHE), spin pumping, non-local, and longitudinal spin Seebeck effect. Since a spin current cannot be directly detected by electric means, one employs other mechanisms, such as the inverse spin Hall effect (ISHE) in metals with strong spin-orbit

interaction to convert a pure spin current into a charge current or charge accumulation and be detected. We explore spin current injection into non-magnetic metals, ferromagnetic insulators, as well as ferromagnetic and antiferromagnetic materials. We devise methods to measure the spin Hall angle, which dictates the efficiency of charge/spin current conversion. We explore the physical phenomena that involve the interplay of charge, spin, and heat in the proximity of magnetic materials, as well as switching of nanomagnets by pure spin current using patterned nanostructure such as magnetic tunnel junctions.

FY 2014 HIGHLIGHTS

(1) A New Method for Self-Consistent Determination of Spin Hall Angle: Despite its importance, the reported values of spin Hall angle for a metal (e.g., Pt, Au, Ta, W), can vary by as much as two orders of magnitude. The disparity in the values of spin Hall angle is one of the most outstanding issues in spin current phenomena. We recently demonstrated a self-consistent method to determine spin Hall angle by employing a simple metal/ferromagnetic insulator structure and use thermally injected spin current from a ferromagnetic insulator into metals of different thicknesses and perform full spin current analyses of the ISHE voltage [Phys. Rev. B 89, 140407 (R), 2014]. (2) Physical Origins of the New Magnetoresistance in Pt/YIG: Recently, we have demonstrated a new type of magnetoresistance (MR) in Pt/YIG [Phys. Rev. Lett. 109, 107204, 2012]. As a nonmagnetic metal, Pt in isolation shows no discernible MR. In contrast, Pt on ferrimagnetic insulator YIG exhibits a sizable MR with characteristics different from all other known MR, including anisotropic MR (AMR), giant MR (GMR), and colossal MR (CMR). Spin Hall MR (SMR) due to spin/charge current conversion and magnetic proximity effect (MPE) have been proposed to account for the new MR. Our recent work [Phys. Rev. Lett 112, 236601 (2014).] shows that SMR has a small contribution mostly at low fields, whereas most of the new MR comes from MPE.

Extreme Thermoelectric Behavior in Low-Dimensional Oxide Conductors

Institution: Miami, University of
Point of Contact: Joshua Cohn
Email: cohn@physics.miami.edu
Principal Investigator: Joshua Cohn
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$125,000 (2014)

PROGRAM SCOPE

The intellectual focus of this project is extreme thermoelectric behavior in bulk, low-dimensional oxide compounds. Two main foci: (1) materials with high Seebeck anisotropy in mutually perpendicular directions near room temperature, with potential for applications using the transverse Seebeck or Peltier effects, and (2) thermomagnetic studies (magneto-thermopower and Nernst) on $\text{Li}_{0.9}\text{Mo}_6\text{O}_{17}$ (LiPB) at low temperature (to 0.3 K) to probe its superconducting and density-wave ground state. Figuring prominently in the proposed work were observations [Phys. Rev. Lett. 108, 056604 (2012)] revealing a giant Nernst coefficient in $\text{Li}_{0.9}\text{Mo}_6\text{O}_{17}$ (LiPB) – among the largest known for metals (~450 $\mu\text{V}/\text{KT}$ at 20 K) and rivaling those of bismuth and graphite – and a thermomagnetic figure of merit $ZT \sim 0.5$ (at 30-50K and high magnetic field), a record in this temperature regime. A goal of this project is to answer remaining questions about the physics underlying this extreme thermomagnetic behavior of this compound and whether it might be made suitable for Ettingshausen cooling (i.e., improving ZT at a practical field scale). The research program involves substantial efforts to correlate physical properties

with structure and stoichiometry. The PI's X-ray scattering determinations of lattice constants and oxygen content analyses (energy or wavelength-dispersive analysis of x-rays) on individual crystals are complemented by materials synthesis (single crystals) and other characterization (neutron scattering, thermal expansion) provided by external collaborator Prof. John J. Neumeier (Montana State University).

FY 2014 HIGHLIGHTS

Research efforts during FY 2014 focused on (1) anisotropic transport measurements (electrical conductivity, Seebeck, and thermal conductivity) in the range 200K - 520K on the Mo oxide, $\text{Li}_{0.33}\text{MoO}_3$, and (2) low-T (to 0.3 K) magneto-transport measurements along the quasi-one-dimensional chains of LiPB in its field-suppressed superconducting state, and (3) a new parallel effort on the study of heat conduction in spin-chain and ladder compounds [e.g., CuSb_2O_6 , BiCu_2PO_6] to explore spin-phonon coupling and magnetic heat transport, potentially relevant to spin caloritronic applications. A new helium-3 probe with 5-T magnet was acquired just prior to the start of FY 2014 – this entailed several low-T runs to test the instrument and to calibrate low-T thermometry (RuO sensors) as functions of temperature and magnetic field. Briefly, these investigations have revealed: (1) very high Seebeck anisotropy and low thermal conductivity in $\text{Li}_{0.33}\text{MoO}_3$ near 300 K and x-ray evidence for a small increase in the b^* lattice constant (transverse to the layer stacking of the triclinic structure) upon cooling through a heretofore unexplained electronic transition near 360 K, (2) a very small effective Fermi temperature in the field-suppressed ground state of LiPB that offers new insight into the nature of its superconducting and competing density-wave orders, and (3) strong resonant spin-phonon scattering in the spin chain and ladder compounds noted above.

Phonon and Electron Transport in Pristine Two-Dimensional Layered Nanostructures and Heterostructures

Institution: Southern California, University of
Point of Contact: Stephen Cronin
Email: scronin@usc.edu
Principal Investigator: Stephen Cronin
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$296,000 (2014)

PROGRAM SCOPE

This project investigates thermal and thermoelectric transport in two-dimensional layered nanostructures and heterostructures. Although graphene is an ideal two-dimensional (2D) material that has enabled fundamental studies of unique low-dimensional physics and potential applications, its lack of an intrinsic band gap presents a challenge for the use of graphene in electronic and energy conversion devices. As a result, other 2D materials with different band gap values have begun to receive increasing attention. In addition, novel device concepts based on heterostructures composed of graphene and different 2D layered materials have emerged recently. The scope of our research includes the following specific topics: (1) Thermal Transport in Two-Dimensional Layered Nanostructures (a) Pristine Suspended Graphene, Hexagonal Boron Nitride, and Germanane (b) Phonon-Edge Scattering in 2D Nanoribbons (2) Thermal Transport in Two-Dimensional Layered Heterostructures (a) Cross-plane Phonon Transport (b) In-plane Phonon transport (3) Coupled Electron-Phonon Transport in Layered Heterostructure Devices (a) Single Tunnel Barriers (b) Field-effect Tunneling Transistors (c) Resonant

Tunnel Diodes (d) Thermionic Energy Conversion Devices. The main goal of this fundamental research effort is to gain new knowledge on the transport and conversion of energy carriers (phonons and electrons) in a new class of 2D materials with novel structures, functionalities, and properties. The structure-property relationships established in this project can serve as the basis for designing high-performance electronic devices and energy conversion devices employing these 2D materials.

FY 2014 HIGHLIGHTS

(1) Thermal Interface Conductance across a Graphene/Hexagonal Boron Nitride Heterojunction: During FY 2014, we reported the first measurement of the thermal transport across a graphene/hexagonal boron nitride (h-BN) interface by electrically heating the graphene and measuring the temperature difference between the graphene and BN using Raman spectroscopy. Because the temperature of the graphene and BN are measured optically, this approach enables nanometer resolution in the cross-plane direction. A temperature drop of 60K can be achieved across this junction at high electrical powers (14mW). Based on the temperature difference and the applied power data, we determine the thermal interface conductance of this junction to be 7.4×10^6 W/m²K, which is below the 10^7 - 10^8 W/m²K values previously reported for graphene/SiO₂ interface. (2) Thermoelectric/Thermionic Transport Across Graphene/Boron Nitride/Graphene Heterostructures: In addition to thermal transport, we also reported thermoelectric transport measurements across a graphene/hexagonal boron nitride (h-BN)/graphene heterostructure device. Using an AC lock-in technique, we are able to separate the thermoelectric contribution to the I-V characteristics of these important device structures. The temperature gradient is measured optically using Raman spectroscopy, which enables us to explore thermoelectric transport produced at material interfaces, across length scales of just 1-2 nm. Based on the observed thermoelectric voltage (ΔV) and temperature gradient (ΔT), a Seebeck coefficient of -99.3 $\mu V/K$ is ascertained for the heterostructure device. The obtained Seebeck coefficient can be useful for understanding the thermoelectric component in the cross-plane I-V behaviors of emerging 2D heterostructure devices. These results provide an approach to probing thermoelectric energy conversion in two-dimensional layered heterostructures.

Densely Aligned Graphene Nanoribbon Arrays and Bandgap Engineering

Institution: Stanford University
Point of Contact: Hongjie Dai
Email: hdai1@stanford.edu
Principal Investigator: Hongjie Dai
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$136,796 (2014)

PROGRAM SCOPE

Graphene has attracted great interest for future electronics due to its high mobility and high thermal conductivity. However, a two-dimensional graphene sheet behaves like a metal, lacking a bandgap needed for the key devices components such as field effect transistors (FETs) in digital electronics. It has been shown that graphene nanoribbons (GNRs) with ~ 2 nm width can open up sufficient bandgaps and evolve into semiconductors to exhibit high on/off ratios useful for FETs. However, a challenging problem has been that, such ultra-narrow GNRs (~ 2 nm) are difficult to fabricate, especially for GNRs with smooth edges throughout the ribbon length. Despite high on/off ratios, these GNRs show very low mobility and low on-state conductance due to dominant scattering effects by imperfections and

disorders at the edges. Wider GNRs (>5 nm) show higher mobility, higher conductance but smaller bandgaps and low on/off ratios undesirable for FET applications. It is highly desirable to open up bandgaps in graphene or increase the bandgaps in wide GNRs to afford graphene based semiconductors for high performance (high on-state current and high on/off ratio) electronics. It has been shown theoretically that uniaxial strains can be applied to a GNR to engineer its bandgap. The underlying physics is as follows. Under uniaxial strain of several percent, though the position of cutting lines (allowed k states) for GNRs is unchanged relatively to the Brillouin zone for graphene, the Dirac point (where $E_g=0$) starts to move away from the corners of the distorted Brillouin zone due to stretched C-C bonds, leading to an increase in the bandgap of armchair GNRs by up to 50% of its original bandgap (i.e. bandgap at zero strain). The objectives of this work are to (1) fabricate high-density aligned graphene nanoribbon (GNR) arrays with GNR widths of 5-20 nm and pitch of <50 nm by using diblock copolymer lithography, (2) develop anisotropic etching of graphene capable of producing GNR edges.

FY 2014 HIGHLIGHTS

In year 2014 we succeeded in strain engineering of graphene nanoribbons, and a paper was published in *Advanced Materials*. Until this work, there has been a lack of reported experimental investigations into creating mechanical strains in GNRs, as well as into its effects on their material properties. In our work, uniaxial strains (0%-6%) were applied to individual GNRs with highly smooth edges by atomic force microscopy (AFM) manipulation and the strain effects on the Raman spectroscopic and electrical properties of GNRs were investigated experimentally for the first time. We demonstrated that the Raman G-band frequency of GNRs showed an approximate linear dependence on uniaxial strain with downshifts under strain at a rate of about -10 cm^{-1} per 1% strain (/%) for GNRs with a width of $\sim 20 \text{ nm}$. Uniaxial strain was found to tune the bandgap of GNRs significantly in a non-monotonic manner, with the bandgap varied between $\sim 25 \text{ meV}$ and $\sim 62 \text{ meV}$ under strain for a 19-nm-wide GNR. These results were in good agreement with theoretical modelings carried out. We have also leveraged the grant to explore the advanced electrical properties of graphene and carbon nanotubes for energy applications, in a paper published in *Nature Communications*. Our motivation is that hydrogen, as a clean energy resource, has been intensely investigated as an alternative to the diminishing fossil fuel. An effective way of producing high purity hydrogen is to electrochemically split water into hydrogen and oxygen in an electrolyzer but thus far there has been a lack of ideal water-reduction electrocatalyst for hydrogen evolution reaction (HER) catalyst except for precious metal platinum (Pt) and its alloys. In our work we found a nickel oxide/nickel (NiO/Ni) hetero-junction like structure attached to mildly oxidized carbon nanotube (NiO/Ni-CNT) exhibiting high HER catalytic activity close to commercial Pt/C catalysts in several types of basic solutions (pH=9.5-14).

Nanophotonics Enhanced Solar Cells

Institution: Stanford University
Point of Contact: Shanhui Fan
Email: shanhui@stanford.edu
Principal Investigator: Shanhui Fan
Sr. Investigator(s): Mark Brongersma; Stanford University
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$184,425 (2014)

PROGRAM SCOPE

The over-arching objective of our project is to develop a fundamental understanding of optical physics of nanophotonic solar cells from a wave-optics perspective, and to use this understanding to develop pathways towards ultra-thin high-efficiency solar cells with thickness on the wavelength or deep sub-wavelength scales. In this project, the theoretical efforts will be directed to understand how nanophotonic engineering may impact both the open circuit voltage and the short-circuit current of ultra-thin solar cells, and towards the design of nanophotonic structures that may reach some of the theoretical limit. The theory efforts will be closely coupled with the experiments that explore a variety of ultra-thin absorber structures. The success of our project will open a pathway towards solar cell structures in a fundamentally different regime of performance as compared to conventional solar cells, with the potential to greatly enhance the efficiency/cost ratio of future solar cell architectures.

FY 2014 HIGHLIGHTS

In 2014 we have made the following advancements: 1. A comprehensive overview, published in Nature Materials, on how one can use dielectric nanostructures to improve the efficiency of solar cells. We argue that high-index dielectric systems, through its variety of optical resonance, provides numerous important opportunities for light trapping, anti-reflection, and open-circuit voltage enhancement that is crucial for solar cell performance enhancement. 2. A detailed balance analysis of single-nanowire solar cells, published in Nano Letters. We show that the Mie resonances of the single nanowire can be used to achieve absorption cross-section significant beyond the geometric cross-section of the wires and thus can be used to enhance the current of single nanowire cell. We also show that these resonances can be utilized for open-circuit voltage enhancement as well. And as a result one can accomplish significant efficiency enhancement in single nanowire cells by controlling optical modes. 3. A proposal to overcome the Shockley-Queisser limit, using only a single semiconductor, published in Nano Letters. For radiative solar cells, the open circuit voltage is no longer a property of the semiconductor, but rather depends critically on the optical modal structure of the cell. Therefore, through nanophotonic engineering, one can control the open circuit voltage of a cell. This opens the possibility of creating a multijunction cell from a single semiconductor, in which the open circuit voltage of each junction is controlled by the photonic environment of each junction. Using detailed balance analysis, we show that such a single-semiconductor multi-junction cell has the potential to overcome the Shockley-Queisser limit. 4. A theoretical elucidation of light trapping effects in photonic crystals, as published in Energy and Environmental Science. We show that the use of Van hove singularity in photonic crystal can be used to enhance light trapping efficiency.

Exploring the Impact of Local Environment on Charge Transfer States at Molecular Donor-Acceptor Heterojunctions

Institution:	Pennsylvania State University
Point of Contact:	Noel Giebink
Email:	ncg2@psu.edu
Principal Investigator:	Noel Giebink
Sr. Investigator(s):	
Students:	0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$240,000 (2014-2017)

PROGRAM SCOPE

Charge transfer from a donor-type to an acceptor-type molecule forms the basis for the photovoltaic effect observed within conjugated molecular systems. The charge transfer (CT) state is a bound geminate charge pair that defines an intermediate state in both charge generation and recombination processes. As such, the CT state possesses a binding energy that still needs to be overcome in order to produce a free charge pair. While some important realizations have been made concerning CT states recently, there still remains a lack of fundamental knowledge regarding what controls CT state energy and the efficiency by which they may be dissociated, and whether or not Frenkel excitons become free charge via the formation of CT states. This research program sets out to comprehensively investigate the various nanoscale environmental factors that determine CT state behavior (dielectric, structural, dynamic, and energetic), as well as to quantify their spatial extent and density of states (DOS) energetic distribution. We will utilize sensitive spectral response measurements, impedance spectroscopy, X-ray scattering, and spectroscopic ellipsometry to probe the structure and optical response of thin films, as well as to extract dielectric properties. Surface-sensitive techniques such as ultraviolet photoelectron spectroscopy, inverse photoelectron spectroscopy, and X-ray photoelectron spectroscopy will be utilized to probe energy levels. Finally, time-resolved and steady-state photoluminescence, electroluminescence, electroabsorption, and pump-probe spectroscopy measurements will be used to probe CT state energetics and dynamics. In this way, the PIs assembled in this collaborative proposal represent a complementary team uniquely suited with the ability to transform our understanding of CT states.

FY 2014 HIGHLIGHTS

Thus far, we have begun to investigate the impact of disorder on CT states at a donor/acceptor (D/A) interface comprising rubrene and fullerene C_{60} . In one, micron-scale grains of rubrene template a relatively highly ordered fullerene layer, whereas the other consists of amorphous rubrene with more disordered C_{60} . The CT states at each of these heterojunctions are markedly distinct, the disordered one exhibiting a single CT feature below the optical edges of the constituent materials, whereas the ordered interface presents two features, the origin of which is currently being investigated via optical measurements such as spectral response and electroluminescence, as well as photoelectron spectroscopy. Additionally, we are making strides in identifying the width of the CT DOS distribution together with its occupation function under normal solar cell operating conditions by systematically exploring spectral shifts between CT photoluminescence and electroluminescence among various heterojunction materials and morphologies. These data, taken together with biased spectral response measurements, where the bias is either an applied voltage or background light, indicate that the occupation function depends strongly on DA interface morphology and is farther from equilibrium in bulk heterojunction devices than in their planar heterojunction counterparts.

Crystallization and Thermoelectric Transport in Semiconductor Micro- and Nanostructures Under Extreme Conditions

Institution: Connecticut, University of
Point of Contact: Ali Gokirmak
Email: gokirmak@enr.uconn.edu
Principal Investigator: Ali Gokirmak
Sr. Investigator(s): Helena Silva; Connecticut, University of
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of this project is to investigate non-equilibrium electro-thermal processes and the crystallization – amorphization behavior of materials. Self-heating of small structures leads to crystallization or melting under extreme thermal gradients and electric fields. The presence of strong electric fields breaks the generation-recombination equilibrium by moving the electrons and holes away from each other. This contribution to heat flow becomes the dominant mechanism with increased generation rates at higher temperatures. In the case of phase change materials nucleated sites perturb the generation-recombination process as well as the potential profile. Hence both carrier transport and electro-thermal processes dynamically change during operation. Experiments to investigate these phenomena are performed on lithographically defined nano-crystalline silicon microstructures and GeSbTe (225) nanostructures as well as thin films. Experimental setups are developed to perform high-temperature Seebeck and Hall measurements on thin film samples for materials characterization. The electro-thermal models are constructed using COMSOL multi-physics platform.

FY 2014 HIGHLIGHTS

We have developed our high-temperature Seebeck and Hall measurement setups and performed temperature dependent measurements on silicon and GeSbTe (225) thin films. We have observed a clear correlation between carrier activation energies and Seebeck coefficients for various polycrystalline fcc structures achieved by changing annealing temperature. The activation energies and the correlations we observe suggest that transport is limited by the grain boundaries. We have constructed numerical models that capture the nucleation and growth processes allowing us to model formation of nano-crystalline and poly-crystalline structures during annealing or self-heating. This dynamic materials model is integrated with electro-thermal models we have developed earlier. We are now finalizing a semiconductor model to accurately capture the electro-thermal processes due to non-equilibrium generation-recombination processes. This model assumes a drift-diffusion approximation in a non-isothermal system. We are hopeful that we can capture some of the interesting transport phenomena in non-homogenous and dynamic materials systems as the material goes through nucleation and growth or amorphization.

Atomic Clusters - Bare, Coated and Supported

Institution: Virginia Commonwealth University
Point of Contact: Puru Jena
Email: pjena@vcu.edu
Principal Investigator: Puru Jena
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$615,000 (2014-2017)

PROGRAM SCOPE

The objective of this project is to provide, by working closely with experimentalists, a fundamental understanding of the structure-property relationships of a novel class of highly electronegative clusters in the gas phase, study their interaction with support and counter-ions, and explore their potential as building blocks of materials with tailored properties. The project deals with four inter-related thematic areas of bare and supported clusters with rather uncommon properties. (1) Using first principles theory we design new highly electronegative clusters whose electron affinities far exceed that of chlorine and

validate their properties by working closely with experimentalists. These species, called super and hyperhalogens, usually consist of a metal atom at the core surrounded by halogen or oxygen atoms. Our goal is to create super and hyperhalogens without a metal, halogen, or oxygen atom by tailoring their size and composition and to push their electron affinities to values even higher than that currently known. (2) By suitably identifying counter ions we explore the ability of their corresponding salts to store hydrogen. (3) Superhalogens with magnetic moments are designed using transition metal atoms as key components. Their magnetic coupling is then studied by assembling them on graphene and noble metal substrates. (4) Using electronegative species as building blocks we explore the potential of multifunctional nanoparticles with Janus anisotropy for application in light harvesting. The computations are carried out using multiscale theoretical approach based on density functional theory (DFT) with hybrid and generalized gradient approximation based exchange-correlation functionals. When needed, quantum chemical methods such as Moller-Plesset perturbation theory and coupled cluster CCSD(T) are used to test the accuracy of the DFT based results.

FY 2014 HIGHLIGHTS

Optical and Electrical Properties of III-Nitrides and Related Materials

Institution: Texas Tech University
 Point of Contact: Hongxing Jiang
 Email: hx.jiang@ttu.edu
 Principal Investigator: Hongxing Jiang
 Sr. Investigator(s): Jingyu Lin; Texas Tech University
 Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
 Funding: \$158,000 (2014)

PROGRAM SCOPE

Hexagonal boron nitride (h-BN) is considered amongst the remaining frontiers in electronic and photonic materials. The scope of this research program is to extend our studies to the “newest” family member of the III-nitride material system, h-BN, and to address issues that have not yet been explored but are expected to profoundly influence our understanding on its fundamental properties and device applications. The proposed research efforts include: (1) Epi-growth. To further develop MOCVD growth processes for achieving high crystalline quality hexagonal phase BN epilayers with smooth surface morphology; (2) Deep UV (DUV) photoluminescence (PL) studies. DUV time-resolved PL will be employed to probe the optical properties and detailed band structures near the fundamental absorption edge and to extract information concerning the band structure, electron and hole effective masses, and exciton parameters in h-BN. The unique layered structure induced anisotropy in the optoelectronic properties in the out-of-plane and in-plane directions will be probed by various techniques, including polarization and time-resolved PL measurements; (3) Probing the roles of native defects and impurities. We will investigate the lateral and vertical transport properties and mechanisms of formation and elimination of native defects during MOCVD growth. The impact of native defects on the doping efficiency in h-BN will be probed. (4) Probing low-dimensional properties. Single layers or a few layers of h-BN will be deposited on sapphire substrate and AlN/sapphire template. The optical and electrical properties of 2D h-BN will be investigated and compared with 3D h-BN and graphene. Exciton binding energy, bandgap, and optical absorption of single sheet h-BN and their evolutions with the number of h-BN layers will be probed.

FY 2014 HIGHLIGHTS

Fundamentally important parameters and the origin of high optical efficiency in layered h-BN have been probed and device quality wafer-scale epitaxial layers have been realized. The measured exciton binding energy of 740 meV in h-BN represents the largest exciton binding energy ever reported for inorganic semiconductors. We have derived a generalized dispersion relation, which provides a direct relationship between the bandgap and effective mass for 2D semiconductors. The theoretical values are remarkably consistent with the exciton parameters deduced from the temperature dependence of the exciton lifetime. Our results revealed that the origin of the extremely high optical efficiency of h-BN is due to its large exciton binding energy and layered structure. The temperature dependence of the hole mobility in h-BN has been measured and is described by the form of T^{-a} with the exponent $a=3.02$, satisfying the 2D carrier transport limit dominated by the polar optical phonon scattering. The optical phonon energy deduced from the temperature dependence of the hole mobility is 192 meV (or 1546 /cm). The temperature dependence of the fundamental energy bandgap of h-BN sheets has been probed. The measured temperature coefficient of the bandgap of h-BN is about 0.43 meV/K, which is 6 times smaller than that of AlN. The weaker temperature dependence of the bandgap and emission wavelength of h-BN is a consequence of its layered structure. Our studies have demonstrated that h-BN represents an ideal platform to probe fundamental properties of 2D material systems and extend our understanding of the optical and charge carrier transport properties beyond the traditional III-nitride semiconductors. The unique properties of h-BN (weak temperature dependence of the bandgap and the extremely large exciton binding energy) can be utilized to fabricate photonic and electronic devices with exceptionally high thermal stability.

Bridging Atomistic and Continuum Scales in Phase-Field Modeling of Polycrystalline Pattern Evolution

Institution: Northeastern University
Point of Contact: Alain Karma
Email: a.karma@neu.edu
Principal Investigator: Alain Karma
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$146,000 (2014)

PROGRAM SCOPE

The vast majority of structural and functional materials of energy relevance are polycrystalline. Those materials are fabricated and operate under a wide range of homologous temperature and stress levels. As a result, their performance, safety, and life time are strongly influenced by the response to stress of grain boundaries (GBs) and their complex interaction with crystalline defects and other materials interfaces. This renewal project is aimed at using state-of-the-art phase field methodologies to advance our fundamental understanding of the behavior of stressed polycrystalline structural and functional materials. It builds on our recent advances in phase field modeling to investigate the fundamental influence of stress in three important classes of energy related materials: (i) structural alloys, (ii) nanocrystalline materials, and (iii) Li-insertion electrode materials. For structural alloys, the proposed research focuses on understanding the effects of solute on grain coalescence through the combination of atomistic scale simulations and mesoscale phase field simulations that model *in situ* X-ray imaging studies of grain boundary (GB) dynamics during alloy solidification. Those experiments, carried out at DOE/BES facilities by our experimental collaborator Dr. Amy Clarke, provide a powerful new avenue to characterize solute effects on GB premelting in relation to hot tearing of structural alloys from the comparison of modeling and experiments. For nanocrystalline materials, we propose to use phase-field computation (PFC) simulations to explore basic mechanisms of stress-driven nanocrystalline grain growth on diffusive time scales, including the role of temperature and dopants. For Li-insertion electrode materials, we will develop a multiphysics phase field modeling platform to investigate complex failure mechanisms mediated by multiple cracks and their interaction with GBs during electrochemical cycling.

FY 2014 HIGHLIGHTS

We have shown both computationally and analytically that grain boundaries that exhibit shear-coupled motion become morphologically unstable in solid alloys that phase-separate into coherent domains of distinct chemical compositions. We have carried out simulations of continuum models demonstrating that this instability is mediated by long-range elastic interaction between compositional domains and grain boundaries. Simulations were carried out for parameters modeling phase-separation in Li-ion battery materials where Li intercalation in olivine particles leads to high dilatation volumes. In these materials, complex interactions between dislocations and Li-rich particles have been observed. The simulation methods employed include a nonlinear elastic model of dislocation dynamics and amplitude equations derived from the phase-field crystal approach. In addition, we have performed a linear stability analysis that predicts the range of unstable wavelengths in good quantitative agreement with simulations. In nonlinear stages, this pattern-forming instability leads to the breakup of low-angle grain boundaries, thereby strongly impacting microstructural evolution in a wide range of phase-separating materials.

Coupling Electrons, Phonons, and Photons for Nonequilibrium Transport Simulation

Institution: Wisconsin-Madison, University of
Point of Contact: Irena Knezevic
Email: knezevic@enr.wisc.edu
Principal Investigator: Irena Knezevic
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$171,497 (2014)

PROGRAM SCOPE

The objective of this project is to develop versatile computational tools for accurate simulation of the far-from-equilibrium and time-dependent quantum transport in realistic semiconductor nanostructures driven by high-intensity dc or ac electromagnetic fields. The key challenge in simulating nonequilibrium time-dependent transport is that one must capture the strong coupling between electrons, phonons, and electromagnetic fields in the same simulation, self-consistently and at every time step.

FY 2014 HIGHLIGHTS

With high-intensity fields, considerable energy is pumped into the electron system, which relaxes by transferring much of it to the lattice; thereby, both electronic and lattice (phonon) systems are far from equilibrium. We investigated the impact of nonequilibrium longitudinal optical (LO) phonons on electron transport in a midinfrared (mid-IR) GaAs-based quantum cascade laser over a range of temperatures (77–300 K) and fields using a newly developed coupled electron and phonon ensemble Monte Carlo (EMC) technique that explicitly takes into account the phonon momentum distribution. The overarching message is that nonequilibrium phonons are extremely important at low temperatures (for GaAs, below about 200 K) and negligible otherwise. At low temperatures and in the presence of nonequilibrium phonons, the electron-phonon absorption rate increases by one to two orders of magnitude, and this microscopic phenomenon has several manifestations. Nonequilibrium phonons lead to a selective enhancement of injection from the lowest injector state into the upper lasing level via LO phonon absorption, which results in higher modal gain and current at a given field and a threshold current density lower and considerably closer to experiment than the calculation with equilibrium phonons. By amplifying phonon absorption, nonequilibrium phonons impede electron energy relaxation and lead to broader electron distributions and higher electronic temperatures than the simulation with thermal phonons. [Y. B. Shi and I. Knezevic, 'Nonequilibrium phonon effects in midinfrared QCLs,' J. Appl. Phys. 116, 123105 (2014)].

EARLY CAREER: Evaluating the Oxidative, Photothermal and Electrical Stability of Colloidal Nanocrystal Solids

Institution: California-Irvine, University of
Point of Contact: Matthew Law
Email: Matt.Law@uci.edu
Principal Investigator: Matthew Law
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

IV-VI nanocrystal solids are a novel class of granular electronic materials with great technological potential (e.g., photodetectors, field-effect transistors, solar cells), but their oxidative and thermal instability present a barrier to practical applications. This project aims to determine the degradation mechanisms of IV-VI nanocrystal (NC) solids (primarily PbSe and PbS) and to introduce new chemical strategies to drastically improve their operating lifetimes and overall performance. The project will employ several *in situ* techniques to study oxidation and thermally-activated processes in NC solids. Variable temperature and variable ambient Scanning Kelvin Probe Microscopy will be developed to map the electronic structure of operating NC materials and monitor their electronic response to changing environmental conditions. *In situ* measurements of atomic and molecular diffusion within NC solids will be made using innovative photoelectron and infrared spectroscopy approaches. Variable-temperature X-ray diffraction studies will provide new insights into the thermal lability of NC solids, including the dynamics of low-temperature rotator phases. This suite of measurements will be used to determine if NC solids can be made sufficiently robust for real technological applications, such as large-scale photovoltaic power conversion. Three strategies to drastically improve the stability of NC materials will be pursued: (i) the use of robust molecular surface ligands, (ii) the conformal coating of NC films with thin inorganic shells grown by room-temperature atomic layer deposition, and (iii) *in situ* creation of core-shell NC solids by low-temperature solution-based ion exchange. Poor stability is a common feature of nanoscale electronic materials, yet stability is all too rarely the focus of basic research. Fundamental studies are therefore needed to elucidate the most important mechanisms of degradation and develop simple yet effective countermeasures.

FY 2014 HIGHLIGHTS

In this fiscal year of the project, we have used scanning Kelvin probe microscopy (SKPM) to map the electric potential across the cross section of operating PbS quantum dot (QD) solar cells as a function of applied bias and illumination. SKPM profiles show an absence of a significant space-charge region in the QD layer when paired with a variety of n-type window layers in a heterojunction configuration. Instead, we find that most of the applied potential is dropped in the n-type metal oxide layer, with very little in the QD layer. The lack of electric field in the QD film indicates the PbS layer is not fully depleted (contrary to what is commonly assumed in the field) and the photogenerated carriers likely reach the contact through diffusion rather than drift. Our results suggest the n-type window layer (ZnO or TiO₂) and the back contact (MoO_x/metal) serve as selective contacts for electron and hole extraction, respectively. This work directly impacts the design of future QD solar cell architectures for enhanced photogenerated charge extraction. We have also demonstrated the first Pb_x QD field-effect transistors (FETs) that do not suffer from the bias-stress effect at room temperature. The bias-stress effect is a phenomenon in which the drain current of a FET changes with time at constant bias conditions. Often such time-dependent currents are associated with charge trapping at the oxide surface resulting in time-dependent screening of the applied gate field. To eliminate the bias-stress effect, we used a pulse of H₂S gas to completely desorb volatile ligands coating the QDs, followed by infilling the QD film with amorphous alumina by low-temperature atomic layer deposition (ALD). We determined that elimination of the bias-stress effect depends on complete ligand removal, the formation of a clean, trap-free PbSe/PbS/alumina interface, and the sealing off of internal pore space to prevent proton migration in the gate field.

Light Trapping, Guiding and Concentrating for Maximizing Solar Energy Conversion

Institution: Rensselaer Polytechnic Inst.
Point of Contact: Shawn Lin

Principal Investigator: Shawn Lin
Sr. Investigator(s): Sajeev John; Toronto, University of
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$400,000 (2014)

PROGRAM SCOPE

Photovoltaic devices convert light directly into electricity. It can offer a limitless, renewable source of energy provided that its light-capture and conversion-efficiency can be improved while using less semiconductor materials. Here, we propose a thin-film architecture to collect and absorb a broad spectrum of sunlight incident from all angles. Another benefit of using a thin film architecture is an improved carrier collection-efficiency. In this program, we will use a three-dimensional photonic crystal to trap and absorb sunlight in a thin slab of semiconductor and to achieve a much improved device performance. Under this program, fundamental innovations are proposed to explore a new optical effect, called “parallel-to-interface refraction”, to be realized in a 3D simple-cubic photonic crystal. This class of 3D photonic crystals, if properly designed, can refract sun-ray into a plane parallel to a photovoltaic cell’s surface over a broad wavelength and angle range. Our first long term scientific goal is to realize the parallel-to-interface refraction effect and experimentally demonstrate the predicted 75% solar absorption of all sunlight incident (400-1200nm) with one micrometer thick of silicon. We will also implement a multi-layer graded-index antireflection coating to minimize reflection and to improve the performance of our device. A new trend in solar collection and conversion is to bend light by 90-degrees using advanced photonics. Under this program, we propose to use a holographic thin film to diffract light by 90-degrees. Our second long term scientific goal is to realize a large-scale holographic film, capable of diffracting a wide spectrum of sunlight by 90-degrees. The three fundamental innovations are: (1) the use of volume hologram to achieve 90-degrees bending of sunlight from; (2) guiding and concentrating sunlight within the thin film by planar optics; (3) directing and converting sun light energy into a high efficiency photovoltaic cell.

FY 2014 HIGHLIGHTS

Over the past 12 months, our highlights are: (1) anomalous thermal radiation from a 3D active photonic-crystal; (2) efficient 90-degree light bending by volume hologram; (3) photonic architectures for high-Temperature Bose-Einstein Condensation. Non-Planckian thermal radiation from a 3D active photonic-crystal: We report the observation of unusual thermal radiation at elevated temperatures ($T=400-900K$) from a 3D metallic photonic-crystal (PhC) that includes a cavity. Upon thermal excitation, PhC’s emissive power at selective wavelengths does not correlate with its absorptivity - a deviation from Kirchhoff law. The ratio of PhC’s emissive power to that of a blackbody at nominally the same surface temperature also far exceeds one- a deviation from Planck’s law. It is further shown that, at resonance, photon gases are excited to beyond Bose-Einstein distribution. The intense EM-field near the metallic PhC/cavity interface may undergo strong feedback and even amplification of thermal radiation rate. Efficient 90-degree bending of light by volume hologram: we propose a new approach to realize a compact, lens-less and nearly all-angle solar-concentrator using a volume-holographic element. In our approach, top-incident light is diffracted by 90-degree into a volume hologram and, hence, converting solar collection problem into a guided-wave problem. We achieved 90-deg light-bending with high efficiency (70%) and without

the use of any external optics. Photonic architectures for high-Temperature Bose-Einstein Condensation (BEC): In this work, we demonstrate theoretically a route to simultaneously achieve very strong exciton-photon coupling and long polariton lifetime using a simple TiO₂ based photonic band gap (PBG) material sandwiching a planar quantum-well slab containing as few as three monolayers of the transition-metal dichalcogenide MoSe₂. This architecture provides a realistic, technologically accessible route toward equilibrium polariton BEC above room temperature.

Effect of Mechanical Strain and Quantum Electronic Stress on Physical Behavior of Bulk Materials and on Growth Property of Solid Nanomembranes

Institution: Utah, University of
Point of Contact: Feng Liu
Email: fliu@eng.utah.edu
Principal Investigator: Feng Liu
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$294,000 (2014)

PROGRAM SCOPE

This project encompasses four diverse but correlated research thrusts: (1) to continue our traditional efforts in the area of strain induced self-assembly of nanostructures in heteroepitaxial growth of thin films, (2) to expand a new research direction in exploring the “quantum electronic stress” effect, a new conceptual extension over the conventional mechanical stress effect we developed recently, (3) to foster a new research direction in studying the effect of strain on topological and electronic phases, such as topological insulator, of thin films, and (4) theoretical studies of group-IV nanomembranes in close collaboration with experiments by Prof. Lagally funded by the “Materials Synthesis and Processing” program of the same DOE-BES division. The common theme of our research efforts will remain focusing on fundamental understanding of stress/strain effect on physical behaviors of materials and on growth property of thin films. The focused specific topics in the four thrusts include: (1) Nonlinear elastic effects on nucleation and growth of strained islands inside and outside a patterned pit, (2) Quantum electronic stress induced solid-state structural phase transitions, (3) Effect of strain on topological and electronic phase transitions in Bi(111) and Sb(111) thin films. (4) Effect of strain on growth, structural, mechanical and transport properties of Si and other solid nanomembranes. Our theoretical/computational project will employ a multi-scale approach, combining several state-of-the-art theoretical and computational techniques, ranging from density-functional-theory based first-principles electronic structure calculations to continuum elasticity theoretical modeling. Broadly, our project will have direct technological impact on advancing electronic and optoelectronic materials for energy applications, to fulfill the mission of the Department of Energy.

FY 2014 HIGHLIGHTS

(1) One recent highlight is our theoretical prediction of “Large-gap Quantum Spin Hall State on Si Substrate”. We show that Si(111) surface functionalized with 1/3 monolayer of halogen atoms exhibiting a trigonal superstructure, provides an ideal template for epitaxial growth of heavy metals like Bi which self-assemble into a hexagonal lattice with high kinetic and thermodynamic stability. Most remarkably, the Bi overlayer is ‘atomically’ bonded to but ‘electronically’ decoupled from the underlying Si substrate, exhibiting isolated quantum spin Hall (QSH) state with a large energy gap of 0.8 eV. This surprising phenomenon is originated from an intriguing substrate orbital filtering effect, which critically selects the

orbital composition around the Fermi level leading to different topological phases. The realization of topological edge states on semiconductor surfaces, which may be used as dissipationless interconnects, potentially will significantly advance the current semiconductor-based technology. (2) Another recent highlight is our discovery of a new form of a 2D material— sd^2 graphene. Graphene, made of sp^2 hybridized carbon, is characterized with a Dirac band, representative of its underlying 2D hexagonal lattice. Fundamental understanding of graphene has recently spurred a surge of searching for 2D topological quantum phases in solid-state materials. However, this new form of 2D material consists of sd^2 hybridized transition metal atoms in a hexagonal lattice, which we called sd^2 “graphene”. It is characterized with bond-centered electronic hopping, which transforms the apparent atomic hexagonal lattice into the physics of a kagome lattice that may exhibit a wide range of topological quantum phases. For example, room temperature quantum anomalous Hall states are demonstrated for one such lattice made of W. We expect these significant findings to open up a new avenue to explore novel materials based on conventional semiconductor technology.

Evolution of Atomic Structure and Bonding in Phase-Change a-GST and c-GST

Institution: Johns Hopkins University
Point of Contact: Evan Ma
Email: ema@jhu.edu
Principal Investigator: Evan Ma
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$134,000 (2014)

PROGRAM SCOPE

Phase-change chalcogenide $Ge_2Sb_2Te_5$ (GST) is well suited for applications not only in rewritable data storage (optical CDs and DVDs), but also in phase-change non-volatile memory. This proposal builds upon our recent success and experience in uncovering the atomic-level structure and poly(morphism) in amorphous GST (a-GST). We will take advantage of our two-pronged computational/experimental approach, employing *ab initio* molecular-dynamics calculations and synchrotron X-ray and transmission electron microscopy experiments. Our goals are two-fold. 1) We aim to understand how the atomic structure and chemical bonding evolve in deeply supercooled GST, with emphasis on the temperature range from above the glass transition (and crystallization) temperature to room temperature. We will monitor the structural developments, especially the fraction of tetrahedrally coordinated Ge atoms and their stability (drift), the degree of Peierls-like distortion, and the fraction of homopolar bonds. 2) For the crystalline counterpart, the c-GST, we will determine the locations of Ge atoms, and assess the effects of defects/distortions on the degree of resonant bonding. In addition, we will characterize the defects induced by electrical current, to explore defect-triggered amorphization; this solid-state c to a collapse, in the absence of melting, has implications for electrically-switched memories.

FY 2014 HIGHLIGHTS

Using *ab initio* molecular dynamics simulations, we have monitored the evolution of atomic structure during the cooling of liquid $Ge_2Sb_2Te_5$ (GST). Irreducible rings (the shortest closed loops) are important in the theory of amorphous materials. We have revealed for the first time how four-membered (ABAB squares) and three-membered rings evolve with temperature in supercooled GST liquids. We found that the number of ABAB squares increases while that of three-membered rings decreases with decreasing temperature. In GST, Ge atoms are supposed to be bonded with Te atoms. However, this is not true in

real liquid GST. We have monitored the number of Ge-Ge bonds (“wrong bonds”) at different temperatures. We found an almost linear relationship between the number of wrong bonds and decreasing temperature. It indicates that the structural ordering in liquid GST evolves in the direction of decreasing homo-polar bonds with cooling, which may help to improve both topological and electronic ordering. Based on this trend, which would be expected to be more obvious if the cooling rate is lower in the simulation, or when the sample is aged for long times, the fraction of homopolar bonds may diminish, which may also lead to the reduction of the population of tetrahedrally bonded Ge. This atomic structural evolution may then help explain the “resistivity” increase (or drift) of the amorphous GST in data storage applications.

Frequency-Dependent Properties of Magnetic Nanoparticle Crystals

Institution: Carnegie Mellon University
Point of Contact: Sara Majetich
Email: sm70@andrew.cmu.edu
Principal Investigator: Sara Majetich
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$113,000 (2014)

PROGRAM SCOPE

This project builds on our magnetic nanoparticle synthesis and measurement capabilities, with a special interest in their frequency-dependent response. This project has supported the Ph.D. research of two graduate students (Krishna Chowdary, now faculty at Evergreen State College, Olympia, WA, and Ryan Booth, now a member of technical staff at the R. J. Lee Group, Pittsburgh, PA). Two of the 2014 papers acknowledging DOE support focused explicitly on the frequency-dependent behavior of magnetic nanoparticle assemblies: “Frequency-Dependent Magnetic Permeability of Fe₁₀Co₉₀ Nanocomposites”, K. M. Chowdary and S. A. Majetich, *J. Phys. D: Appl. Phys.* 47, 175001 (2014). “High-frequency permeability of Ni and Co particle assemblies”, V. K. Sakharov, R. A. Booth, and S. A. Majetich, *J. Appl. Phys.* 115, 17A517 (2014). The other two 2014 publications come from polarized neutron scattering on similar magnetic nanoparticle crystals: “Particle Moment Canting in CoFe₂O₄ Nanoparticles”, K. Hasz, Y. Ijiri, K. L. Krycka and J. A. Borchers, R. A. Booth, S. D. Oberdick, and S. A. Majetich, *Phys. Rev. B* 90, 180405(R) (2014). “Origin of Surface Canting within Fe₃O₄ Nanoparticles”, K. L. Krycka, J. A. Borchers, R. A. Booth, S. A. Majetich, Y. Ijiri, and J. J. Rhyne, *Phys. Rev. Lett.* 113, 147203 (2014). The Majetich portion of the neutron scattering work is solely supported by this DOE grant. We go to the NIST Center for Neutron Research for experiments and are active in data analysis, but the sample preparation is our unique contribution to the collaboration. Typically we travel to NIST twice a year, and students do neutron scattering in addition to their main projects. Part of the Ph.D. thesis research of Ryan Booth and Samuel Oberdick is based on neutron scattering work. Other parts of Sam Oberdick’s thesis research are supported by DARPA, and are clearly distinct from the fundamental studies supported by DOE.

FY 2014 HIGHLIGHTS

The main accomplishment this fiscal year was the improved understanding of the spin configuration within a magnetic nanoparticle, based on polarized neutron scattering. In simple models, monodomain nanoparticles have uniform magnetization throughout. However, many researchers have measured reduced magnetization in nanoparticles, relative to the bulk material, which has previously explained the reduction in terms of a surface spin glass, magnetic dead layer, or more complex ordered

arrangements. Our small angle neutron scattering experiments on magnetic nanoparticle crystals ruled out most of these models. Applying a magnetic field to monodisperse Fe_3O_4 nanoparticle crystals causes their surface spins to cant uniformly, while the spins in the core align parallel to the field. The effect is reversible and temperature-dependent. Because the origin of this symmetry breaking was unclear, we developed our own model that included exchange, anisotropy, magnetostatic, and Zeeman energies. Because the exchange energy depends on the number of magnetic neighbors, the orientation of the surface spins is most sensitive to the other energies. We found that the Zeeman energy exceeded the anisotropy and magnetostatic contributions for Fe_3O_4 nanoparticles, and that the competition between exchange and Zeeman effects led to surface spin canting. To test the model further, we prepared two other types of magnetic nanoparticle crystals and did polarized neutron scattering measurements on them. In CoFe_2O_4 nanoparticles, the anisotropy energy is ten times higher than for Fe_3O_4 , and no shell formation was seen, as predicted by the model. MnFe_2O_4 nanoparticles were also investigated, because they have comparable magnetization to that of Fe_3O_4 but a much lower Curie temperature, and therefore weaker exchange. Preliminary results show a strong field-dependence to the scattering, and the data are currently being analyzed.

Rational Design of Hybrid Nanocrystal/Silicone Architectures: From Fundamentals of Energy Transfer to Applications of Energy Sustainability

Institution: Texas-Dallas, University of
Point of Contact: Anton Malko
Email: anton.malko@utdallas.edu
Principal Investigator: Anton Malko
Sr. Investigator(s): Yves Chabal; Texas-Dallas, University of
Yuri Gartstein; Texas-Dallas, University of
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$233,000 (2014)

PROGRAM SCOPE

The proposed program is aimed to provide a fundamental understanding and explore practical utility of novel thin-film photovoltaic (PV) structures based on energy transfer (ET) between highly absorbing colloidal nanocrystal quantum dots (NQDs) and highly conducting Si semiconductor components combined in hybrid nanostructures. The light's energy is initially absorbed by NQDs and then transferred, via radiative (RET) and non-radiative (NRET) energy transfer, into a thin flexible Si layer for further electron-hole separation and transport. The strength and novelty of our approach is based on the fact that NRET and RET are longer distance interactions as compared to standard charge transfer and do not involve physical transfer of charge carriers across an interface, thus largely avoiding associated interface quality issues. We aim to determine the experimental conditions for efficient directional ET from optically thick NQD multilayers into underlying nanostructured Si substrates optimized for electron-hole pair separation and electrical transport. Our experimental efforts are supplemented by extensive theoretical modeling of NRET and RET conditions as to achieve optimum efficiencies. We are developing a new class of NQDs with enhanced photophysical properties (superior photostability and long-lived multiexcitonic states) in the near-infrared spectral region necessary for efficient sunlight harvesting. Furthermore, we have been utilizing ET-based platform as a testbed to study advanced concepts for Si sensitization. These include plasmonic and molecular antennae effects to extend ET interaction range, collection of sub-bandgap photons and study of various methods to avoid thermalization losses when harvesting high-energy photons. The last effort aims to explore conditions

for multiexciton ET from novel NQDs and initial experiments in singlet exciton fission in phosphorescent (other than NQDs) materials coupled to Si substrates.

FY 2014 HIGHLIGHTS

In the first year we concentrated on the development of the grafting strategies and approaches to create densely packed, multilayer size-gradient nanocrystal structures with directed energy flow towards the silicon substrate. We proceeded with layer-by-layer deposition using amine-modified linkers to prepare nanocrystal multilayers. We applied time-resolved optical spectroscopy methods to measure energy transfer (ET) efficiency through the nanocrystal bi-layers and into Si and have shown that our linking strategy is effective in creating defect-free nanocrystal solids. We have also started to explore an alternative/complementary assembly technique, where dense nanocrystal arrays are obtained via slow sedimentation from the films on the water surface. Our first results have shown considerable promise as we obtained very uniform and nearly closely-packed NQD monolayers on Si. In collaboration with colleagues at LANL we pursued the development of novel, photostable infrared-active nanocrystals able to augment absorption and ET in the infrared portion of the solar spectrum. New class of lead-based, core/shell PbSe/CdSe and PbS/CdS nanocrystals has been developed that show enhanced optical absorption and emission properties in the infrared ($\sim 1 \mu\text{m}$) spectral region. In parallel, we performed studies of the multiexciton emission properties of similar (emitting in the visible) CdSe/CdS ultraphotostable nanocrystals. ET from multiexcitons is supposed to further enhance solar conversion efficiencies and our focus on studying of the biexciton emission efficiencies in different types of nanocrystals allows us to explore the applicability of this approach in hybrid systems. Based on our successes with nanocrystal grafting, we started to develop electrically addressable Si samples and recorded steady-state photocurrent enhancement in nanocrystal-sensitized hybrid structures.

Surface Engineering by Simultaneous Action of Multiple External Fields

Institution: Massachusetts, University of
Point of Contact: Dimitrios Maroudas
Email: dmarouda@engin.umass.edu
Principal Investigator: Dimitrios Maroudas
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$220,000 (2014)

PROGRAM SCOPE

This research program aims at enabling surface engineering strategies based on the fundamental understanding and predictive modeling of the surface morphological response of solid materials subjected to the combined action of multiple external forces. We focus on the surface morphological evolution and stability of electrically conducting and semiconducting solids under the simultaneous application of mechanical stresses, electric fields, and temperature gradients; materials of interest include fcc metals, such as Cu, Ag, and Al, and semiconductors, such as Si and chemically functionalized or defect engineered graphene-based metamaterials. We emphasize: identifying the conditions under which the multiply driven surface morphology is stable, exploring the complexity of the corresponding various morphologically stable surface patterns, and stabilizing and controlling nanoscale patterns on surfaces. Specifically, we investigate the morphological response to the combined action of multiple external forces of bulk solid surfaces, surfaces of thin films grown epitaxially on thick or thin substrates, as well as nanoscale surface features such as coherently strained epitaxial islands on substrate surfaces.

The analysis of complex pattern formation as a result of the driven evolution of surface features (directed assembly), including distributions of single-layer epitaxial islands and vacancy islands, offers new paradigms of multiply driven surface nanopatterning. The research is based on a modeling approach that combines theoretical analyses of surface/feature morphological stability with self-consistent dynamical simulations of driven surface/feature evolution based on properly parameterized continuum and multi-scale surface transport models that we develop. Employing these models, we conduct systematic studies of the effects of multiple forcing conditions, varied over a broad range of material and operating parameters, on surface morphological response.

FY 2014 HIGHLIGHTS

We examined the surface morphological stability of conducting crystalline elastic solids in uniaxial tension under the action of a temperature gradient alone and simultaneously with an electric field. We established that properly directed and stronger-than-critical thermal gradients and electric fields can be used both individually and synergistically to stabilize the planar surface morphology. Our findings set the stage for an effective, practical approach to inhibiting morphological instabilities that cause surface cracking of crystalline solids. We have developed a weakly nonlinear theory for the occurrence of tip-splitting instabilities that cause formation of secondary ripples on surfaces of stressed solids, without or with the simultaneous action of externally applied electric fields and/or thermal gradients, and the number of ripples that form on the surface as a function of surface perturbation wavelength. We have conducted a systematic simulation study of an approach to surface nanopatterning through electric-field-driven assembly of single-layer epitaxial islands on face-centered cubic crystalline substrates. We have discovered entire classes of complex pattern formation starting from either a large single island or an assembly of relatively small islands that undergo a sequence of coalescence and break-up events. We have determined the dependence of the nanopattern features on the single island size or the assembly's intrinsic geometrical parameters, island edge diffusional anisotropy parameters, and the duration of application of the electric field. We have also studied the assembly of crystals of colloidal particles and established: the effects of the attractive inter-particle potential range on the phase behavior and polymorphic transitions between different crystalline configurations, how the assembly can be controlled to result in close-packed crystalline structures, and the equilibrium colloidal crystal shape as a function of the crystal size.

Acceptor Defects in ZnO and Related Materials

Institution: Washington State University
Point of Contact: Matthew D. McCluskey
Email: mattmcc@wsu.edu
Principal Investigator: Matthew D. McCluskey
Sr. Investigator(s): Leah Bergman; Idaho, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$151,000 (2014)

PROGRAM SCOPE

Zinc oxide (ZnO) is an electronic material with desirable properties for a range of energy applications. ZnO is a wide band gap (3.4 eV) semiconductor that emits light in the near-UV region of the spectrum, with high efficiency. Despite its advantages, the lack of fundamental knowledge about dopants and defects presents an obstacle to the development of practical devices. Reliable p-type doping, required for high-performance transistors, lasers, or light-emitting diodes, has been elusive. The scientific

literature contains numerous reports that nitrogen doping can produce p-type ZnO. However, recent first-principles calculations, and experimental results from the prior DOE funding period, suggest that nitrogen is a deep acceptor, with the acceptor level 1.3 eV above the valence-band maximum. The current project will provide a fundamental understanding of defects in ZnO that could lead to reliable p-type conductivity. First, alloying ZnO with the chalcogens sulfur, selenium, or tellurium will raise the valence band. By tuning the valence band, one may realize a reduced nitrogen acceptor binding energy. This approach can be summarized as “if you cannot bring the acceptor to the valence band, bring the valence band to the acceptor.” Alkali dopants (lithium and sodium), which have lower binding energies than nitrogen, could prove especially fruitful. A second strategy for p-type doping is suggested by studies on ZnO nanocrystals, which show evidence for an acceptor level 0.46 eV above the valence-band maximum. The identity of this acceptor is currently unknown. In this project, the fundamental properties of acceptor defects in ZnO and related materials will be investigated. The results of these optical and electrical characterization studies could provide the basis for the long-sought goal of reliable p-type doping of ZnO. More broadly, this investigation will provide physical insight into defects in oxide semiconductors, in bulk crystals, thin films, and nanocrystals.

FY 2014 HIGHLIGHTS

(1) Acceptors in ZnO nanocrystals: Using commercial ZnO nanocrystals of diameter ~ 90 nm, we provide experimental evidence that they contain hydrogenic acceptors. Infrared (IR) absorption peaks and a photoluminescence (PL) peak were observed, consistent with those previously observed in ~ 20 nm diameter ZnO nanocrystals. High field (W-band) electron paramagnetic resonance (EPR) measurements revealed an axial center with $g_{(\text{perp})} = 2.0015$ and $g_{//} = 2.0056$, along with an isotropic center at $g = 2.0035$. The two defect centers detected by EPR are not necessarily the same as the acceptor observed by IR and PL. (2) Annealing of ZnO thin films: The objective of this study is to find annealing conditions that enhance UV photoluminescence (PL) at ~ 3.3 eV and understand the underlying defect dynamics. Annealing experiments were performed on two as-grown ZnO thin films: one film was annealed in O_2 and the other in an Ar environment. The annealing temperature and times were 900°C and 1 hour, respectively. ZnO films were grown by sputtering for 1 hour at 250°C on quartz substrates. The as-grown sample exhibits a very weak UV-PL, and a strong visible PL at ~ 2.8 eV, tentatively attributed to zinc interstitials. Annealing under an O_2 environment diminished the 2.8 eV band; however, new defect centers were created that activate the PL at 2.18 eV, attributed to oxygen interstitials. The UV PL shows a significant increase. These results can be explained in terms of the low migration barrier for Zn interstitials that enable them to diffuse either to the lattice sites or out to the environment. However, the oxygen rich environment saturates the sample, resulting in oxygen interstitial defect centers. Annealing in an Ar environment resulted in reduction of the 2.8 eV band.

Interfaces in Electronic and Structural Materials

PROGRAM SCOPE

Development of revolutionary new materials for future energy applications relies on progress in fundamental understanding of materials' interfaces and our ability to predict, design and control their properties. The objective of this program is to advance the fundamental understanding of interfaces, especially in materials subject to deformations and high temperatures, and to develop new methods for computational prediction of interface properties. The proposed research focuses on interfaces in thermoelectric materials using bismuth telluride Bi_2Te_3 as a model system. Specific goals include investigations of: (1) effect of crystallographic characteristics, applied stresses, temperatures and chemical composition on atomic structure, thermodynamic characteristics, mechanical strength and motion of internal interfaces in Bi_2Te_3 alloys, and (2) effect of interfaces on thermal conductivity of this material. The main approach to achieving these goals is based on atomistic computer simulation methods, primarily molecular dynamics and a variety of Monte Carlo techniques. These methods are capable of delivering critical atomic-level information about the interface structures and predicting mechanical, thermodynamic and kinetic properties of interfaces. Extensive first principles calculations will be performed for calibration of a new many-body angular-dependent interatomic potential that will be developed for Bi_2Te_3 alloys in order to enable quantitative large-scale atomistic simulations. The results of the simulations will be validated against experimental data for grain boundary structures, mechanical and thermoelectric properties of Bi_2Te_3 . The project is expected to make a significant impact on the state of knowledge in interface science by improving fundamental understanding of mechanical, thermal and dynamical properties of interfaces, especially in thermoelectric materials. This goal is relevant to the BES mission and is aligned with DOE's Grand Challenges.

FY 2014 HIGHLIGHTS

1. Phase transformations at interfaces present a profound fundamental interest as complex examples of phase transitions in low-dimensional systems. We have developed a new methodology of atomistic simulations that has revealed multiple grain boundary phases and reversible first-order phase transformations between them. Furthermore, we have demonstrated that interface phase transformations can strongly impact transport properties, for example atomic diffusion along grain boundaries. Atomistic calculations of Ag diffusion in two different structural phases of a Cu grain boundary demonstrate excellent agreement with experimental measurements, providing the first convincing evidence for the existence of structural phase transformations in high-angle grain boundaries and demonstrate the possibility of their detection by boundary diffusion measurements and atomistic simulations. The interface phase transformations can also influence electric and thermal resistance of interfaces and offer a means of achieving new properties via design optimal microstructures. 2. Massive first-principle DFT calculations have been conducted for various crystalline structures of Bi and Te. The obtained first-principles database has been used to construct many-body angular-dependent interatomic potentials for Bi and Te. The potentials accurately reproduce a wide range of properties of these elements, including structural energies, phase transformations, melting temperatures, phonon dispersion relations, thermal expansion, point defect formation and migration energies and many other properties. Work is currently underway to develop a similar first-principles database for developing the Bi-Te cross-interaction functions describing the Bi-Te binary system, particularly the bismuth telluride Bi_2Te_3 .

Colloidal Semiconductor Dense Films for Red, Green, and Blue Lasers

Institution: Brown University
Point of Contact: Arto Nurmikko
Email: Arto_Nurmikko@brown.edu
Principal Investigator: Arto Nurmikko
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$420,000 (2014-2017)

PROGRAM SCOPE

The primary objective of this project is to create a solid thin film photonic material platform which can leverage recent work to advance colloidal semiconductors towards practical single material based lasers across the visible spectrum. We seek to understand multiple physical properties of very dense, closely packed CdSe-based II-VI semiconductor core-shell solid thin films which, contrary to earlier work in the field, have now been shown to retain the high luminescence efficiencies (up to 90% and beyond) which the red, green, and blue (RGB) quantum dots exhibit in the starting high concentration solution form. Inherently, we take advantage of the ability to define any specific wavelength of emission within RGB color range by control of the quantum dot (QD) size.

FY 2014 HIGHLIGHTS

Colloidal quantum dots (CQD) are now making their entry to full-color displays, endowed by their brightness and single-material base. By contrast, many obstacles have been encountered in their use towards lasers. We have now demonstrated optically pumped distributed feedback (DFB) lasers, based on close-packed, solid films self-assembled from type-I CQDs. Notably, the single mode CQD-DFB lasers could reach such a low threshold as to be pumpable with a compact pulsed source in a quasi-continuous wave regime. Our results show the spatially and temporally coherent laser beam outputs with power of 400 microwatts and an internal quantum efficiency of 32%. Further, we have extended the surface emitting distributed feedback (DFB) lasers from the red across green and blue from densely packed colloidal quantum dot (CQD) films by varying the quantum dot size. The solid CQD films were deposited on periodic grating patterns to enable 2nd-order DFB lasing action at mere 120, 280, and 330 microjoules per square centimeter of optical pumping energy densities for red, green, and blue DFB lasers, respectively. The lasers operated in single mode operation with less than 1 nanometer of full-width-half-maximum. We measured far-field patterns showing high degree of spatial beam coherence. Specifically, by taking advantage of single exciton optical gain regime from our engineered CQDs, we can significantly suppress the Auger recombination to reduce lasing threshold and achieve quasi-steady state, optically pumped operation.

Metamaterials as a Platform for the Development of Novel Materials for Energy Applications

Institution: Boston College, Trustees of
Point of Contact: Willie Padilla
Email: willie.padilla@duke.edu
Principal Investigator: Willie Padilla
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$99,999 (2014)

PROGRAM SCOPE

The PI will explore the fundamental properties of metamaterials (MMs) and their potential for energy applications in support of the mission of the Department of Energy and the office of Basic Energy Sciences. The advent of metamaterials provides novel electromagnetic responses and enables study of exotic materials – particularly in the microwave through THz and up into far IR parts of the electromagnetic (EM) spectrum – providing an ideal platform to explore a rich variety of science, from optics, condensed matter physics, materials science, to nanoscience. The PI proposes to advance the understanding of these materials through fundamental investigations of the experimental and theoretical properties of metamaterials and to provide a knowledge base for the discovery, prediction and design of new materials with novel structures, functions, and properties. The research activities emphasize the computational design and fabrication of the materials, and the characterization of their electromagnetic properties. There are a number of novel properties of the proposed materials which make them ideally suited for basic research with a view toward potential energy applications:

- Absorptivities and emissivities of metamaterials may be tailored, enabling applications such as thermophotovoltaics and lighting. Other materials lack this engineerability thus adding complexity to a given design.
- Approaches based on metamaterials may be readily scaled to various energy ranges, i.e. THz, infrared, optical. Metamaterials do not depend on, and are not limited by, the inherent electronic band structures of the constituent materials.
- Alternative metamaterial designs can be utilized for similar electromagnetic response, enabling flexibility.
- Metamaterials are multifunctional, i.e. tailored absorptivities and emissivities naturally incorporate filtering and optimization, reducing the necessity of additional materials.

FY 2014 HIGHLIGHTS

(1) Dynamic 3 State Metamaterial A 3-state tunable metasurface that shows all wave-matter interaction states (Reflection, Transmission, and Absorption) in one device was demonstrated. Our initial work was performed at X-band (8 to 14 GHz). Working at microwave frequencies simplified the fabrication process allowing us focus on the fundamental science behind creating a switchable 3-state system. The tuning was achieved by reverse biasing varactor diodes mounted onto the metasurface. By changing the capacitance of the varactor diodes, the impedance of the metasurface at one unique frequency is altered and thus the absorption, reflection and transmission spectra of the metasurface are tuned. S-parameter extraction is used to show the shifting of resonance peaks, and the extracted impedance results explain the 3-state tuning phenomena. Investigation into materials suitable for high temperature near infrared (NIR) Metamaterials Metamaterial emitters for thermal photovoltaic (TPV) applications can be expected to be used at temperatures on the order of 1000K. At these temperatures however most of the properties and characteristics of traditionally used materials are not ideal. The temperatures will exceed the melting point for most metals and certain combinations of materials will form eutectic mixtures (i.e. silicon and gold). We have begun work on examining different materials for use in metamaterial absorbers/emitters. For conventional metamaterial designs we are looking at high melting point metals such as platinum and dielectrics such as aluminum oxide to prevent eutectic formation.

Exploring the Impact of the Local Environment on Charge Transfer States at Molecular Donor-Acceptor Heterojunctions

Institution: Princeton University
Point of Contact: Barry Rand
Email: brand@Princeton.edu
Principal Investigator: Barry Rand

Sr. Investigator(s): Antoine Kahn; Princeton University
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$580,002 (2014-2017)

PROGRAM SCOPE

Charge transfer from a donor-type to an acceptor-type molecule forms the basis for the photovoltaic effect observed within conjugated molecular systems. The charge transfer (CT) state is a bound geminate charge pair that defines an intermediate state in both charge generation and recombination processes. As such, the CT state possesses a binding energy that still needs to be overcome in order to produce a free charge pair. While some important realizations have been made concerning CT states recently, there still remains a lack of fundamental knowledge regarding what controls CT state energy and the efficiency by which they may be dissociated, and whether or not Frenkel excitons become free charge via the formation of CT states. This research program sets out to comprehensively investigate the various nanoscale environmental factors that determine CT state behavior (dielectric, structural, dynamic, and energetic), as well as to quantify their spatial extent and density of states (DOS) energetic distribution. We will utilize sensitive spectral response measurements, impedance spectroscopy, X-ray scattering, and spectroscopic ellipsometry to probe the structure and optical response of thin films, as well as to extract dielectric properties. Surface-sensitive techniques such as ultraviolet photoelectron spectroscopy, inverse photoelectron spectroscopy, and X-ray photoelectron spectroscopy will be utilized to probe energy levels. Finally, time-resolved and steady-state photoluminescence, electroluminescence, electroabsorption, and pump-probe spectroscopy measurements will be used to probe CT state energetics and dynamics. In this way, the PIs assembled in this collaborative proposal represent a complementary team uniquely suited with the ability to transform our understanding of CT states.

FY 2014 HIGHLIGHTS

Thus far, we have begun to investigate the impact of disorder on CT states at a donor/acceptor (DA) interface comprising rubrene and fullerene C₆₀. In one, micron-scale grains of rubrene template a relatively highly ordered fullerene layer, whereas the other consists of amorphous rubrene with more disordered C₆₀. The CT states at each of these heterojunctions are markedly distinct, the disordered one exhibiting a single CT feature below the optical edges of the constituent materials, whereas the ordered interface presents two features, the origin of which is currently being investigated via optical measurements such as spectral response and electroluminescence, as well as photoelectron spectroscopy. Additionally, we are making strides in identifying the width of the CT DOS distribution together with its occupation function under normal solar cell operating conditions by systematically exploring spectral shifts between CT photoluminescence and electroluminescence among various heterojunction materials and morphologies. These data, taken together with biased spectral response measurements, where the bias is either an applied voltage or background light, indicate that the occupation function depends strongly on DA interface morphology and is farther from equilibrium in bulk heterojunction devices than in their planar heterojunction counterparts.

Collaborative Research: Polymeric Multiferroics

Institution: Kansas, University of
Point of Contact: Shenqiang Ren
Email: shenqiang@ku.edu
Principal Investigator: Shenqiang Ren

Sr. Investigator(s):

Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)

Funding: \$47,000 (2014)

The University of Maryland part of this project is listed separately under Principal Investigator: Manfred Wuttig

PROGRAM SCOPE

The goal of this project is to investigate room temperature magnetism, spin resonance, magnetoelectric coupling of polymeric multiferroics. A unique organic multiferroic material system with the understanding of magnetism, magneto-transport, magnetic field effects and magnetoelectric coupling, could have potential impacts on organic sensor, memories, and potentially high T_c organic superconductors. A new family of organic charge-transfer complexes has been emerged as a fascinating opportunity for the development of all-organic ferroelectrics and spintronics due to its weak hyperfine interaction and low spin-orbit coupling; nevertheless, direct observations of room temperature magnetic spin ordering have yet to be accomplished in organic charge-transfer complexes. Furthermore, room temperature magnetoelectric coupling effect hitherto known multiferroics, is anticipated in organic donor-acceptor complexes because of magnetic field effects on charge-transfer dipoles, yet this is also unexplored. The PI seeks to fundamental understanding of the synthetic control of organic complexes to demonstrate and explore room temperature multiferroicity. Our experimental work is a joint effort with Dr. Manfred Wuttig at the University of Maryland, College Park.

FY 2014 HIGHLIGHTS

We have synthesized thiophene nanowire/Au nanocluster nanohybrids as a prototypical charge-transfer system, which exhibits magnetic field effects and spin-optoelectronic properties (*Angewandte Chemie International Edition*, 53, 7316, 2014). The experimental results have been confirmed through theoretical modeling. By applying external stimuli on organic multiferroics, some key findings are observed as following: 1) spin correlated transport behavior of crystalline polymeric multiferroics due to thermal induced triplet bipolarons; 2) electric field and light controlled magnetic susceptibility and magneto-dielectric coupling through the control of singlet and triplet charge transfer states; 3) Magnetic field effects and photon-controlled ferroelectricity in polymeric multiferroics at room temperature (*ACS Nano*, 8, 3671, 2014; *Advanced Materials*, DOI:10.1002/adma.201403396, 2014, selected as the Frontispiece for *Advanced Materials*; *Nano Letters*, 14, 5308, 2014; *Scientific Report*, DOI:10.1038/srep06126, 2014).

High Performance Bulk Thermoelectric Materials

Institution: Houston, University of

Point of Contact: Zhifeng Ren

Principal Investigator: Zhifeng Ren

Sr. Investigator(s):

Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)

Funding: \$233,747 (2013-2014)

PROGRAM SCOPE

Solid-state thermoelectric energy conversion is a promising technology to convert the waste heat into electricity or to cool devices/systems in an environmentally friendly manner, leading to significant energy saving and reduced environmental impact. We proposed to study ways to enhance thermoelectric properties in a number of materials by a nanocomposite approach using a quick and economic ball milling and hot pressing process. The work involves improving of the thermoelectric figure of merit (ZT) of a few existing good thermoelectric materials. This project will also provide educational opportunities to graduate students, postdocs, and visiting professors on clean energy research.

FY 2014 HIGHLIGHTS

In fiscal year 2014, we published eight papers, one in Nature Nanotechnology, one in Nature Communication, two in Nano Energy, one in PRB, one in APL, one in Light: Science & Applications, and one in New Journal of Physics. One student has graduated with a PhD degree. In these eight papers, we have a few important developments: 1. We found CoO nanoparticles made by ball milling are efficient catalyst for water splitting under one Sun radiation. 2. We discovered a new way to make metallic nanomesh exhibiting outstanding flexibility, light transmittance, and electrical conductivity. These new materials will be used as flexible transparent electrodes for flexible electronics. 3. We drastically improved the figure-of-merit of MgAgSb. With such improvement, it is aimed for wide spread usage for heat to electricity conversion in temperatures lower than 300°C.

Defect Studies of CZTSe & Related Thin Film Photovoltaic Materials

Institution: Utah, University of
Point of Contact: Michael A. Scarpulla
Email: scarpulla@eng.utah.edu
Principal Investigator: Michael A. Scarpulla
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$300,000 (2014)

PROGRAM SCOPE

Thin film photovoltaics have seen great advances in the past 3 years with three materials (CdTe, Cu(In,Ga)Se₂, and CH₃NH₃PbI₃) achieving high efficiency solar cells at 19% or greater. Cu₂ZnSn(S,Se)₄ or CZTSSe is very close in crystalline and electronic structure to Cu(In,Ga)Se₂ which, if fundamental understanding and control of its electronic defects can be achieved, could be used for building terawatts of photovoltaic energy generation unconstrained by supplies of its constituent elements because they are earth abundant. This project seeks fundamental understanding of the electronic states present in CZTSSe and their origins in the bulk or in grain boundaries. This is being pursued through capacitive spectroscopy measurements such as deep level transient spectroscopy primarily. We are also studying the composition fluctuations on the mesoscale of 30 nm to 30 um using transmission x-ray tomography and attempting to link this to observed electronic defects. Lastly, we are investigating bulk CZTS samples including both single crystals and those containing grain and phase boundaries in order to understand how these structural defects manifest electronically.

FY 2014 HIGHLIGHTS

In 2014 we continued our study of the minority electron trapping defect which we located recently in CZTS samples fabricated from nanoparticle precursors at Purdue. We established that it exists as a distribution of energy separations from the conduction band centered on 0.59 eV and that its electron capture cross-section is $2 \times 10^{14} \text{ cm}^2$. Combining simulation with experiment, we established reliable values for its total concentration at $10^{15} / \text{cm}^3$ and showed how it (somewhat counterintuitively) can fill and empty with electrons during the experiment. Also the simulation allowed projection of the effects of this defect on the minority carrier lifetime and open circuit voltage of CZTS photovoltaic devices. This accounting for the 'missing' V_{oc} in CZTS indicates that another mechanism is probably also operating - a finding that has been speculative to date.

Study of Materials and Interface Properties for High-Efficiency Spin Injection: Spin Dependent Quantum Phenomena in Ferromagnetic Graph

Institution: California-Riverside, University of
Point of Contact: Jing Shi
Email: jing.shi@ucr.edu
Principal Investigator: Jing Shi
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

A focus of this BES-funded project is to develop a better understanding of magnetic/non-magnetic interfaces for more efficient spin injection. Spin injection can be accomplished by a spin-polarized charge current or a pure spin current without any charge current. Interfaces play a critical role in both. During the funding period, we propose to study the interfaces of magnetic oxide/organic semiconductors, magnetic metal (oxide)/graphene, magnetic oxide/metals, magnetic oxide/topological insulators, etc. We grow and characterize magnetic oxide thin films such as LaSrMnO, yttrium iron garnet first, and then fabricate heterostructures using various techniques. We employ magneto-transport, spin pumping, and thermal/thermoelectric transport to investigate the properties of relevant interfaces and their effects on spin injection and spin transport.

FY 2014 HIGHLIGHTS

One highlight of the funded project is the finding of the physical origin of the magneto-resistance in heterostructures of heavy metals with yttrium iron garnet (YIG) which is a ferri-magnetic insulator. Controversies existed about the newly discovered magnetoresistance effects in such a system. One mechanism is called the spin Hall magnetoresistance which is due to the transport of spin currents across the interface of metal/magnetic insulator. By performing a systematic temperature dependence study, we have found the characteristic features predicted for this spin current induced magnetoresistance. In addition, we studied the interplay between the spin Hall magnetoresistance and the conventional anisotropic magnetoresistance as the spin diffusion length is varied (PRL). Another highlight is the study of the proximity-induced ferromagnetism in graphene using YIG as a substrate. In a Scientific Reports article, we demonstrated the proximity effect in graphene/STO. We adopted the same transfer technique to fabricate graphene/YIG and found ferromagnetism in graphene. If graphene is spin-polarized by the proximity effect, a variety of interesting phenomena can be realized. Similar

interface effect has been investigated in metal/metal bilayer systems such as Pd/NiFe and Ta/NiFe. We have identified various contributions such as the proximity-induced anomalous Nernst effect and spin Seebeck effect in the systems. In FY 2014, we have published four papers, including one in Phys. Rev. Lett., one in Scientific Reports, one in New Journal of Physics, and one in Appl. Phys. Lett. The PI gave an invited talk at the APS March meeting. We submitted a paper to Phys. Rev. Lett. in May, 2014 which was accepted in December (appeared in Jan. 2015).

EARLY CAREER: Nanostructured Colloidal Self-Assembly and Controlled Alignment of Anisotropic Nanoparticles

Institution: Colorado, University of
Point of Contact: Ivan Smalyukh
Email: Ivan.Smalyukh@Colorado.edu
Principal Investigator: Ivan Smalyukh
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Harvesting, storage, and conversion of energy among its different forms strongly depend on available materials and their properties. Self-assembly of nano-sized functional units is an exceptionally promising way of designing inexpensive artificial composite materials with new macroscopic physical behavior and properties. The main objective of this project is to explore self-organization of anisotropic nanoparticles into colloidal composites with tunable ordered structures. The research is focusing on understanding and control of self-assembly of metal and semiconductor nanoparticles, as well as on material behavior arising from their ordered self-organization and alignment. Fundamental studies of shape-dependent colloidal interactions and ordering of quantum dots and plasmonic metal nanoparticles are expected to reveal underpinning physical mechanisms that guide mesoscale morphology and ultimately determine material properties of the self-assembled composites. These properties are characterized and correlated with hierarchical structures and composition. Analytical and numerical modeling of colloidal interactions and material properties provide important insights at different stages of this project. This research may enable new, cheaper, and more efficient renewable energy technologies, a new breed of energy-efficient information displays and consumer devices, as well as a fertile ground for new basic science.

FY 2014 HIGHLIGHTS

According to the original plan of the proposal, we have focused on synthesis, dispersion, and switching of various plasmonic metal nanoparticles in thermotropic liquid crystals. We have developed plasmonic nematic colloids with facile switching of ordered anisotropic metal nanoparticle ensembles by low-voltage fields and low-intensity light. Practical guest-host devices, in which dichroic dye molecules follow electrical switching of a liquid crystal host, remain elusive for decades despite promising efficient displays and emergent applications such as smart windows. This is mainly because of poor stability, surface precipitation, and limited means for property engineering of the dyes. To overcome these challenges, we develop plasmonic metal nanoparticle analogs of dichroic guest-host liquid crystals. Nematic dispersions of aligned anisotropic gold nanoparticles are obtained by polymer passivation of their surfaces to impose weak tangential boundary conditions for orientation of anisotropic host molecules. Control of the ensuing surface interactions leads to long-range ordered colloidal dispersions, allowing for collective optical and electrical switching of rod- and platelet-like nanoparticles. Our

research resulted in the following publications: [1] Q. Liu, Y. Yuan, and I. I. Smalyukh. Electrically and Optically Tunable Plasmonic Guest-Host Liquid Crystals. *Nano Lett.* 14, 4071–4077 (2014). Funding: \$140,000 (2014)

PROGRAM SCOPE

Transition-metal oxides exhibit rich complexity in their fundamental physical properties determined by the intricate interplay between structural, electronic and magnetic degrees of freedom. This project would focus on correlated systems like Ruddlesden-Popper type double layer perovskites where anisotropy is likely to play an even more crucial role than in pseudocubic perovskites. Special attention would be given to exploring the role of dimensionality through systematic experimental studies and establishing correlation between the structure, electronic and magnetic properties in single crystals, thin films and nanoparticles. In continued studies on the $\text{Pr}_{1-x}\text{Sr}_x\text{CoO}_3$ cobaltite system we intend to explore the effect of reduced dimensionality (thin films and nanoparticles) on the intriguing coupled structural/magnetocrystalline anisotropy driven transition observed in polycrystalline systems in our prior work. In addition we would also extensively probe the fundamental ground state physics in the $\text{Ca}_3\text{Co}_2\text{O}_6$ system which has spin chains arranged on a triangular lattice geometry. This results in competing magnetic ground states that can be tuned by temperature, field and structural changes. All these systems are of current interest and have important unresolved issues that we intend to solve through our combination of DC, AC and RF magnetization studies coupled with neutron scattering. In addition to our signature RF susceptibility and magneto-caloric effect (MCE) experiments, we would initiate broadband high frequency magnetoimpedance measurements to probe spin dynamics and spin Seebeck effect (SSE) measurements to investigate the coupling between spin and heat transport in these complex oxides.

FY 2014 HIGHLIGHTS

Our major accomplishments during the 2013-2014 period include: (1) Using magneto-caloric effect (MCE) method to establish a new magnetic phase diagram for the spin chain cobaltite $\text{Ca}_3\text{Co}_2\text{O}_6$ that exhibits geometric frustration with intrinsic low-dimensionality; (2) Discovery of an inverse magnetocaloric effect (IMCE) in hydrothermally synthesized single crystalline $\text{La}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ nanowires; (3) First systematic investigation into the collective contributions of interface and surface spins to the exchange bias (EB) in $\text{Fe}/\gamma\text{-Fe}_2\text{O}_3$ core-shell nanoparticle systems; (4) Exploring a new approach of tuning EB in hybrid $\text{Au-Fe}_3\text{O}_4$ nanostructures using an interfacial strain. In particular, we have established a

comprehensive phase diagram of $\text{Ca}_3\text{Co}_2\text{O}_6$ from the temperature and magnetic field dependence of magnetic entropy change. Our new findings assert the recent theoretical predictions of the existence of a spin-density wave ground state at zero field, providing new insights into the collective magnetic phenomena in geometrically frustrated 1D magnets (Physical Review B 89, 144414, 2014). We have discovered the IMCE in $\text{La}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ nanowires, which is absent in its bulk counterpart. Our study points to the importance of disordered surface spins and sheds light on the origin of the EB effect in nanostructured manganites (Nanotechnology 24, 505712, 2013). We have demonstrated, in $\text{Fe}/\gamma\text{-Fe}_2\text{O}_3$ core-shell nanoparticles, that there exists a critical particle size (~ 10 nm), above which the spins at the interface between Fe and $\gamma\text{-Fe}_2\text{O}_3$ contribute primarily to the EB, but below which the surface spin effect is dominant. Such knowledge is key to manipulating EB in magnetic nanostructures for spintronics applications (Applied Physics Letters 104, 072407, 2014). We have demonstrated an interfacial strain between Au and Fe_3O_4 as a driving force for enhanced surface spin disordering and hence the EB effect in the Au- Fe_3O_4 composite nanoparticle system.

EARLY CAREER: Probing Coherent States of Light and Matter in Two-Dimensional Semiconductors

Institution: Northwestern University
Point of Contact: Nathaniel Stern
Email: n-stern@northwestern.edu
Principal Investigator: Nathaniel Stern
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

The objective of this program is to investigate cavity-enhanced optical coupling between photonic resonators and two-dimensional monolayer semiconductors such as transition metal dichalcogenides. When reduced to a single atomic layer, the band structure of these nanomaterials displays degenerate valleys in momentum space that can be separately addressed by polarized light. We propose to explore a fundamentally new regime of interfacing photons with nano-materials using excitations of specific valley quantum number, potentially revealing new avenues for probing coherent phenomena in layered 2D systems. Drawing on progress in photonics, nanoscale materials, and quantum optics, our approach combines monolayer material synthesis with solid-state quantum optics and on-chip photonic device circuits to realize a new vision of valley-sensitive quantum manipulation using light. This project will explore several main directions. We study mechanisms of valley-specific light-matter coupling in monolayer semiconductors. Enabling this, we seek to advance strategies for integrating these materials into dielectric photonic resonators with exquisite control over the material's optical environment. In the proposed experiments, we will investigate new methods of probing coherent phenomena in 2D materials using hybrid light-matter excitations. The ability to engineer light-matter interactions with the next-generation of layered nano-materials will have long-term impact by advancing possibilities for controlling matter using light, such as coherent preparation and control of valley states and exploiting symmetries of low-dimensional semiconductor materials in integrated photonic and polaritonic devices.

FY 2014 HIGHLIGHTS

So far, we have achieved optical evidence for exciton-polaritons in large-area monolayers of transition metal dichalcogenides (TMDCs) integrated with dielectric Bragg reflector mirrors. We have observed optical coupling using white-light reflectivity, revealing a measured light-matter coupling constant the

same order-of-magnitude as predicted by associated calculations We have now started applying these methods to observe light-matter coupling in related layered materials grown by our collaborators. Further, we have demonstrated the coupling of MoS₂ monolayers to photonic resonators through measurement of cavity-coupled photoluminescence collected by a high-magnification objective. For our next steps, we will pursue technical advances to translate the measurements to low temperatures where valley polarization becomes important and to illuminate the mechanisms for energy transfer between monolayer materials and photonic devices. This initial progress will lead to more detailed understanding of the coupling strength and excitation dynamics in this hybrid light-matter system.

Spin Functionality Through Complex Oxide Heteroepitaxy

Institution: Stanford University
Point of Contact: Yuri Suzuki
Email: ysuzuki1@stanford.edu
Principal Investigator: Yuri Suzuki
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$250,000 (2014)

PROGRAM SCOPE

In this program, we address a strategic materials challenge associated with spin electronics that may be an energy efficient alternative to charge based electronics where power dissipation during dynamic operation and standby places limits on scaling. We focus on the development of novel complex oxide thin films and heterostructures with spin functionality where surfaces/interfaces and coherent epitaxial strain play a critical role in the realization of the long-range magnetic order. Many of these emergent magnetic phenomena are not accessible in bulk form and depend on the atomically precise synthesis of the materials. Therefore the development of atomically precise complex oxide thin films and heterostructures with spin functionality generated at surfaces/interfaces or by epitaxial strain is key to the success of this program. In particular, we have studied (i) heterostructures in which the interfaces gives rise to spin functionality not observed in the two constituent materials and engineered by carrier mediated exchange interactions or valence discontinuities at ferromagnetic interfaces and (ii) thin films in which epitaxial strain can induce spin-state transitions or metal-insulator transitions to stabilize ferromagnetic and/or metallic ground states. Our approach combines atomic scale epitaxy with careful local structural, electronic and magnetic characterization in the form of x-ray absorption spectroscopy, x-ray magnetic circular dichroism, x-ray resonant magnetic scattering, magnetic force microscopy, transmission electron microscopy and electron energy loss spectroscopy as well as macroscopic magnetic and electronic characterization.

FY 2014 HIGHLIGHTS

We have demonstrated interfacial ferromagnetism in CaMnO₃ based superlattices, ferromagnetism in epitaxial cobaltite thin films, as well as unexpected behavior in ultrathin films of CaMnO₃. One of our major accomplishments has been to demonstrate that interfacial ferromagnetism is generated in just one single unit cell of CaMnO₃ as predicted by theory. Through a combination of polarized neutron reflectometry and exchange bias measurements, we definitively showed that the interfacial ferromagnetism can only be explained in terms of a ferromagnetic double exchange interaction among the Mn ions in a single unit cell of the CaMnO₃ layers at each interface. Recent results indicated that the exchange bias continues to increase and showed no sign of saturation at CaMnO₃ thicknesses of up to

20 unit cells. This trend can be explained in terms of a long range antiferromagnetic correlation observed in neutron diffraction experiments. We also demonstrated that this emergent interfacial ferromagnetism observed in $\text{CaRuO}_3/\text{CaMnO}_3$ superlattices is a much more general phenomena. We found similar emergent behavior when we replace the itinerant metal CaRuO_3 with LaNiO_3 . Since LaNiO_3 undergoes a thickness dependent metal-insulator transition, we have been able to demonstrate that the metallicity in the layer adjacent to the CaMnO_3 is an essential ingredient to the interfacial ferromagnetism. We have also definitively demonstrated the origin of ferromagnetism in epitaxial LaCoO_3 thin films not found in the bulk. The presence of high spin (HS) Co^{3+} and Co^{2+} , in addition to low spin (LS) Co^{3+} , in different proportions depending on the substrate choice suggests that a combination of superexchange interactions based on correlated hopping among HS and LS Co^{3+} and superexchange interactions among HS Co^{2+} and LS Co^{3+} in the presence of ordered oxygen vacancies is responsible for the observed ferromagnetic ground states.

Understanding Structure-Property Relationships in Ferroelectric Oxides

Institution: New Jersey Institute of Technology
Point of Contact: Trevor Tyson
Email: trevor.a.tyson@njit.edu
Principal Investigator: Trevor Tyson
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$95,000 (2014)

PROGRAM SCOPE

We are focusing on the small ion perovskite E-phase systems and extending structural studies down to temperatures below 10 K, where the total measured polarization rapidly increases and where contact with DFT ($T=0$) measurements may be made. Moving towards materials with possible device applications, we will examine nano-scale materials as a path toward high density storage. Detailed measurement of the structural properties and dynamics will be conducted over a range of length scales from atomic to mesoscopic scale using, x-ray absorption spectroscopy, x-ray diffuse scattering, x-ray and neutron pair distribution analysis and high resolution x-ray diffraction. Changes in vibration modes which occur with the onset of polarization will be probed with temperature and pressure dependent infrared absorption spectroscopy. The multiple length scale synchrotron based measurements may assist in developing more detailed models of these materials and possibly lead to device applications. An important contribution of this work will be the training of graduate students and postdoctoral researchers in materials synthesis, synchrotron based spectroscopy and x-ray scattering techniques.

FY 2014 HIGHLIGHTS

[1] "Detailed Structural Studies Polar State in Freestanding Strontium Titanate Nanoparticles" T. A. Tyson *et al*, Appl. Phys. Lett. 105, 091901 (2014). Monodispersed strontium titanate nanoparticles were prepared and studied in detail. It is found that ~ 10 nm as-prepared stoichiometric nanoparticles are in a polar structural state (with possibly ferroelectric properties) over a broad temperature range. A tetragonal structure is found as the particle size is reduced. The results indicate that nanoscale motifs of SrTiO_3 may be utilized in data storage as assembled nano-particle arrays in applications where chemical stability, temperature stability and low toxicity are critical issues. [2] "Absence of significant structural changes near the magnetic ordering temperature in small-ion rare earth perovskite RMnO_3 " T. Yu *et al*, J. Phys.: Condens. Matter 26, 495402 (2014). Detailed structural measurements on multiple length

scales were conducted on a new perovskite, ScMnO_3 , and on orthorhombic LuMnO_3 as a benchmark. The measurements place upper limits on any structural changes to be at most one order of magnitude lower than density functional theory predictions. [3] "Structural changes related to the magnetic transitions in hexagonal InMnO_3 " T. Yu *et al*, Phys. Rev. B. 90, 174106 (2014). Two magnetic ordering transitions are found in InMnO_3 . Multiple length scale structural measurements reveal enhanced local distortion found to be connected with tilting of the MnO_5 polyhedra as temperature is reduced. Coupling is observed between the lattice and the spin manifested as changes in the structure near both of the magnetic ordering temperatures (at ~ 42 K and ~ 118 K). External parameters such as pressure are expected to modify the coupling. [4] "Pressure Dependent Structural Changes and Predicted Electrical Polarization in Perovskite RMnO_3 " T. Wu *et al*, submitted to Phys. Rev. B. (see arXiv link arxiv.org/pdf/1403.7998).

Uncovering and Surmounting Loss Mechanisms in Nitride Light Emitters

Institution: California-Santa Barbara, University of
Point of Contact: Chris Van de Walle
Email: vandewalle@mrl.ucsb.edu
Principal Investigator: Chris Van de Walle
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$120,000 (2014)

PROGRAM SCOPE

The overarching aim of the present project is to understand energy losses in nitride light emitting diodes (LEDs) and devise methods of overcoming them. Light emission from solid-state light emitters is still suffering from limited efficiency. This constitutes a key issue for the nitride light-emitting diodes (LEDs) that form the basis for solid-state lighting, but LEDs based on conventional semiconductors also exhibit limited efficiencies. Understanding the microscopic origin of various physical pathways that lead to those losses is crucial for the improvement of future devices. We study loss mechanisms based on cutting-edge first-principles calculations as well as semi-empirical modeling. The aim is to calculate radiative and nonradiative recombination rates without any fitting to experiment. Shockley-Read-Hall recombination will be quantified for impurities and point defects relevant to the quantum-well structures. Absorption due to free and bound carriers will be evaluated. Limitations in hole transport, which are severely impeding carrier distribution over multiple wells, will also be addressed. The calculation of nonradiative recombination rates requires methodological developments that will be valuable and applicable to other materials system as well. Our goal is for our insights to result in recommendations for improved materials growth, as well as in novel structures, based on band-structure, wave-function, and electric-field engineering, aimed at promoting carrier distribution and alleviating the effects of any remaining nonradiative recombination or absorption processes.

FY 2014 HIGHLIGHTS

(1) Nonradiative carrier capture rates: One of the goals is to understand the microscopic origin of Shockley-Read-Hall (SRH) recombination centers in nitride light emitters. SRH is proportional to the first power of the carrier density, and has a distinct impact on overall device efficiency. Recombination consists of two capture events: electron capture and hole capture. We have developed a practical first-principles methodology to calculate carrier capture coefficients. All the ingredients for the theory, including vibrational frequencies and electron-phonon coupling constants, are determined consistently

from hybrid functional calculations. We have also put forward a methodology to deal with bulk scattering states during a nonradiative capture process. The methodology has been applied to selected defects in GaN and ZnO, chosen as benchmark cases because of the availability of reliable experimental results. The agreement with experiment is excellent. (2) First-principles luminescence lineshapes: The study of radiative transitions provides a lot of useful information about defect geometries, vibrational properties, etc. It also serves as a further benchmark for the accuracy and reliability of our methodologies for treating electron-phonon interactions. Building on our development of a methodology to calculate luminescence lineshapes for defects with very strong electron-phonon coupling, we have now developed an approach for studying defects with moderate coupling, a case in which luminescence lineshapes have more structure, and often many contributing phonon frequencies can be identified. As a test case, the methodology was applied to the nitrogen-vacancy (NV) center in diamond, a defect which serves as an excellent benchmark. Very good agreement was obtained.

Mesoscale Interfacial Dynamics in Magnetolectric Nanocomposites

Institution: Virginia Polytechnic Inst. and State U.
Point of Contact: Dwight Viehland
Email: viehland@mse.vt.edu
Principal Investigator: Dwight Viehland
Sr. Investigator(s): Shashank Priya; Virginia Polytechnic Inst. and State U.
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$106,770 (2014)

PROGRAM SCOPE

Multiferroic materials have a coexistence of at least two ferroic orders (ferroelectric, ferromagnetic, or ferroelastic). In multiferroic materials, the coupling interaction between the different order parameters can produce new phenomena, such as the magnetoelectric (ME) effect. The ME response is the appearance of an electric polarization P upon applying a magnetic field H , and/or the appearance of a magnetization M upon applying an electric field E . Magnetoelectricity has been observed as an intrinsic effect in some natural materials at low temperature; however, such single phase materials suffer from extremely weak ME exchange. Better alternatives are two-phase composites consisting of magnetostrictive and piezoelectric phases, which have been shown to have large ME coefficients. Said composites exploit a unique product ME tensor property that depends upon the individual strictions of the piezoelectric and magnetostrictive phases, the elastic stiffness and integrity of the interphase interfaces, the phase distribution and the dimensionality of its connectivity, and any elastic constraint; amongst other things. The specific objectives of this program are as following (i) development of new self-assembled morphologies and anisotropies in two phase ME epitaxial layers; (ii) determine microstructure of the interfaces between magnetic and piezoelectric phases, using electron microscopies; and (iii) find the correlation between local and bulk magnetoelectric responses to develop physical relationships that elucidate the fundamental nature of linear and non-linear coupling at varying length scales.

FY 2014 HIGHLIGHTS

In the last year, we have made progress in the following areas. (i) We have shown the volatile and nonvolatile changes in the M-H curves with electric field in Mn doped CoFe_2O_4 layers grown on $(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ - x [PbTiO_3] (PMN-PT) crystals. These studies have demonstrated a large electric field tunable magnetic anisotropy, in particular an electric field induced magnetic phase transformation was

observed for layers grown on (110) oriented substrates. The phase transformation can be reversible or irreversible, resulting in volatile and/or nonvolatile magnetic easy axis rotations respectively. (ii) Growth and characterization of magnetostrictive Fe-Ga layers deposited on PMN-PT crystals. It was shown that an electric field can irreversibly and reversibly modulate the magnetization. (iii) Integration of perovskite/multiferroic layers on semiconducting substrates to provide understanding of transport mechanisms and reveal the control parameters for nonlinear responses. We have performed high resolution transmission electron microscopy to investigate the interface of the high-k materials deposited on various orientation (100), (110) and (111) of Ge layer using molecular beam epitaxy (MBE) on GaAs substrate. Valence and conduction band offset of dielectrics on crystallographically oriented Ge layers, and the band alignments of the integrated BaTiO₃- BiFeO₃ (BTO-BFO) solid solution layers were quantified. (iv) Characterization of interfacial interactions in PZT/CFO/PZT magnetoelectric trilayers grown on Pt/Ti/Si substrates.

Thermodynamic, Kinetic and Electrochemical Studies on Mixed Proton, Oxygen Ion and Electron (Hole) Conductors

Institution: Utah, University of
Point of Contact: Anil Virkar
Email: anil.virkar@utah.edu
Principal Investigator: Anil Virkar
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$158,000 (2014)

PROGRAM SCOPE

The principal objective of the work is to conduct thermodynamic, kinetic and electrochemical studies on mixed proton, oxygen ion and electron (hole) conductors. The work involves theory and experiments. Transport processes are analyzed using linear non-equilibrium thermodynamics. Onsager coefficients including cross terms in coupled transport are determined. Transport processes in fuel cells, electrolyzers and lithium ion batteries are examined using linear non-equilibrium thermodynamics. Role of low level electronic transport on chemical potentials of electrically neutral species is assessed. Relative directions of ionic and electronic flows determine whether or not chemical potentials are bounded within the electrolyte. It is shown that if the ionic (e.g. H⁺, O²⁻, Li⁺) and electronic currents are parallel, the chemical potentials of the corresponding neutral species (H₂, O₂, Li) in the electrolyte can exceed electrode values. This can lead to either electrolyte reduction or precipitation (and pressurization) of neutral species (H₂, O₂, Li) and failure of the electrochemical devices. Thermodynamic stability of electrochemical devices such as fuel cells, electrolyzers, lithium ion batteries is examined. Experimental part involves the use of AC and DC techniques to investigate transport properties (ionic and electronic conductivities, Onsager transport coefficients) and a study of local thermodynamics by embedded probes. Using these techniques, spatial distributions of chemical potentials of electrically neutral species (H₂, O₂, Li) inside an electrolyte are measured. The role of coupled transport is also examined in the stability of proton exchange membrane fuel cell cathodes. The thermodynamics of catalyst-support interaction are examined both theoretically and experimentally. This includes a study of electrochemical Ostwald ripening of platinum-based nanocatalysts and the role of catalyst support.

FY 2014 HIGHLIGHTS

(1) Developed a novel technique for the measurement of electronic conductivity of predominantly ionic conductors by an embedded electrode method. The technique measures exceptionally low values of electronic conductivity with no redistribution of composition. Electronic conductivity of yttria-stabilized zirconia (YSZ) was measured at as low a temperature as 500°C. A paper is published in J. Electrochem. Soc. (2015). (2) Examined electrochemically induced pressure due to coupled transport of ionic and electronic pressure, which demonstrates the role of unbounded chemical potentials. A paper was published in Procedia IUTAM (2014). (3) Theoretical analysis is conducted on reversible fuel cells based on mixed ionic electronic conducting electrolyte materials. It is shown that some level of electronic conductivity through the electrolyte is beneficial since it tends to smooth out the chemical potential variation through the electrolyte membrane. A manuscript has been submitted to the Int. J. of Hydrogen Energy (2014). (4) A parametric equation was developed which describes voltage vs. current density polarization curves of solid oxide fuel cells in terms of out-of-cell fundamental measurements of the kinetics of electrocatalysis and gas diffusion through porous media. Using the model, for the first time realistic characteristics of fuel cells can be predicted in terms of fundamental materials property measurements. A manuscript based on this work will be submitted for publication within the next month. (5) Theoretically examined the role of catalyst size distribution and catalyst-support interactions on platinum catalyst stability. Mono-dispersed catalysts resist Ostwald ripening due to very low thermodynamic driving force for growth and thus exhibit excellent stability. It was also shown that contact angle between the catalyst and the support governs stability. An invited talk was presented at the Fall Meeting of the Electrochemical Society. A manuscript is under preparation.

Nanocrystal-Based Dyads for Solar to Electric Energy Conversion

Institution: Pittsburgh, University of
Point of Contact: David Waldeck
Email: dave@pitt.edu
Principal Investigator: David Waldeck
Sr. Investigator(s): Ron Naaman; Weizmann Institute of Science
Students: 2 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$185,000 (2014)

The Duke University part of this project is listed separately under Principal Investigator: David Beratan

PROGRAM SCOPE

We are exploring nanoparticle-based materials that promise to provide a systematic and modular approach to creating a new generation of solar energy conversion devices. The project team (comprised of researchers at U. Pittsburgh, Duke Univ., and the Weizmann Institute of Science) is working to develop a systematic and quantitative approach to creating supramolecular assemblies of linked nanoparticles that function as charge transfer elements.

FY 2014 HIGHLIGHTS

(1) Ligand Tuning of Valence Band Offsets: We have studied, both experimentally and computationally, the electronic energies of CdSe nanoparticles (NPs) as a function of size and capping ligand. These results show how the energy position and the size-dependent behavior of the energy bands of CdSe can be modulated by the chemical nature of the capping ligand. -- J. Phys. Chem. C. (2013) 22401–22411. (2) Electric-field Effect on the Charge Transfer between Semiconductor Nanoparticles and Conjugated

Polymers: Excitonic solar cells, such as organic bulk heterojunction devices, utilize donor-acceptor (D-A) energy offsets to dissociate electron-hole pairs, whereas conventional p-n junction solar cells employ an internal electric field for the same purpose. Recently, we created electrostatic assemblies of conjugated polymers and semiconductor nanoparticles that incorporate static electric fields which promote electron transfer. -- Phys. Chem. Chem. Phys. 16 (2014), 5066 – 5070. (3) Depleted Bulk-Heterojunction: We investigated the effects of annealing on the detailed interface structure and energy conversion behavior of TiO₂/PbS heterojunction solar cells. We showed that annealing causes intermixing of the TiO₂ and PbS phases, thereby increasing the junction area within the depleted bulk heterojunction (DBH) layer and promoting the carrier extraction from PbS QDs to TiO₂. -- J. Phys. Chem. C 118 (2014) 14749-14758. (4) Plasmonic Effects on Solar to Electrical Conversion: We examined how the placement of core-shell plasmonic particles influenced the conversion efficiency in PbS/ TiO₂ bulk heterojunction cells. This work shows that the solar to electrical conversion efficiency is improved by two effects: 1) the enhanced scattering and electric fields caused by the plasmonic particles and 2) the enhanced light scattering caused by morphological changes in the back electrode which result from the plasmonic particle incorporation. -- Solar Energy Materials and Solar Cells 128 (2014).

Fundamental Piezotronic and Piezo-Phototronic Effects in Nanowires

Institution: Georgia Institute of Technology
Point of Contact: Zhong Wang
Email: zhong.wang@mse.gatech.edu
Principal Investigator: Zhong Wang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$137,123 (2014)

PROGRAM SCOPE

The fundamental effect of mechanically-induced polarization charges on electronic and optoelectronic processes of charge carriers in piezoelectric materials has been long overlooked, due to the fact that conventional piezoelectric materials are mostly insulating. Semiconductor materials such as ZnO, GaN and CdS are also piezoelectric but not as extensively utilized in piezoelectricity due to their relatively small piezoelectric coefficients. The coupling between strain-induced polarization and charge carrier process in piezoelectric semiconductors, known as piezotronic/piezo-phototronic effect and first proposed by the PI in 2006 and 2009, respectively, provides fundamental approaches to modulate electronics/optoelectronics characteristics by tuning the junction/contact properties, which is unavailable in existing methods without modifying the interface structure or chemistry. Piezoelectric polarization charges can serve as a “gate” controlling signal that effectively controls the carrier transport across the interface/junction. This is the piezotronic effect. These polarization charges can also effectively modulate the optoelectronic processes, such as generation, separation, diffusion and/or recombination, of charge carriers. This is the piezo-phototronic effect. A fundamental study is essential for advancing early theoretical/experimental work and exploring the nature of these two emerging effects. The objective of this proposal is to extend the scope of piezotronics and piezo-phototronics and develop a more comprehensive understanding of these emerging effects in different material/structure systems for potential applications. Then, the fundamental theory will be explored to study the charge processes in piezotronic structures. This proposal is a renewal of prior funded BES DOE (DE-FG02-07ER46394) project.

FY 2014 HIGHLIGHTS

The PI's group has made major accomplishments for this project within FY 2014, focusing on the fundamental study of piezoelectric polarization charges on carriers' electronic and optoelectronic processes in low-dimensional piezoelectric semiconductor. Specifically, the PI's group has

- Reported the first experimental investigation of piezoelectricity and piezotronic effect in single atomic layer 2D MoS₂ and its application in mechanical energy harvesting and piezotronic sensing (Nature, 514, 470-474, 2014).
- Demonstrated the first piezotronic effect enhanced Schottky-contact ZnO micro/nanowire humidity sensor (Nano Res. 7, 1083-1091, 2014).
- Developed the first ZnO Nanowire Film Based Temperature Sensor with enhanced sensing by piezotronic effect (ACS Applied Materials & Interfaces, 6, 5955-5961, 2014).
- Carried out detailed study on piezo-phototronic effect in optoelectronic devices based on wurtzite semiconductor nanowires (Physical Chemistry Chemical Physics, 16, 2790-2800, 2014).
- Reviewed the progress and provided prospective for the field of piezotronics and piezo-phototronics by two invited review papers in high-profile journals (Nano Today, 8, 619-642, 2013, and National Science Review, 1, 62-90, 2014).

EARLY CAREER: Plasmon-Mediated Electrochemical Reactions: the Influence of Nanoparticle Structure

Institution: Texas-Austin, University of
Point of Contact: Katherine A Willets
Email: kwillets@cm.utexas.edu
Principal Investigator: Katherine A Willets
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project seeks to identify whether coupling electrochemical reactions to plasmonic nanoparticle electrodes can impact the redox potentials of the reaction, thereby lowering energy barriers to effect desired reactions of interest. To study electrochemical reactions on the nanoscale, we use optical readouts of the redox state of molecules, including surface-enhanced Raman scattering and fluorescence.

FY 2014 HIGHLIGHTS

We have characterized the intensity-dependent redox response of our optical probe, Nile Blue, showing that light alone can impact redox potentials, although not as dramatically as when the probe is coupled to nanoparticle electrodes. We have also shown that coupling the Nile Blue to nanoparticle aggregates changes the electrochemical behavior of the probe, although the mechanism for the observed behavior is still under investigation. We have developed a simple, inexpensive strategy for fabricating nanoparticle electrodes using block copolymer lithography and have created arrays of electrodes that span the relevant wavelength window of the Nile Blue absorption and emission. So far, the redox potentials track with the spectrum of the probe, rather than the plasmon resonance of the electrode substrate. Nonetheless, they can be favorably shifted, based on preliminary data.

Charge Transfer Across the Boundary of Photon-Harvesting Nanocrystals

Institution: Cornell University
Point of Contact: Frank Wise
Email: frank.wise@cornell.edu
Principal Investigator: Frank Wise
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$157,000 (2014)

PROGRAM SCOPE

The goal of this project is to understand the fundamental processes that govern interfacial charge transfer across nanocrystal boundaries. We carry out use-inspired fundamental studies of charge transport in nanocrystal assemblies, and from nanocrystals into other semiconductor materials with two principal goals: (1) to understand and control electronic structure and transport properties across nanoscale interfaces, and (2) to create confined-but-connected nanostructures that balance quantum-confinement and –coupling for optimized light capture and charge transport. Major themes include the role of dimensionality in charge and energy transport and the physical and chemical properties of nanocrystal surfaces. The work is done in the context of photovoltaic devices, but the knowledge that we gain will also be relevant to a variety of settings, including molecular electronics, sensors, light emitters, and electrocatalysis. The device configurations that we consider combine silicon and solution-synthesized nanocrystals in inexpensive, efficient solid-state solar cells.

FY 2014 HIGHLIGHTS

Atomically-coherent nanocrystal assemblies offer the potential for size-engineered electronic and optical properties, along with band-like carrier transport. We have demonstrated assembly and epitaxial connection of PbSe nanocrystals into paracrystalline superlattices. Self-assembly at a liquid-liquid interface is employed along with in-situ small-angle x-ray scattering. Superlattice order with a correlation distance more than 100 nm is revealed by x-ray scattering and transmission electron microscopy. Assemblies with square and hexagonal symmetries have been produced. Measurements of field-effect transistor structures indicate that charge-carrier transport in these films is thermally-activated, with a delocalization length of ~ 10 nm. These results are consistent with calculations, which underscore the critical role of energy and structural disorders on the properties of the assembly. Nanosheets (or colloidal quantum wells) represent the limiting case of atomically-coherent structures, and are of major interest in their own right. To date there are only a couple reports of synthesis of lead-salt nanosheets. By increasing the reactivity of the precursors compared to the prior synthesis, we have demonstrated synthesis of PbS nanosheets with controllable thickness and shape. Ideally, nanocrystal surfaces would be terminated with atoms or molecules that passivate all surface defects while allowing strong electronic coupling of adjacent nanocrystals. We have shown that ligand removal by ammonium sulfide treatment, followed by iodine treatment, can produce improved surfaces by creation of a thin shell of lead iodide. When this treatment is applied to nanocrystals passivated by the combination of long oleate ligands along with cadmium and chlorine ions, the resulting films exhibit both reduced defect density and improved carrier transport compared to previous films. The films will be assessed in photovoltaic devices.

EARLY CAREER: Functional Domain Walls as Active Elements for Energy Technology

Institution: California-Berkeley, University of
Point of Contact: Junqiao Wu
Email: wuj@berkeley.edu
Principal Investigator: Junqiao Wu
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This project aims to understand and exploit novel physics and functionalities of domain walls in transition metal oxides for their use as active elements to direct matter and energy. Heterophase and homophase domain walls are mobile and nanoscale elements existing in a wide range of materials; they can host remarkable, emergent functionalities that are absent in the bulk. This may lead to a variety of new energy technologies that are superior to existing ones. The PI seeks to understand the fundamental mechanism governing diffusion and recombination of point defects facilitated by domain walls, demonstrate ultra-sensitive transduction of wind and heat based on domain wall motion, explore and exploit effects of domain walls in electrothermal transport for nanoscale thermal management, and finally probe the physical behavior of correlated electrons confined within domain walls as a quasi-two-dimensional electron liquid.

FY 2014 HIGHLIGHTS

(1) We developed a VO_2 nanowire-based microthermometer for quantitative evaluation of electron beam heating. This microthermometer can serve as a thermal flow meter to investigate sample heating from the incident electron beam inside electron microscopes. Owing to its small size the vanadium dioxide nanowire-based microthermometer has a large measurement range and high sensitivity, making it a good candidate to explore the temperature environment of small spaces or to monitor the temperature of tiny, nanoscale objects. Published at *Nature Commun.*, 5, 4986 (2014). (2) We directly observed nanoscale Peltier and Joule effects at metal-insulator domain walls in vanadium dioxide nanobeams. Published at *Nano Lett.*, 14, 2394(2014). (3) We discovered monolayer behavior in bulk ReS_2 due to electronic and vibrational decoupling. Such vanishing interlayer coupling enables probing of two-dimensional-like systems without the need for monolayers. Published at *Nature Commun.*, 5, 3252 (2014). (4) We demonstrated powerful, multifunctional torsional micro muscles activated by phase transition. These torsional muscles combine multiple functions as torsional actuators, micro catapults, proximity sensors, as well as memristors. Being able to sense a distanced object and then respond by rotating to a different configuration, the torsional muscles simulate active neuromuscular systems with all-inorganic materials. Published at *Adv. Mater.* 26, 1746 (2014). (5) We discovered a temperature-gated thermal rectification effect for active heat flow control using asymmetric VO_2 nanowires. To the best of our knowledge, this is the first demonstration of solid-state active-thermal devices with a large rectification ($\sim 20\%$) in the rectifier state. This temperature-gated rectifier can have substantial implications ranging from autonomous thermal management of heating and cooling systems to efficient thermal energy conversion and storage. Published at *Nano Lett.*, 14, 4867 (2014).

Delafossite Semiconductor Nanocrystals for p-type Dye-sensitized Solar Cells

Institution: Ohio State University
Point of Contact: Yiying Wu
Email: wu@chemistry.ohio-state.edu
Principal Investigator: Yiying Wu
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$174,000 (2014)

PROGRAM SCOPE

A major challenge in developing efficient p-type dye-sensitized solar cells (p-DSCs) is the lack of p-type wide-bandgap semiconductors with good transparency and high hole mobility. Our prior results have clearly shown that CuGaO₂ holds a great promise as the p-type semiconductor in p-DSCs. Therefore, in this renewal project, we will systematically investigate Cu(I)-based p-type delafossite semiconductors including CuAlO₂, CuGaO₂ and CuScO₂. The goal is to understand the basic chemistry and crystallization process in the hydrothermal synthesis of these delafossite nanocrystals, determine their band energies, and measure the charge carrier dynamics at the semiconductor/dye/electrolyte interface. The results will be important not only for dye-sensitized solar cells, but also for other fields such as transparent electronics, organic photovoltaics and photoelectrochemical cells for solar fuels. The use of CuAlO₂, CuGaO₂ and CuScO₂ can overcome the limitations of the commonly used NiO in p-DSCs. (1) These delafossites do not have partially filled 3d orbitals, and thus are more transparent than NiO to the visible light. (2) These delafossites have significantly higher hole mobility than NiO. The top of valence band of CuAlO₂, CuGaO₂ and CuScO₂ is from the mixing of Cu-3d orbitals and O-2p orbitals that reduces the localization of the valence band edge. The high hole mobility in our proposed delafossites should have a profound effect on the kinetics of hole transport and recombination reactions in p-DSCs. The results from this renewal proposal will have an impact to the fundamental materials science of delafossites. The knowledge will establish an understanding of the crystallization of delafossite nanocrystals, and also the physical properties of the delafossite/electrolyte junctions. Moreover, these delafossites have the technologically important applications as the p-type transparent conducting oxides.

FY 2014 HIGHLIGHTS

A major achievement is the successful synthesis of CuGaO₂ nanocrystals based on our established understanding of its crystallization mechanism. This will pave the road for our subsequent research on CuGaO₂-based p-DSCs. We have also synthesized 7 new dye molecules for efficient hole injection in p-DSCs. Another interesting result is the generation of high cathodic photocurrents via sensitizing a degenerate n-type semiconductor: tin-doped indium oxide (ITO). This discovery was counter-intuitive, because dye-sensitized solar cells (DSCs) are majority carrier devices. Conventional wisdom uses n-type semiconductors for n-type DSCs and p-type semiconductors for p-type DSCs. Our dye-sensitized ITO electrode delivers a cathodic photocurrent as high as 5.90 mA cm⁻², which is close to the highest record for p-type DSCs. Ultrafast transient absorption spectroscopy studies indicate that the cathodic photocurrent results from reduction of the photoexcited sensitizer by free electrons in the conduction band of ITO. Our results reveal a new perspective toward the selection of semiconductors for sensitized photocathodes. This novel type of photoelectrode has promising applications in DSCs and solar fuels. Another result is about the concept of "solar battery", which is related to DSCs, but is outside the scope of my proposal. This work describes an interesting photo-assisted charging approach to address the overpotential challenge in Li-O₂ batteries. The novelty is in the use of a redox couple to integrate a dye-

sensitized photoelectrode with the oxygen electrode in a Li-O₂ battery. This is a unique way to utilize the solar energy to compensate the energy cost in the charging process. I am enthusiastic of this work. It shows an elegant example on how to use photoelectrochemical approaches to solve battery challenges, and represents a new direction in battery research.

Enhancement of Magnetoelectric Coupling in Nanoengineered Oxide Films and Heterostructures by Laser MBE

Institution: Temple University

Point of Contact: Xiaoxing Xi

Email: xiaoxing@temple.edu

Principal Investigator: Xiaoxing Xi

Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)

Funding: \$122,215 (2014)

PROGRAM SCOPE

The main focuses of the project are the (BaTiO₃)_n/(CaMnO₃)_n short-period superlattices, which have been predicted to exhibit interface-induced giant magnetoelectric coupling. BaTiO₃ is highly resistant to oxygen octahedral rotations, which suppress the MnO₆ octahedral rotation in CaMnO₃, leading to a ferroelectric ground state whose polarization depends strongly on the magnetic ordering. The enhancement of the magnetoelectric coupling is the strongest for the shortest superlattice period $n = 1$. This mechanism is different from the enhancement of magnetoelectric coupling by strain and charge mediation at oxide interfaces. It represents a new and novel paradigm in the search for strong multiferroic materials. The artificially built layered materials (BaTiO₃)_n/(CaMnO₃)_n superlattices will be grown by laser molecular beam epitaxy (MBE) from separate oxide targets. This approach is different from laser MBE practiced in the most other labs, where compound targets are used to grow films (for example, growing SrTiO₃ films from a SrTiO₃ target). In our research, targets of BaO, TiO₂, CaO, and MnO₂ will be used and ablated alternately to deposit one atomic layer at a time. For example, the basic sequence of the atomic layer deposition for a (BaTiO₃)₁/(CaMnO₃)₁ superlattice will be BaO- TiO₂-CaO- MnO₂, which repeats itself. We have demonstrated that the atomic layer-by-layer mode of the laser MBE growth is superior to the conventional laser MBE in achieving stoichiometry control and more suitable for the synthesis of the short-period superlattices in this project. The success of this project will further establish that laser MBE from separate oxide targets is capable of producing oxide thin films and

heterostructures with equally extraordinary quality as can be achieved by reactive MBE. Various structural, ferroelectric, and magnetic measurements will be performed to detect ferroelectricity, determine the magnetic ordering, and characterize the magnetoelectric coupling in these thin film samples.

FY 2014 HIGHLIGHTS

(1) Based on previous year's results, we have furthered the understanding and control of the atomic layer-by-layer growth by laser MBE from separate oxide targets via RHEED intensity oscillation, which has led to homoepitaxial SrTiO₃ films of better stoichiometry and crystalline perfection. In particular, RHEED intensity oscillations of nonstoichiometric SrTiO₃ layer followed by stoichiometric growth present double peak features, which is a very sensitive method to control the stoichiometric growth. (2) Using this growth technique, we have grown epitaxial LaAlO₃ films with different stoichiometry from La₂O₃ and Al₂O₃ targets on SrTiO₃. We have found that the interfacial layers are conducting for all LaAlO₃ film stoichiometry and the interfacial properties do not change with stoichiometry more than the doping effect, contrary to the published results claiming that Al off-stoichiometry is necessary for the formation of the 2D electron gas. (3) Using this growth technique, we have grown the Ruddlesden-Popper phase of La_{n+1}Ni_nO_{3n+1} with n=4 from La₂O₃ and Ni₂O₃ targets. This phase has not been grown by any other growth technique. The result demonstrates that this growth technique is a powerful tool for growing materials not possible for other growth techniques, important for materials by design. (4) Using this technique, we have grown epitaxial CaMnO₃ films from CaO and MnO₂ targets on different substrate. The electronic structure of the films measured by the polarization dependence x-ray absorption spectroscopy and hard x-ray photoemission spectroscopy shows extraordinary high film quality. The result lays the foundation for the growth of the (BaTiO₃)_n/(CaMnO₃)_n short-period superlattices.

Hetero-Junctions of Boron Nitride and Carbon Nanotubes: Synthesis and Characterization

Institution: Michigan Technical University
Point of Contact: Yoke Khin Yap
Email: ykyap@mtu.edu
Principal Investigator: Yoke Khin Yap
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$333,500 (2014-2016)

PROGRAM SCOPE

Co-axial hetero-junctions of boron nitride nanotubes (BNNTs) and carbon nanotubes (CNTs) are theoretically predicted to have appealing properties that are not available in pure BNNTs and CNTs. Experimental realization of these of BNNTs/CNTs junctions was hindered by the absence of common growth techniques for both types of nanotubes. During the previous funded project, we have obtained a breakthrough on controlled growth of BNNTs on substrates by catalytic chemical vapor deposition (CCVD) technique using Fe, and Ni catalysts. Since we have previously reported on the growth of single- and multi- walled (SW and MW) CNTs by CCVD using the same catalysts, a common route to grow BNNTs and CNTs on substrates is thus obtained. Based on this unique capability, this new research project will synthesize BNNTs/CNTs junctions by CCVD and investigate their unique physical properties. The nature of the project is very challenging, but will lead to cutting-edge sciences. The far reaching goal of this project is to grow desired BNNTs/CNTs junctions with tunable band structures and properties. Isolated and superlattices of these BNNTs/CNTs junctions are expected to be multi-functional, with

unique electronic, photonic, magnetic, and spintronic properties. Thus, BNNTs/CNTs junctions are important nanotubular structures for energy efficient device fabrication and application. Every devices fabricated by using BNNTs/CNTs junctions would be useful for multiple applications at the nanoscale. Finally, this project will also strengthen our current collaborations with multiple Department of Energy's Nanoscale Science Research Centers (NSRCs), including the Center for Nanophase Materials Sciences at Oak Ridge National Laboratory, and the Center for Integrated Nanotechnologies at Sandia National Laboratories and Los Alamos National Laboratory.

FY 2014 HIGHLIGHTS

The project was started on September 1, 2014. One graduate student and one postdoc are working on improving the uniformity of the Au quantum dots on the QDs-BNNTs. Two users proposals have also being submitted to the Center for Nanophase Materials Sciences (CNMS) at Oak Ridge National Laboratory to gain access to some needed facilities.

Tailoring Thermal Radiative Properties with Doped-Silicon Nanowires

Institution: Georgia Institute of Technology
Point of Contact: Zhuomin Zhang
Email: zhuomin.zhang@me.gatech.edu
Principal Investigator: Zhuomin Zhang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$104,980 (2014)

PROGRAM SCOPE

A new kind of anisotropic metamaterial with a hyperbolic dispersion in a broad infrared region is proposed. It is based on aligned doped-silicon nanowire (D-SiNW) arrays, which are relatively easy to fabricate at the wafer scale. D-SiNW-based metamaterials have unique thermal radiative properties, such as broadband omnidirectional absorption whose width and location can be tuned by varying the filling ratio and/or doping level. Furthermore, extremely high figure of merit (FOM) can be achieved in a wide spectral region, suggesting that D-SiNW arrays may be used as a negative refraction material with much less loss than other structured materials, such as layered semiconductor materials. A combined theoretical and experimental investigation will be performed to characterize D-SiNW arrays for tailoring thermal radiative properties. Both the effective medium approximation (EMA) and finite-difference time-domain (FDTD) method will be used to study wave propagation, energy density, and radiation absorption in the inhomogeneous medium. Angle-resolved transmittance and reflectance measurements of fabricated samples will be performed using a Fourier-transform infrared spectrometer with different polarizations at wavelengths from 2 to 20 μm . Near-field thermal radiation between anisotropic materials with hyperbolic dispersions will also be predicted for potential application in energy harvesting. This project aims at realizing D-SiNW-based metamaterials for thermal radiation control as well as for near-field thermal imaging in the mid-infrared. It is well aligned with the PI's long-term goal of providing leadership and expertise in thermal radiation at the nanoscale for energy harvesting and infrared sensing applications. Furthermore, other metamaterials such as multilayered structures, periodic gratings, and graphene will also be investigated for near-field and far-field thermal radiation characteristics and applications.

FY 2014 HIGHLIGHTS

We have shown (Liu *et al.*, 2013, APL_103, 213102) that a vertically aligned carbon nanotubes array can enhance near-field radiation through the hyperbolic modes. A number of different nanostructures containing doped Si are shown to enhance near-field heat transfer over bulk doped-Si, such as doped-Si nanowires (D-SiNWs), doped-Si nanoholes (D-SiNHs), multilayered metamaterials, and D-Si gratings (Liu *et al.*, 2014, IJHMT_73, 389). Recently, we obtain the energy streamlines through two semi-infinite uniaxial anisotropic effective medium structures, separated by a vacuum gap (Bright *et al.*, 2014, Opt. Express_22(S4), A1112). This work offers an estimate of the critical lateral dimension. We have also investigated the validity of the effective medium theory (EMT) in predicting the near-field radiative heat transfer between multilayered metamaterials. Combining the Bloch theory with the cutoff wavevector, the application condition of EMT is presented and verified (Liu *et al.*, 2014, JHT_136, 092703). Graphene has attracted great attention in nanoelectronics, optics, and energy harvesting. We have investigated the near-field radiative heat transfer between graphene-covered corrugated silica based on the exact scattering theory (Liu and Zhang, 2014, APL_104, 251911). Graphene can improve the radiative heat flux between silica gratings by more than an order of magnitude, suggesting possibilities for more efficient thermal management and photon energy harvesting. Furthermore, by combining graphene plasmons and hyperbolic modes, we have demonstrated photon tunneling with near-unity probability across a broad frequency range and large wavevector space (Liu *et al.*, 2014, ACS Photonics_1, 785). It is found that near-field heat transfer coefficient between D-SiNWs can be improved further (by several folds) when covered by a graphene sheet, thanks to the hybridization of graphene plasmons and broadband hyperbolic modes.

DOE National Laboratories

EARLY CAREER: Light-Stimulated Epitaxy of Novel Semiconductor Alloys and Heterostructures

Institution: National Renewable Energy Laboratory
Point of Contact: Bill Tumas
Email: Bill.Tumas@nrel.gov
Principal Investigator: Kirstin Alberi
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The primary objective of this project is to investigate the influence of photons on the growth of semiconductor thin films by molecular beam epitaxy in order to 1) improve our basic understanding of growth mechanisms, 2) selectively stimulate and manipulate processes that lead to atomistic growth control and 3) advance the synthesis and investigation of novel semiconductor alloys and heterostructures. Continuing to push the boundaries of synthesis through the exploration of radically new approaches tailored to deliberately alter or enhance specific growth processes will be a key factor in overcoming longstanding synthesis challenges that pose a barrier to materials research. Light offers the unique ability to modify growth processes through the selective injection of energy into the surface of a growing film and the photogeneration of carriers. Studies specifically focus on exploring the basic mechanisms through which photons affect adatom mobility, bonding, the incorporation of alloying species and interface formation at low growth temperatures. This information is used to tailor the growth of new semiconductor alloys and heterostructures that are difficult to synthesize by traditional

techniques. Once synthesized, the properties of these new materials and heterostructures are explored for use in energy-related applications, such as photovoltaics and solid-state lighting.

FY 2014 HIGHLIGHTS

We have determined several mechanisms by which photons and photogenerated carriers affect growth processes. The influence of light stimulation on adatom migration was probed by in-situ measurements of the layer-by-layer to step flow growth mode transition. Contrary to previous understanding, our measurements showed that the adatom diffusion length in GaAs actually decreases under illumination. Surface morphology measurements with atomic force microscopy (AFM) also show that broadband illumination roughens the surface. We have attributed these changes to the blocking of adatom attachment sites at step edges by photogenerated carriers, which is similar to the reported role of hydrogen in GaAs growth. Additionally, we have shown that photogenerated carriers can be used to tune the Fermi energy during growth and suppress undesired growth processes driven by Fermi level pinning. Movement of the Fermi energy away from the Fermi stabilization energy as well as Fermi level pinning are known to significantly influence dopant incorporation and diffusion, defect formation, surface reconstruction and growth processes governing surface morphology. Our experimental measurements of n and p-type doped GaAs demonstrate that photon irradiation during growth reduces surface segregation and migration of dopants. These results are explained on the basis that splitting of the quasi Fermi levels by the photogeneration of carriers reduces the surface electric field and the formation of defects, which facilitate dopant atom drift and diffusion, respectively. These results suggest that light stimulated epitaxy techniques can be used to improve the growth of highly doped structures with reduced thicknesses. This information will also serve as a guide to the ongoing investigation of light stimulated growth of II-VI semiconductors and heterostructures.

EARLY CAREER: Spatially Resolved Ionic Diffusion and Electrochemical Reactions in Solids

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Nina Balke
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The functionality of energy storage systems, such as Li-ion batteries, is based on and ultimately limited by the rate and localization of ion flows through the device on different length scales ranging from atoms over grains to interfaces. The fundamental gap in understanding ionic transport processes on these length scales strongly hinders the improvement of current and development of future battery technologies. The goal of this proposal is to create, through nanometer-resolution imaging of ionic flows, fundamental understanding of the local mechanisms which define a rechargeable battery. Using Electrochemical Strain Microscopy, which utilizes the intrinsic link between unit cell volume and Li-ion concentration, it is possible to separate and characterize transport processes in the electrodes and across electrode/electrolyte interfaces, allowing us to decipher the single stages of ionic transport through the battery. With this knowledge it will be possible to identify and overcome the bottlenecks which lead to predominant limitations in present battery technology such as low energy storage density or capacity loss during cycling. The success of this proposal will propel ORNL, both directly and through

collaborative teams, into a highly competitive position for new DOE energy research and development centers, as well as EERE and DOE BES programmatic support.

FY 2014 HIGHLIGHTS

Several signal generating mechanisms need to be considered during standard scanning probe based characterization techniques in order to get closer to quantification of localized ionic transport through electrochemical strain microscopy (ESM) measurements. ESM was developed to detect ionic transport with nanometer resolution using strain, generated through ion concentration changes, to explore structure-functionality relationships in Li-ion battery cathodes and anodes. During ESM, the local ion concentration can be changed by applying a bias to the Scanning Probe Microscopy (SPM) tip in contact with the sample and the ionic transport is detected through changes in sample volume based on the Vegard law which correlates ionic concentration and unit cell volume. Due to the nature of this experiment, not only Vegard-type volume changes, but also other electrochemical processes happening in the probed volume can contribute to the measured ESM signal, e.g. the formation of chemical dipoles. Therefore, it is crucial to discuss and explore all phenomena happening under the biased SPM tip. We identified these processes and, based on their dependences on sample and experimental parameters, developed experimental techniques to differentiate between them. This is not only crucial for ESM but for any other type of SPM technique where local electrical biases are applied, e.g. ferroelectric materials. These new experimental measurement concepts were then tested on a variety of material classes. In addition to the standard cathode and anode materials for Li-ion batteries, we also explored the reversibility of Li-ion motion in previously unexplored solid electrolytes. Here, the biased SPM tip can locally extract Li-ions from the electrolyte and form Li-metal on the sample surface. The kinetics and reversibility of this phenomenon were studied. Working on all elements of the battery will give us a better picture of all processes relevant for battery operations.

Light-Matter Interaction Phenomena using Subwavelength Engineering of Material Properties

Institution:	Sandia National Laboratories-Albuquerque
Point of Contact:	Richard Schneider
Email:	rpschne@sandia.gov
Principal Investigator:	Igal Brenner
Sr. Investigator(s):	Ting Luk; Sandia National Laboratories-Albuquerque Michael Sinclair; Sandia National Laboratories-Albuquerque Jean-Jacques Greffet; Institut d'Optique Ronen Rapaport; Hebrew University of Jerusalem
Students:	5 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$950,000 (2014)

PROGRAM SCOPE

The project goal is to obtain a fundamental understanding and control of light-matter interaction through engineering material properties at the subwavelength scale. Our approach involves using both localized and propagating metamaterial photon modes coupled to semiconductor heterostructures. The metamaterials allow tailoring the photonic mode properties, while the semiconductor heterostructures enable the creation of electronic and vibrational transitions with desired characteristics. The ultimate goal is to control the flow of energy between photons, phonons, and electrons in ways that are not possible with natural materials. One thrust will investigate strong coupling of the localized modes of planar metamaterial nanocavities and other plasmonic structures to semiconductor transitions. The

ultra-small volume of the localized resonant “cavity” modes of the metamaterial resonators, along with the ability to tailor the near-field overlap with the adjacent semiconductor structures enable the exploration of strong light–matter coupling in this technologically relevant system. Achieving such coupling could offer new ways to control processes that depend on electron-phonon scattering, create new record optical nonlinear materials or novel emitters at infrared wavelengths, and create condensates of excitons without the use of complex microcavities. A second thrust will explore the coupling of the propagating modes of hyperbolic metamaterials to semiconductor transitions when absorber/emitters are embedded within semiconductor superlattice hyperbolic metamaterials. The hyperbolic isofrequency surfaces of these deep subwavelength metamaterials lead to unusual electromagnetic mode behavior such as broadband enhanced density of propagating states and very large photon momentum. This can profoundly alter light–matter interactions and could be used for the design of advanced absorbers and emitters for energy conversion, lighting applications, and single photon sources.

FY 2014 HIGHLIGHTS

Previous attempts at increasing the strong light-matter coupling between metamaterial and plasmonic nanocavities and different types of emitters or solid-state excitations with a dipole moment, focused mainly on the properties of the two-level system while ignoring the effect of the metamaterial geometry. In this fiscal year, we demonstrated experimentally that the strong light-matter coupling can be described by a simple equivalent circuit model and that the electrostatic capacitance of the single metamaterial nanocavity is the crucial parameter determining the coupling. We made progress in the understanding and use of epsilon-near-zero modes. These modes arise in very thin layers when the permittivity is close to zero and they are characterized by a nearly flat dispersion. We proved that these modes are long-range plasmons for layers much thinner than the skin depth. These modes lie to the right of the light line and are related to the Berreman modes, which lie to the left of the light line. In a different but related work, we used Berreman modes in very thin highly doped semiconductor layers to create narrowband thermal emission, when the samples were heated. We have performed full wave simulation and analytic modeling of semiconductor hyperbolic metamaterials (SHMs), and have compared their performance to metal-based hyperbolic metamaterials. We find that the combination of small layer thicknesses and infrared operating wavelengths allows the SHMs to achieve much larger photon momentum states than are achievable with the metal based systems. This, in turn, should lead to much larger densities of states and much larger emission enhancements. We have also designed and initiated growth of a set of SHMs on which we will fabricate metallic metamaterial resonators and demonstrate strong coupling to the longitudinal resonance of the hyperbolic permittivity.

Characterization of Functional Nanomachines

Institution: Lawrence Berkeley National Laboratory
 Point of Contact: Xiang Zhang
 Email: XZhang4@lbl.gov
 Principal Investigator: Michael Crommie
 Sr. Investigator(s): Alex Zettl; Lawrence Berkeley National Laboratory
 Carlos Bustamante; Lawrence Berkeley National Laboratory

 Steven G. Louie; Lawrence Berkeley National Laboratory
 Gerard Marriott; Lawrence Berkeley National Laboratory
 Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
 Funding: \$911,000 (2014)

PROGRAM SCOPE

The goal of this program is to understand the fundamental principles of nanomachine systems and to apply those principles toward the creation of new nanomachines capable of converting energy into directed mechanical action at the nanoscale. We seek to understand the microscopic mechanisms underlying nanomechanical processes in both synthetic and naturally occurring nanomachines that operate in different dissipative environments.

FY 2014 HIGHLIGHTS

First atomically-resolved imaging of polymerization at a surface via Bergman cyclization has enabled microscopic determination of single-polymer chemical and electronic structure. This has provided insight into a new microscopic coupling mechanism for surface molecules. Infra-red scanning tunneling microscopy (IRSTM) spectra were quantitatively modeled for the first time. This demonstrates that IRSTM is a viable new tool for simultaneously determining atomic-scale molecular structure, intermolecular interactions, and substrate coupling for adsorbed molecules. Single-molecule laser-tweezer methods were used to show that RNA polymerase dynamics conform to a linear Brownian ratchet model. This provides important new understanding of how molecular-machine behavior regulates biological gene expression. A new technique has been developed to fabricate high quality graphene resonators using polymer-free, direct transfer onto carbon grids. Fabry–Perot interference of the resonators was used to determine graphene's intrinsic bending rigidity.

Proximity Effects in Charged Oxide Heterostructures

Institution: Argonne National Laboratory
Point of Contact: Michael Norman

Principal Investigator: Jeffrey A. Eastman
Sr. Investigator(s): Dillon Fong; Argonne National Laboratory
Paul Fuoss; Argonne National Laboratory
Peter Zapol; Argonne National Laboratory
Anand Bhattacharya; Argonne National Laboratory
Brian Stephenson; Argonne National Laboratory
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$1,272,000 (2014)

PROGRAM SCOPE

The mission of the Proximity Effects in Charged Oxide Heterostructures program is to fundamentally understand and thereby control defect behavior in oxide heterostructures. We perform *in situ* synchrotron x-ray studies of thin film synthesis and heterostructure behavior in controlled environments, complemented by first-principles simulations and multiscale computational theory to reveal the effects of interfacial proximity on defect behavior and the resulting electrochemical properties. In recent years, it has become clear that many of the remarkable properties discovered in the field of complex oxide heterostructures may be related to charged defects and their behavior at interfaces. Such phenomena, however, remain poorly understood due to the inherent difficulties in probing defect-interface interactions at the atomic-level and in the environments relevant to defect evolution. We address this problem by growing heterostructures with precise cation ordering and variable oxygen concentrations, enabling the systematic investigation of defect formation and migration

behavior both during synthesis and while processing in different electrochemical environments. Throughout this program, the atomistic results are fed back to computational theory to gain insight into the mechanisms and the electronic and energetic processes taking place during defect structure evolution. Through this combined *in situ* x-ray / computational theory approach, our ultimate goal is to form a knowledge-basis of defect behavior, which will be analyzed for the discovery of descriptors that can enable large-scale predictions of interface-dependent defect transport kinetics and provide new insight for the design and synthesis of materials with tailored, tunable, and multifunctional defect-engineered properties.

FY 2014 HIGHLIGHTS

We grew layered films by oxide MBE, finding that although MBE permits growth with atomic level control, the layers can rearrange themselves dynamically during deposition. This can lead to significant roughening of the growth surface and a general loss of vacancy ordering. These *in situ* x-ray results were obtained using the world's first oxide MBE system on a synchrotron beamline at Sector 33 of the Advanced Photon Source. Results were published in Nature Materials. Through in-situ X-ray studies, we determined the effects of substrate surface polarity on the ferroelectric-to-paraelectric phase transition behavior of PbTiO_3 films grown on a polar surface of DyScO_3 . The electrical boundary conditions imposed by the substrate surface result in significant T_C suppression and different domain structures in films with and without non-polar insulating or conducting intermediate layers. Results were published in Applied Physics Letters. We used an *in situ* x-ray approach to study SrRuO_3 single crystal films, finding that the activity for the oxygen evolution reaction (OER) depends on surface orientation. The Ru cation oxidation state increased during the OER, followed by significant surface roughening. This was the first demonstration of the inverse relationship between activity and stability for oxide systems, and points out the need for new materials that strike the proper balance between activity and stability. Results were published in Nature Communications. We investigated oxygen octahedral tilt transitions and tilt structures in $\text{LaAlO}_3/\text{SrTiO}_3$ heterostructures, finding that the tilt transition temperature for LaAlO_3 was significantly elevated with respect to the bulk and depends on film thickness. These results indicate that most LaAlO_3 films undergo an irreversible tilt transition when cooling from the deposition temperature, with a resulting domain structure and average tilt angle that depends on thickness as well as strain. Results were published in APL Materials.

Atomistic and Mesoscopic Study of Metallic Glasses

PROGRAM SCOPE

The goal of this project is to gain fundamental understanding of the science of metallic liquids and glasses and to develop a theory that is capable of guiding the experimental development of new bulk metallic glasses (BMG) with superior properties. Because of the strongly disordered atomic structure metallic glasses have exceptionally high strength. The recent development of BMG has greatly improved

the potential for application of metallic glasses as a structural material. However, the basic science of metallic glasses at the atomistic level remains poorly developed. As a consequence, the experimental effort to develop new BMG is largely guided by empirical principles and intuition. This difficulty originates from the fact that in the liquids and glasses atoms are strongly correlated in spite of the apparent disorder in the structure, and to describe such a structure we directly face the many-body problem. In this program we seek fundamental understanding of atomistic mechanisms which control the structural and dynamic properties of metallic liquids and glasses through combination of tightly coupled simulation, theory and experiment. To overcome theoretical difficulty we use a novel approach, based upon the concept of fluctuations in the local topology of atomic connectivity network. The computational effort includes classical as well as first-principles calculation molecular dynamics (MD) simulation. Experimental studies include synchrotron x-ray and neutron scattering and nanoscale mechanical testing. Our plan is to create guiding principles of BMG formation and deformation through this study, leading to the development of metallic glasses with superior properties. This will be accomplished by making full use of excellent scientific and technical expertise of the co-PI's and the PI, and outstanding facilities at ORNL and other DOE laboratories, including the Spallation Neutron Source (SNS) and the high-speed computers at ORNL.

FY 2014 HIGHLIGHTS

In FY 2014 we made significant advances in understanding various fundamental aspects of mechanical deformation in metallic glasses. (1) We showed that mechanical deformation in metallic glasses is triggered by a small group of atoms, involving just five atoms on average. This was achieved through the use of the activation-relaxation technique to detect the saddle point in the potential energy landscape. This result represents an important breakthrough because it shatters the myth that some highly collective process is involved in deformation in metallic glasses. (2) We also discovered a structural signature of ductility. Metallic glasses are promising as structural materials because of their extremely high strength, but most of them have small, or no ductility, which severely limits their application. We discovered that the structural response to elastic loading which can be detected by x-ray diffraction is related to ductility. This is a major development, because we now have a clue as to improve ductility. We hope to develop new, more ductile, metallic glasses using this finding as a guide. (3) We succeeded in characterizing the structural heterogeneity of metallic glasses through nanomechanical testing, and in describing the structural heterogeneity in terms of defect strength and distribution. We found that the effective defect density drops significantly with the structural relaxation, and the fracture of metallic glasses changes from a significantly plastic mode to an extremely brittle one. (4) Finally we have calculated the energy landscape of metallic liquids at high temperatures and demonstrated how it can elucidate the properties, such as viscosity and relaxation time. The concept of potential energy landscape (PEL) is a powerful approach, but it is very difficult calculate, or even to visualize, the actual PEL. We proposed the new concept of local energy landscape (LEL) and successfully applied it to high temperature metallic liquids.

Jointly funded by the Chemical Sciences, Geosciences, & Biosciences Division and Materials Sciences and Engineering Division

PROGRAM SCOPE

This research consortium, co-led by the Indian Institute of Science-Bangalore and the National Renewable Energy Laboratory, sets out to create an environment for cooperation and innovation “without borders” to develop and ready emerging and revolutionary solar-electricity technologies toward the long-term success of India’s Jawaharlal Nehru National Solar Energy Mission and the U.S. DOE SunShot Initiative. SERIIUS carries out fundamental and applied research, analysis and assessment, outreach, and workforce development through specific bi-national projects in three research thrusts: (1) Sustainable Photovoltaics (PV) to develop next-generation materials, devices, and advanced manufacturing processes tailored to the needs, environment, and resource availability of India and the US; (2) Multiscale Concentrated Solar Power (CSP) to overcome critical science and engineering challenges for reliable multiscale (including small 25–500 kW) CSP systems; and (3) Solar Energy Integration (SEI) to identify and assess key technical, economic, environmental, and policy barriers, enabling a research agenda for technical readiness in India and of benefit to the U.S. SERIIUS has created a bi-national network for fostering new ideas and collaborations to expedite a sustainable industry. SERIIUS is developing disruptive technologies through foundational research in PV and CSP to address the critical barriers for solar energy development in India that intersect the grand challenges for solar energy in the U.S. SERIIUS is jointly funded under the Joint Clean Energy Research and Development Center (JCERDC) through the U.S. DOE and the Government of India over a 5-year period (starting October 1, 2012). The Consortium is also supported by cost share from its members. The Consortium comprises 32 partners from India and the U.S.; further information on these organizations and specific SERIIUS activities is available on its website: www.SERIIUS.org.

FY 2014 HIGHLIGHTS

Photovoltaic Thrust: • Development of new polymers for dye-sensitized solar cells (DSSC) and organic photovoltaics (OPV) based on starting molecule computational analysis, and initial device development and subsequent testing across the team. • Initial CZTS electrodeposition showed correct phase formation without hydrazine on Willow Glass; nanoparticle-based CIGS resulted in meaningful efficiencies. • The electroluminescence technique was developed as a tool to evaluate heterojunction with intrinsic thin layer (HIT) solar cells. Tests on initial 1-cm² and subsequent 25-cm² samples were accomplished. Initial results demonstrate that this can be an important basic diagnostic for HIT and other solar cells. • Developing a comprehensive database for insolation and reliability vs. climate across

India to provide a basic understanding of resource availability and failure modes in order to produce mitigation strategies for this significant Indian problem. • Developing an understanding of the dust and soiling problems in India and the development of coatings-based mitigation strategies. • New nano-hybrid encapsulation technology gives very low water vapor transmission rate (WVTR). Multiscale Concentrated Solar Power Thrust: • Optimization and engineering models for new scalable systems using CO₂-based Brayton (high temperature) and organic-based Rankine cycles (low temperature) have produced new technology-specific designs that are now under construction. • A new turboexpander is being fabricated and will be evaluated in a new test bed for high-temperature Brayton cycle. • A tubular serpentine receiver was designed; CFD model predicts an efficiency > 74%. • New Earth-abundant high-performance reflector and absorber coatings developed. • New low-cost heliostats have been developed at very low capex and are begin tested. Solar Energy Integration Thrust: • Analysis of policies and techno-economics of grid-connected PV in India Roadmap • Draft Roadmap for Energy Storage for India was developed. • Technology improvement opportunities for PV and CSP thrusts are being defined.

PROGRAM SCOPE

Electronic Material Program (EMAT) discovers and creates semiconductors of novel composition and morphology for energy applications by removing chemical and physical constraints that limit materials performance and growth. The program has three thrust areas: (1) Semiconductor quantum membranes: Spatial confinement, probing, and functionalization; (2) Band structure and interface tuning on command: Engineering band structures in semiconductor alloys, and electronic and structural properties at interfaces; (3) Control of phase transitions at the nanoscale. Common to these research themes is a synthetic strategy that allows us to control structure and phase transitions at the nanoscale. In the case of quantum membranes, our ability to make and control free-standing 2-D semiconductors enables study of the interplay of quantum confinement and surface/interface properties with electronic structure and carrier transport at a fundamental level. Our control of materials composition via highly non-equilibrium synthesis techniques allows us to tune band structures and interface properties on command. By exploiting new insights in the nanoscale control of phase transitions, we can synthesize new functional structures.

FY 2014 HIGHLIGHTS

We have developed a new growth mode for semiconductor thin films using the vapor-liquid-solid (VLS) technique (Scientific Reports, 2013). As a proof of concept, InP thin films are grown on non-epitaxial substrates (e.g., metal foils or amorphous glass) using the thin-film VLS process with an ultralarge grain size of up to ~ 1 mm and optoelectronic properties (including luminescence yield) approaching those of epitaxially grown layers. We also developed the nucleation and growth theory for this new mode of material synthesis. The work presents a promising route for low-cost growth of high quality III-V semiconductors for PV applications and beyond. In another project, we made the first experimental observation of spatially indirect transitions in heterobilayer transition metal dichalcogenides. Understanding where excitons are generated and recombined in heterobilayers presents the basis for any work done in this field. Our work clearly presents an important advance in this regard (PNAS, 2014). In addition, we reported the first experimental demonstration of indirect to direct band gap transition in 2D semiconductor multilayers using WSe_2 as a material platform (Nano Letters, 2014). This presents an important finding since the multilayers of most transition metal dichalcogenides are indirect band gap, limiting their application for optoelectronic devices. The research output of the program has resulted in over 30 journal publications since last year (including PNAS, Nature Materials, Nature Communications, Scientific Reports, PRB, Nano Letters), 11 of which are co-authored by multiple EMAT PIs.

Superconducting Materials

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Qiang Li
Sr. Investigator(s): Weidong Si; Brookhaven National Laboratory
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$692,000 (2014)

PROGRAM SCOPE

This program studies basic relationships between nanostructures and the macroscopic properties of superconductors. Both basic understanding and understanding of materials aspects for practical use are sought. Emphasis is on raising the critical temperature, T_c , and the critical current density, J_c , because they determine the limits to energy applications. Research activities focus on the responses of superconductivity and critical current to chemical, structural, and defect tuning in two classes of superconductors: (1) iron chalcogenides, and (2) cuprates. The key to increasing J_c is in controlling the pinning of magnetic vortices by defects in superconductors. In this program, defects are introduced precisely by controlled growth and ion irradiation. The goal is to create a landscape of tailored defects of desirable morphology and dimensions in superconductors that can produce the most effective vortex pinning in a broad range of temperatures and magnetic fields. Majority of materials are synthesized in thin film forms using an advanced pulsed laser deposition system capable of atomic layer-by-layer growth, and subsequently characterized via a range of techniques including transport, magneto-optical imaging, electron and optical spectroscopy, transmission electron microscopy, scanning tunneling microscopy, among others. We seek to understand and control the transport properties of superconducting materials by tackling a few key science issues, from the macroscopic to the atomic levels. Progress in the understanding of these two classes of materials could provide new strategies for enhancing T_c and designing new superconductors capable of enduring high magnetic fields and carrying high currents.

FY 2014 HIGHLIGHTS

We found post-annealing of a polar (001) Ceria surface can produce stable surface reconstructions, which have markedly different surface activities for the growth of iron-chalcogenide and cuprate thin films on CeO₂ buffered substrates. YBa₂Cu₃O₇ film grown on (001) CeO₂ surface having the longest, fourfold period, reconstruction exhibits a twofold increase in critical current density over surfaces with shorter period reconstructions. These findings opened a new avenue for catalysis mediated solid state synthesis of new complex materials. Iron chalcogenide (FeSe_{0.5}Te_{0.5}) thin films made with CeO₂ buffer are found to have both record high critical temperature and critical current density J_c under high magnetic field. Through proton irradiation, we achieved several fold enhancement of J_c . Furthermore, the films made on CeO₂ buffered bi-axially aligned flexible metal substrates have similar high performance to those made on CeO₂ buffered single crystalline. These studies demonstrated the potential of iron-based superconductors for energy applications. Grain boundary junctions were fabricated in the epitaxial FeSe_{0.5}Te_{0.5} thin films on [001] tilt SrTiO₃ bi-crystal substrates. Critical current densities across the junctions with different mis-orientation angles were measured at magnetic fields up to 30 T. A critical mis-orientation angle of a 9 degree was identified that separates the strong coupling region from the weak link region. The critical current densities across the grain boundary with a 24 degree mis-orientation angle can be modulated by the magnetic field, indicating a Josephson Effect that may be used for superconducting electronic applications where grain boundary Josephson junctions are required.

Field-Structured Composites

Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$115,000 (2014)

PROGRAM SCOPE

This project is focused on creating vorticity in dilute particle suspensions by subjecting them to multiaxial magnetic or electric fields. These induce flows can create highly effective heat and mass transfer, fluid mixing, and biomimetic fluid dynamics.

FY 2014 HIGHLIGHTS

We have discovered two countably infinite classes of fields that can induce vorticity: symmetry-breaking rational fields and rational triads. Symmetry-breaking rational fields are comprised of two orthogonal field components whose frequencies form a ratio that is rational and a third mutually orthogonal field component that is dc. Using number theory and set theory we have developed an analytical theory that is able to predict the direction of the fluid vorticity for any given frequency ratio, as well as the dependence of this vorticity on phase and sign of the dc field. A similar theory has been developed for rational triads, but in this case all three orthogonal field components are alternating. We have used these complex fields to create a variety of striking biomimetic dynamics. All of these results are published in Soft Matter, resulting in two invited journal covers.

Electronic Processes in Solid State Organic Electronic Materials

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor
Email: ttaylor@lanl.gov
Principal Investigator: Richard Martin
Sr. Investigator(s): Enrique Batista; Los Alamos National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$221,000 (2014)

PROGRAM SCOPE

The central goal of this program is to advance our understanding of the fundamental physical principles controlling the behavior of organic electronic devices, and how these principles determine the performance in known and newly proposed devices. We focus our attention on the following fundamental questions: (i) How does molecular structure control the morphology, and charge and energy transport properties of condensed phases of organic materials, particularly at organic/inorganic and organic/organic interfaces? (ii) How are the electronic and optical properties of the interfaces affected by the presence of appropriately tailored molecules? (iii) In what way does this control the subsequent fundamental properties such as exciton dissociation, exciplex recombination, charge transport and energy transport at the interface?

FY 2014 HIGHLIGHTS

In the final year of this project we wrapped up our investigations of charge transfer effects at organic/organic and organic/inorganic interfaces in order to bring the program to a close. Our efforts addressed a number of issues, ranging from the 'Effect of Packing on Formation of Deep Carrier Traps in Amorphous Conjugated Polymers' (Kilina, *et al.*) to the formulation of "Interface Design Principles for High Efficiency Organic Semiconductor Devices" (Nie, *et al.*) Significant progress was also made in measuring and modeling the effect of a magnetic field on the electroluminescence of organic light emitting devices (Crooker, Liu, *et al.*).

Electronic and Optical Processes in Novel Semiconductors for Energy Applications

Institution: National Renewable Energy Laboratory

Principal Investigator: Angelo Mascarenhas
Sr. Investigator(s): Brian Fluegel; National Renewable Energy Laboratory
Kirstin Alberi; National Renewable Energy Laboratory
Eugene Fitzgerald; Massachusetts Institute of Technology
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$1,230,000 (2014)

PROGRAM SCOPE

Advanced energy technologies require high-performance materials, which in photovoltaics (PV) translates to new semiconductor materials to efficiently absorb sunlight, and in solid-state lighting (SSL), to new semiconductor alloys for direct conversion of electricity to white light. A goal of this project is

fundamental materials research for the realization of semiconductors that transcend the existing limitations that constrain present PV and SSL technologies. It specifically addresses the current unavailability of efficient high bandgap (2.1 eV) and low bandgap (1 eV) absorbers for PV, and efficient amber emitters for SSL, via technologies based on GaAs substrates. The key to transcending the present limitations is understanding and controlling fundamental electronic and optical processes in semiconductor alloys, which is another goal of this project. Towards this, the project will focus on understanding the phenomena of spontaneous ordering in high bandgap lattice-mismatched AlInP, and the abnormal electronic structure and properties of isoelectronic dopants N and Bi in GaAs. Additionally, it will address recent observations of new excitations in photogenerated bipolar plasmon gasses, so as to achieve an understanding of collective phenomena that could enable semiconductors with novel, useful properties. Through collaborative efforts, this project utilizes the high-magnetic field facility at the NHFML (Los Alamos) and growth facilities at the CINT (Sandia labs).

FY 2014 HIGHLIGHTS

(1) We have successfully grown high quality epitaxial films of the dilute alloy dilute GaAsBi on GaAs substrates using a new MBE system. This is key to demonstrating the phenomenon of isoelectronic codoping of Bi and N into GaAs with the goal of regularizing the abnormal properties of the dilute alloy. Success in meeting this goal will have a profound impact in enabling the design of high efficiency multijunction solar cells grown lattice-matched to GaAs substrates in contrast to current technologies that are based on lattice-mismatched and lift-off approaches that are significantly more complex and expensive. (2) For almost four decades there has been an ambiguity concerning the precise value for the direct-to-indirect crossover in AlInP and AlGaAs with different values reported in various handbooks. Since this is of critical importance in the design of solar cell and LEDs, we precisely determined this crossover in both AlInP and AlGaAs semiconductor alloys using a very novel approach. (3) A new technique was developed to study long-range exciton diffusion in semiconductor material and applied to polycrystalline CdTe as well as single crystal CdTe which are at the forefront of current photovoltaic technologies, to show how carrier transport in these materials is influenced by defects and grain boundaries. (4) Results using femtosecond laser pulses to generate coherent acoustic phonons in the dilute Bismide alloy GaAsBi suggested that the incorporation of Bi in GaAs causes an enhancement of the hydrostatic deformation potential because of the resonant state in the valence band due to isolated Bi impurities. (5) A magnetically driven indirect-to-indirect crossover in AlGaAs was demonstrated using the NHMFL facilities at LANL. (6) Using the NHMFL facilities at LANL the effect of alloy statistical fluctuations on electronic properties of AlGaAs semiconductor alloys were investigated and its role in the direct-indirect crossover elucidated.

Complex Hydrides - A New Frontier for Future Energy Applications

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov
Principal Investigator: Vitalij K. Pecharsky
Sr. Investigator(s): L. Scott Chumbley; Ames Laboratory
Duane Johnson; Ames Laboratory
Marek Pruski; Ames Laboratory
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$528,000 (2014)

PROGRAM SCOPE

Every energy-related application of hydrogen (H₂) requires safe and efficient storage. H₂ can be stored as a compressed gas, a cryogenic liquid, or in an H-rich solid. The first two approaches require substantial energy for compression or liquefaction, and, therefore, entail multiple containment, safety, and economical issues. Conversely, H-rich solids are believed to be the best medium to store high-purity H₂ required for fuel cells. Solid hydrides ensure high volumetric density of the fuel because in many of them the volumetric density of H₂ at ambient conditions is nearly twice that of a cryogenic liquid at 20 K, reaching 120 g H₂/l. The specific objectives of this FWP are to address issues that will advance basic science of complex hydrides and open up possibilities for their future use by drawing on the experience and expertise of principal investigators in materials science, physics and chemistry of complex hydrides, X-ray diffraction (XRD), high-resolution solid-state nuclear magnetic resonance (NMR), electron microscopy, and first-principles theory and modeling.

FY 2014 HIGHLIGHTS

A successful strategy for the solvent-free, room temperature mechanochemical synthesis of alane (AlH₃) via a solid state metathesis reaction of LiH and AlCl₃ has been developed. Alane, one of the forefront materials for practical solid-state hydrogen storage, has a hydrogen capacity of 10% by weight and gives up hydrogen in a single step at the temperature that is close to the operating temperature of hydrogen fuel cells. Prior to this work, realizing the enormous potential of alane has been frustrated by the lack of a straightforward method for its synthesis. The novelty of the process is the addition of AlCl₃ to the reaction mixture in three steps, hence completely suppressing parasitic side reactions that lead to a nearly complete loss of hydrogen from the system. By adding AlCl₃ to LiH in three steps and applying gas pressure, quantitative yield of AlH₃ – an important energetic material – has been achieved. X-ray diffraction, solid state NMR, and temperature programmed desorption analyses importantly established the mechanism of mechanochemical transformation: $3\text{LiH} + \text{AlCl}_3 \rightarrow 3\text{LiCl} + \text{AlH}_3$. This quick and efficient production method meets DOE requirements for hydrogen storage applications pending development of an economical large-scale synthesis process.

Extraordinary Responsive Magnetic Rare-Earth Materials

Institution:	Ames Laboratory
Point of Contact:	Duane Johnson
Email:	ddj@ameslab.gov
Principal Investigator:	Vitalij K. Pecharsky
Sr. Investigator(s):	L. Scott Chumbley; Ames Laboratory Karl Gschneidner; Ames Laboratory
Students:	1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$1,125,000 (2014)

PROGRAM SCOPE

Responsive systems, where a small change of an extrinsic thermodynamic variable, such as temperature, pressure, or magnetic field, triggers an intrinsic phase change, have both fundamental and technological significance. Alloys and compounds that exhibit strong field-, temperature-, or pressure-controlled reactions, tunable by chemistry, crystallography, and processing, provide broad benefits to energy-related applications, such as sensors and smart materials, and materials for energy conversion, generation, and utilization devices. Responsive materials, therefore, have the potential to make

transformative changes that can be used to help meet our Nation's future energy demands. Conventional (and strong) stimuli are temperature and pressure, but a magnetic field is weak and often an underappreciated trigger, whose role in initiating strong changes in solids is much less understood. Knowledge of the mechanisms delivering minor-stimulus driven phase change that is then followed by a major perturbation of properties is crucial for guiding the discovery of new materials, and is the focus of this research. Our goal is to uncover the underlying electronic, atomic and microscopic interactions that result in an extraordinarily strong coupling of the magnetic and crystal lattices in chosen model systems representing rare earth-based intermetallic materials. Development and validation of phenomenological models of transformations that range from magneto-volume to magnetic-martensitic is one of our prime objectives.

FY 2014 HIGHLIGHTS

Combining a light and a heavy lanthanide leads to unique magnetism in a single material and in FY 2014 an unusual coexistence of ferro- and ferrimagnetism, metamagnetism, Griffith phase, and large exchange bias has been discovered in $\text{Pr}_{0.6}\text{Er}_{0.4}\text{Al}_2$. The material undergoes a trivial ferrimagnetism to paramagnetism transition in a zero magnetic field, but it exhibits multiple functionalities in magnetic fields greater than 40 kOe. Integrated experimental and theoretical study indicates that the underlying physics results from opposite signs of first and second nearest neighbor interactions, crystal field splitting, and magnetic instability related to effectively spherical average 4f charge density distribution. Additionally, the complex magnetic structure of Gd_5Ge_3 has been investigated by neutron powder diffraction down to 3.6 K. The primary antiferromagnetic ordering occurs at 82 K and produces a magnetic cell that is tripled with respect to the underlying orthorhombic crystal cell. The propagation vector is $k_1 = [0\ 0\ 1/3]$. At 74 K, the magnetic order becomes "anti-C" with a propagation vector $k_2 = [1\ 0\ 0]$. A third change in the magnetic order occurs at 40 K, and the new magnetic structure is essentially the "anti-C" structure but with the addition of a tripled magnetic component corresponding to a propagation vector $k_3 = [1/3\ 0\ 0]$.

Nanostructured Materials for Thermoelectric Energy Conversion

Institution:	Lawrence Berkeley National Laboratory
Point of Contact:	Xiang Zhang
Email:	XZhang4@lbl.gov
Principal Investigator:	Rachel Segalman
Sr. Investigator(s):	Jeff Urban; Lawrence Berkeley National Laboratory Joel Moore; Lawrence Berkeley National Laboratory Ramamoorthy Ramesh; Lawrence Berkeley National Laboratory Peidong Yang; Lawrence Berkeley National Laboratory Chris Dames; Lawrence Berkeley National Laboratory
Students:	5 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding:	\$1,406,000 (2014)

PROGRAM SCOPE

Investigation of the basic science of thermoelectricity and phonon transport, entailing the design of new nanostructured materials in order to gain fundamental understanding of how thermopower, electrical conductivity, and thermal conductivity can be manipulated independently so that the thermoelectric figure of merit can be improved. This program investigates several classes of novel materials ranging

from polymer hybrids to oxides, coupled with a strong theoretical component to guide understanding of the fundamental limits of these properties.

FY 2014 HIGHLIGHTS

In this period we have significantly advanced our understanding and control of transport in inorganic-organic hybrid materials. We have demonstrated a fundamentally new methodology to atomically resurface Te nanowires and band convert them from p-type to n-type materials, enabling integration into monomaterial modules. We have furthered our understanding of heat transport in silicon nanostructures by showing, for the first time, ballistic phonon transport in holy silicon nanostructures and providing new understanding of the dimensional criteria for crossover from ballistic to diffusive transport. Moreover, in superlattices, we directly observed the crossover from quantum mechanically coherent phonon transport to incoherent diffusive transport in superlattice materials. In the final period, we will further the coherent phonon work, extending it to silicon nanostructures as well. And we will also advance the promising work in band-conversion nanomaterials for thermoelectrics, pursuing the inverse behavior of n-type to p-type control. Controlling this class of physics in nanomaterials provides a fundamentally new handle to enhance the scalability and performance of nanoscale thermoelectrics.

Metamaterials

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov
Principal Investigator: Costas Soukoulis
Sr. Investigator(s): Thomas Koschny; Ames Laboratory
Jigang Wang; Ames Laboratory
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$398,000 (2014)

PROGRAM SCOPE

Many of the technologies that underpin our economy and enable our standard of living depend on advanced materials. Therefore, the engine for progress in many scientific disciplines is the discovery and understanding of new materials. Metamaterials are novel artificial materials that enable the realization of innovative properties unattainable in naturally existing materials. This research project will explore the theoretical understanding, analysis, development, fabrication, and experimental characterization of metamaterials, and investigate their feasibility for applications. In view of the complexity of electromagnetic interactions in metamaterials, state-of-the-art computational techniques to understand these materials, and collaboration with experimentalists to fabricate and characterize them, are essential. Finding and understanding mechanisms that minimize loss and increasing the operating frequency will be critical for future applications, such as solar energy harvesting and biomedical/terahertz imaging. We will develop new 3D nanofabrication techniques such as direct laser writing and experimentally realize dynamic and tunable metamaterials employing nonlinear and gain materials. Finally, we will characterize the physical properties of metamaterials and develop unique optical characterization techniques.

FY 2014 HIGHLIGHTS

We experimentally demonstrated broadband THz generation from resonant metallic metamaterials. A 40nm thin resonant metasurface can generate a non-linear response and THz generation efficiency that rivals millimeter thick standard non-linear crystals while completely eliminating the phase-matching problem. We developed patentable metamaterials for dispersion management, combining slow light and low absorption in matched, asymmetrically coupled interacting resonator metamaterials. This allows for tunable and very compact dispersion compensation devices to be developed, e.g. for use in fiber optical communication. We simulated and experimentally demonstrated diffractive photo-imprint materials on GaAs surfaces, which can be used for spatial and temporal THz pulse modulation. We analyzed the achievable surface conductivities in photo-excited GaAs surfaces and showed that they can be as good or better conductors than graphene while being similarly tunable. Moreover, we investigated the suitability of graphene for THz application. Because in current literature there is a significant gap between theoretical assumptions and experimental data on graphene, we demonstrate a simple set of figures of merit to compare graphene performance and direct optimization. We developed a new approach to low-loss resonators for metamaterials that does not suffer from the high dissipative losses metals encounter at optical frequencies. This concept is based on dark resonant bound states in dielectric structures or inclusions that are coupled to the propagating electromagnetic field by small, nonresonant metallic or dielectric scatterers. Finally, resonant magnetic permeability and negative index of refraction, n , from a single metallic film patterned as the Babinet complement of an electric quadrupole resonance was demonstrated numerically and the designs will be used to fabricate $n < 0$ at GHz and THz.

Synthesis and Characterization of Nanomaterial Heterostructures and Assemblies

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson

Robert Konik; Brookhaven National Laboratory
Yimei Zhu; Brookhaven National Laboratory
Matthew Sfeir; Brookhaven National Laboratory
Joerg Appenzeller; Purdue University
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$729,000 (2014)

PROGRAM SCOPE

The ability to synthesize, functionalize, and purify nanomaterials and to understand their transport, optical and mechanical properties lies at the forefront of current materials science research. As shown in the DOE report on Basic Research Needs for Solar Energy Utilization, nanostructured materials offer several potential advantages for solar energy conversion by providing relatively high electron and hole transport efficiencies, excitation multiplication possibilities, high surface-to-volume ratios, and short electron-hole diffusion lengths to junctions. However, the role of nanoscale heterojunctions in promoting exciton dissociation and charge separation is not understood. It is expected that junctions between low dimensional materials will behave differently as compared with bulk junctions. We will address the important question of the efficiency of charge separation versus recombination or trapping in a prototype heterogeneous nanomaterial systems: 0d-1d nanomaterial hybrids. We also expect to

develop a fundamental emphasis on synthesizing and understanding more complex nanoscale materials, including metallic heterostructures, of significance to the solar initiative. We have the ability to synthesize high quality samples and to study the properties and structure (both electronic and physical) of individual nanomaterial samples, thus eliminating the uncertainties in ensemble averaging over many structures. Working with our theoretical collaborators, these studies will clarify the potential of nanoscale heterojunctions for charge separation in solar electric generation.

FY 2014 HIGHLIGHTS

(1) We have synthesized and structurally characterized novel semiconducting nanoscale composite heterostructures composed of zero-dimensional (0D) CdSe nanocrystals coupled with both one- and three-dimensional (1D and 3D) rare earth metal-doped lanthanum metal phosphate materials. Subsequent optical characterization has demonstrated a clear dependence of the intrinsic charge and energy transfer processes in these systems on both (i) morphology and (ii) the presence of dopants. Our results show that our 1D and 3D heterostructures evince both photoluminescent (PL) quenching and a shorter average lifetime of CdSe quantum dots (QDs) as compared with unbound CdSe QDs. Optical heterostructure data are explained in terms of the energy level alignments of the constituent QDs and phosphates. *RSC Advances*, v.4, 34963 (2014). (2) Double-walled carbon nanotube (DWNT) - CdSe heterostructures with the individual nanoscale building blocks linked together by 4-aminothiophenol (4-ATP) have been successfully synthesized using two different and complementary routes, i.e. covalent attachment and pi-pi stacking. In general, heterostructures generated by non-covalent pi-pi stacking interactions evinced not only higher QD coverage density but also possibly more efficient charge transfer behavior as compared with their counterparts produced using covalent linker-mediated protocols. *Dalton Transactions*, v.43, 7480 (2014). (3) We have reported on the synthesis, structural characterization, and intrinsic charge transfer processes associated with novel luminescent 0-D CdSe nanocrystal – 1-D cerium phosphate: Tb nanowire composite heterostructures. Our composite heterostructures evinced both PL quenching and a shorter average lifetime as compared with unbound CdSe QDs and cerium phosphate: Tb nanowires. We propose that a photo-induced 0D-1D charge transfer process between CdSe and cerium phosphate: Tb accounts for the observed PL quenching and shorter lifetimes. *J. Phys. Chem. C*, v.118, 5671 (2014).

Sub-Wavelength Metamaterial Physics and Applications

Funding: \$630,000 (2014)

PROGRAM SCOPE

This program explores a new class of photonic materials, metamaterials, by designing artificial atoms and molecules and their interactions. Our research investigates the novel physics of metamaterials to uncover unprecedented materials properties beyond that of natural materials.

FY 2014 HIGHLIGHTS

We have studied the unusual optoelectronic properties of single atomic layers of transition metal dichalcogenide (TMDC) materials, the two-dimensional semiconductors that hold great promise for nanoelectronic and photonic applications. Using two-photon excitation spectroscopy, we probed monolayers of tungsten disulfide, one of the most promising of 2D materials, and found evidence for the existence of excitonic dark states - energy states in which single photons can be neither absorbed nor emitted. These excitons were predicted from *ab initio* calculations to have an unusual energy sequence, plus excitonic binding energy and bandgaps that are far larger than was previously suspected for 2D TMDC materials. The discovery of very large excitonic binding energy and bandgaps and its nonhydrogenic nature in 2D semiconductor materials is important not only for understanding the unprecedented light-matter interaction arising from strong many-body effect, but also for electronic and optoelectronic applications, such as ultra-compact LEDs, sensors and transistors.

Elucidation of Hydride Interaction Mechanisms with Carbon Nanostructures and the Formation of Novel Nanocomposites

Institution: Savannah River National Laboratory

Sr. Investigator(s): Joseph Teprovich; Savannah River National Laboratory
Aaron Washington; Savannah River National Laboratory
Jay Gaillard; Savannah River National Laboratory
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$642,000 (2014)

PROGRAM SCOPE

This program continues to support the Office of Basic Energy Sciences (BES) mission through the development of a basic understanding of the formation and the physicochemical properties of carbon nanostructures, formed by the interaction of doped carbon nanomaterials with hydrides and/or hydrogen gas. For many years extensive work has been conducted on hydrogen interaction with metals and alloys forming hydrides. The research work on metal hydrides involved significant number of studies and characterization efforts, where chemical, electronic, optical and magnetic properties were determined. Our work continues to focus on the unique class of materials, metal-doped carbon nanostructure and their interaction with hydrogen. Our work will continue to focus on understanding the formation of these materials and on investigating their chemical, electronic, optical and magnetic properties when reacted with hydrogen. Previous work in our group through BES programs has led to advances in control over a material's properties at the electronic, molecular, and atomic level, which serve as the foundation of new energy technologies and can support other aspects of DOE missions. Our group has observed related properties in the materials such as hydrogen storage and luminescence with potential applications in clean energy and energy storage. However, developing customizable functional materials requires relating the microstructure of the materials to their physical properties. Our research activities will be aimed at developing and characterizing a novel class of hydride materials based on metal-carbon nanostructures. The current work will investigate different carbon materials utilizing their structure as building blocks for achieving unique properties based on zero, one and two dimension (0D, 1D, 2D) structures such as fullerenes, carbon nanotubes and graphene respectively.

FY 2014 HIGHLIGHTS

Theoretical calculations (Prof. Jena, VCU) reveal that a new class of highly electronegative species can be created when a central metal atom is surrounded by superhalogen moieties. Building on this knowledge we were able to synthesize and characterize a stable hyperhalogen salt, $K[Al(BH_4)_4]$, whose anion, $Al(BH_4)_4^-$, has an extremely high electron affinity. Unlike the few hypersalts synthesized so far, this new salt is stable at temperatures of up to 154°C. Besides providing a new functional material, the work validates the use of computational studies for rational design of new compounds based on superhalogens and hyperhalogens. Building on our previous study of ionic mobility in a $LiBH_4-C_{60}$ system, a series of electrochemical measurements were performed to quantify the lithium ionic mobility in the material under various conditions. This study also demonstrated that the material can be used as a solid electrolyte in an all solid-state lithium ion battery. Theoretical calculations by Prof. Jena's group indicated that the $Li+BH_4^-$ bonding is perturbed in the presence of C_{60} resulting in a highly mobile Li ion due to the $C_{60}-BH_4^-$ interaction. This suggests a nanoionic mechanism is responsible for the enhanced Li ion mobility due to the formation of new interfaces at the nanoscale favoring the production of charge carriers. Further Laser-Desorption/Ionization Time-of-Flight Mass Spectrometry (LDI-TOF-MS) analysis of a sodium intercalated fullerene (Na_xC_{60}) in the hydrogenated state provided the first spectroscopic evidence for the formation of $C_{60}H_{60}$ among other highly hydrogenated fullerenes ($C_{60}H_{>36}$). This finding was also confirmed through deuteration of the same material to form $C_{60}D_{60}$. Current efforts in this system are focusing on the isolation of the $C_{60}H_{60}$ from the other fullerenes for further analysis and characterization. Our current work is aimed at understanding how hydrogen interaction with C_{60} and other carbon nanomaterials can potentially lend itself to other energy storage systems and energy conversion devices.

Synthesis and Processing Science

Institutions Receiving Grants

EARLY CAREER: Templated Bottom-Up Synthesis of Semiconducting and Nanostructured Graphene Materials

Institution: Wisconsin-Madison, University of
Point of Contact: Michael Arnold
Email: msarnold@wisc.edu
Principal Investigator: Michael Arnold
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of this project is to develop a fundamental understanding of how nanostructured graphene materials can be rationally synthesized from the bottom-up with atomic precision and exceptional properties. The research will focus on studying the nucleation and kinetics of graphene growth during chemical vapor deposition (CVD) on catalyst substrates in confined patterns and channels, controlling the crystallinity of the graphene materials, and learning the mechanisms that determine atomic ordering at their edges. The understanding that is gained will result in novel high-performance materials that could impact a number of energy technologies of national importance including low-energy semiconductor electronics, the efficient generation of electricity from solar and infrared light, and the high-density storage of energy in batteries.

FY 2014 HIGHLIGHTS

(1) We succeeded in understanding the effects of catalyst crystallography, precursor flux, and growth rate on graphene CVD at low temperature (T). Understanding growth at low T is important for improving the fidelity of nanostructured graphene that is grown via the process of barrier-guided CVD that we developed and studied in previous support periods. We learned that graphene is grown more efficiently on Cu(111) than on other low-index Cu facets. Through control over the precursor flux and growth rate, we successfully synthesized continuous, high-quality monolayer graphene films at 750 °C, which is 125 °C lower than previous reports using CH₄ as a precursor and Cu as the catalyst and ~250 to 325 °C lower than the typical T used in literature to grow graphene via CVD. (2) We studied and developed a novel method to thermally anneal out etch-induced disorder from the edges of top-down patterned graphene nanostructures. In FY 2013, we identified a hydrogen concentration dependent critical methane concentration (CMC) in which the net growth rate of graphene during atmospheric pressure graphene CVD on Cu is zero, which occurs when intermediate CH hydrocarbons attach to graphene edges at the same rate as graphene etches. In FY 2014, we succeeded in converting disordered edges of graphene nanostructures into relatively smooth zigzag edges via annealing on a Cu(111) substrate at the CMC. This work is important because now graphene nanostructures with smooth zigzag edges can be achieved using any conventional top-down subtractive lithography. (3) In preliminary data, we have discovered how to directly grow graphene nanoribbons that are extremely narrow (< 10 nm) and that have smooth armchair edges, directly by CVD. Remarkably, the ribbons are self-defining and grow from the bottom-

up without any lithographic template, and they align themselves. This is a breakthrough in nanoribbon synthesis that will be studied further in FY 2015.

Studies of Surface Reaction and Nucleation Mechanisms in Atomic Layer Deposition

Institution: Stanford University
Point of Contact: Stacey Bent
Email: bent@stanford.edu
Principal Investigator: Stacey Bent
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

Atomic layer deposition (ALD) is a method for depositing thin films of numerous semiconducting, insulating and metallic materials using an alternating series of self-limiting reactions between gas phase precursors and the substrate. ALD is proving to be an enabling technique for creating the innovative nanostructured materials needed for future applications, including those in solar energy and photoelectrocatalysis. The aim of this project is to perform both experimental and theoretical studies to uncover surface reaction and nucleation mechanisms active during ALD. A combination of *in situ*, *ex situ*, and *in vacuo* X-ray photoelectron spectroscopy, infrared spectroscopy, synchrotron radiation photoelectron spectroscopy, and synchrotron radiation X-ray diffraction studies are employed, together with complementary density functional theory calculations and nucleation modeling. The research focuses on representative ALD systems for the deposition of two categories of material: binary and ternary metal oxides, such as zinc tin oxide, and noble metals, such as Pt and Ru. These materials are chosen not only for their technological importance to the energy area, including their useful optoelectronic or catalytic properties, but also because they serve as prototypical systems that allow exploration into fundamental question about ALD. The mechanistic details obtained from these studies can be used to guide and inform future precursor and process development. The work is expected to lead to new insights into ALD processes. Overall, the main objectives of this study are to develop an improved understanding of the chemical reactions driving both nucleation and steady state growth in ALD, and to provide the scientific foundation required for the ultimate design and synthesis of new materials for applications in energy, electronics, and catalysis.

FY 2014 HIGHLIGHTS

We carried out studies to advance the understanding of surface reaction and nucleation mechanisms in atomic layer deposition (ALD) with a focus on two important categories of ALD materials: metals and metal oxides. We completed and tested a portable reactor for *in situ* ALD studies. The chamber design allows it to be incorporated within a rotating diffractometer and permits use for both x-ray scattering and diffraction studies. In metal ALD, we investigated nucleation during Pt ALD on graphene. We demonstrated selective ALD of Pt at the line defects of graphene, notably grain boundaries, due to the enhanced chemical reactivity of these defects. We investigated the effect of a more reactive counter reactant, i.e. ozone, on nucleation and growth during Pt ALD on silicon dioxide. The growth rate using ozone is higher than that using either air or oxygen counter reactants. We performed *in situ* and *ex situ* thin film diffraction and scattering studies of Pt ALD at the Stanford Synchrotron Radiation Lightsource (SSRL). We tracked Pt ALD growth from initial island nucleation, to island growth, coalescence, and film formation. We showed that the in-plane strain of the Pt lattice changes from compressive strain to

tensile strain when the individual islands coalesce into a continuous film. The growth of zinc tin oxide (ZTO) was studied as a model system for ALD of ternary metal oxides, using alternating growth of tin oxide and zinc oxide. We showed that the ZTO growth rate is strongly reduced as compared to the growth rates of the binaries, due to a significant reduction in surface reaction site density during the tin oxide cycle, which may be a consequence of the different numbers of ligands on the two precursors. The correlation between precursor molecular structure and material growth that we established for the ZTO system will likely apply to other ALD processes as well.

Molecule-Sorbent Interactions in Metal Organic Framework Materials

Institution: Texas-Dallas, University of
Point of Contact: Yves Chabal
Email: chabal@utdallas.edu
Principal Investigator: Yves Chabal
Sr. Investigator(s): Jing Li; New Jersey-Rutgers, State University of
Timo Thonhauser; Wake Forest University
Students: 3 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014)

PROGRAM SCOPE

The aim of this program is to develop a fundamental mechanistic understanding of the interaction of small molecules— H₂, N₂, O₂, CO₂, H₂O, NH₃, SO₂, NO, NO₂, CH₄ and C_xH_y—in porous metal organic framework (MOF) materials, using a combination of novel synthesis, theoretical analysis, and characterization. In particular, we combine high-pressure/low-temperature infrared (IR) absorption and Raman measurements, adsorption isotherms and isosteric heat of adsorption measurements with first-principles calculations based on van der Waals density functional (vdW-DF) modeling, to study the behavior of a number of molecules in different MOF materials. One of the goals is to provide insight concerning the role of unsaturated metal centers or active sites grafted to combine with especially designed ligands to enhancing molecular uptake, selective adsorption, and diffusion. The short term impact of our work will result from the control and the understanding of common MOF systems, making it possible to determine the theoretical loading limits and stability of a specific class of materials, and the diffusion and the co-adsorption interactions of a variety of gases and gas mixtures. The long term impact will involve the development of 1) theoretical and experimental methods to gain a fundamental understanding of molecular interactions within these systems, and 2) new classes of microporous MOFs with enhanced molecular binding, selectivity, and diffusion properties.

FY 2014 HIGHLIGHTS

Water adsorption was shown to be reversible in MOF-74 below the water condensation pressure at room temperature. At ~150 °C, a reaction takes place even at low water vapor pressures. This finding provides insight into the long-lasting question of MOF-74 degradation and adds to the understanding of molecular water interaction with cation-exposed surfaces to enable development of more efficient catalysts for water dissociation. By examining the competitive co-adsorption of several small molecules in M-MOF-74, we find that the binding energy at the most favorable (metal) site is not a sufficient indicator for prediction of molecular adsorption and stability in MOFs. Instead, the occupation of the open metal sites is governed by kinetics, whereby the interaction of the guest molecules with the MOF organic linkers controls the reaction barrier for molecular exchange. A new Co-MOF was shown to be capable of effective capture and separation of xenon from other noble gases, as a first example of

commensurate adsorption of atomic gases near ambient conditions. We have also developed new luminescent MOFs (LMOFs) that show fast and effective detection of high explosives such as 1,3,5-Trinitroperhydro-1,3,5-triazine (RDX). The effect of porosity and electronic structure of the LMOFs on their sensing performance was evaluated, and the importance of both electron and energy transfer processes on the fluorescence response elucidated. In addition, we investigated a water stable zirconium-porphyrin MOF as acid sensor that exhibits distinct and reversible colorimetric and fluorescent 'turn-off-turn-on' pH response. Computationally screening MOF-74 structures with 25 different metals for their adsorption properties, we found a series of possible MOFs that bind CO₂ stronger than H₂O and thus are excellent candidates for novel carbon-capturing applications.

Metal Oxide Core Shell Nanostructures as Building Blocks for Efficient Light Emission

Institution: California-Los Angeles, University of
Point of Contact: Jane Chang
Email: jpchang@seas.ucla.edu
Principal Investigator: Jane Chang
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The goal of this research is to synthesize core-shell nano-structured metal oxide materials and investigate their structural, electronic and optical properties to understand the microscopic pathways governing the energy conversion process, thereby controlling and improving its efficiency. To rationally design such a core-shell nano-structured metal oxide material with larger absorption cross-sections, this work tackles two critical aspects of the materials engineering: (1) elucidate the growth mechanism of these nanostructured materials and its effect on the resulting photo-efficiency and (2) control the spatial distribution of optically active rare-earth (RE) ions by atomic layer deposition, since the location and spatial distribution of the rare-earth-ions as well as the microstructure and morphology are critical to the optical performance of these materials at reduced dimension and dimensionality. Specifically, this program focuses on: a) developing a hydrothermal process to synthesize the nanometered core and a radical enhanced atomic layer deposition process to control the distribution and activity of the dopant ions in the shell, b) monitoring the formation of metal hydroxides and metal oxide nanostructures by synchrotron radiation based x-ray absorption and diffraction analyses, c) identifying the chemical coordination of the rare-earth ions in the host and quantifying the concentration of optically active rare-earth ions, d) measuring the photoluminescence of these nanostructures and determining the absorption cross section for rare-earth ions and its dependencies on the doping concentration and the host composition, and e) integrating these synthesized one-dimensional rare-earth doped materials into simple devices to test their optical performance. This research provides optimized processes for synthesizing complex rare-earth ion doped metal oxide nanostructures and thin films, and lay the foundation of future generations of optical devices.

FY 2014 HIGHLIGHTS

Core-shell nano-structured metal oxide materials were synthesized and investigated for their structural, electronic and optical properties. The growth mechanism of the RE-oxide nanostructure cores during hydrothermal processing was delineated by synchrotron radiation based x-ray absorption and diffraction analyses. The shell was synthesized primarily by sol-gel processing and more recently by atomic layer

deposition and it reduced the effect of the surface quenching sites by increasing the distance between active ions and the surface hydroxyl groups. The luminescent fingerprint can be controlled with proper doping in the shell structure and a precision control of the dopant distribution. A theoretical comparison between the optical Judd-Ofelt analysis and the modeled extended X-ray absorption fine structure (EXAFS) spectroscopy was used to understand the effects of the dopant concentration and particle architecture on the luminescence parameters. By spatially controlling the RE dopant within a core-shell nanostructure, it is possible to increase the luminescence intensity and emission lifetimes. Furthermore, the effect of luminescence sensitization with the addition of Yb^{3+} was studied based on the upconversion luminescence dynamics and emission spectrum indicating a competing depopulation mechanism for the $^4I_{11/2}$ energy level. Finally, an efficient and high quality $\text{RE}^{3+}:\text{LaPO}_4$ white light phosphor was designed with specific criteria based on the energy dynamics elucidated from the study of $\text{Er}^{3+}:\text{Y}_2\text{O}_3$ nanoparticles. Simulation work is under way to study the resonant energy transfer (RET) in closely packed optically active rare earth ion core-shell systems exhibiting discrete and inhomogeneous ion distributions and to assess their potential impact of rapidly developing processing technology. Specifically, the effects of RE ion identity and proximity on the photoluminescence (PL) are investigated for various metal oxide hosts.

A Unified Understanding of Residual Stress in Thin Films: Kinetic Models, Experiments and Simulations

Institution: Brown University
Point of Contact: Eric Chason
Email: eric_chason_phd@brown.edu
Principal Investigator: Eric Chason
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$145,000 (2014)

PROGRAM SCOPE

The goal of our research is to develop a quantitative understanding of residual stress in polycrystalline films in terms of the underlying fundamental kinetic processes and microstructural parameters. Thin films are critical to many advanced technologies, but the residual stress can severely limit their performance or induce failure. The stress is measured in real-time while the film is growing using a wafer curvature technique. We are developing models to relate the measured stress to the underlying physical processes under different conditions. Our approach is to describe the stress at the point where different grains within the film meet (called the triple junction) as the film grows. The resulting stress is explained in terms of balance between attractive forces between the grains and insertion of atoms from the surface into the boundary between grains. It explains the dependence on the growth rate, microstructure and material parameters as well as the dependence on the surface morphology as the film evolves from isolated islands to a flat film. To explore and refine this model, we perform carefully-designed experiments to quantify the relationship between the processing conditions, microstructure and resulting stress. We use the growth of lithographically-patterned films to create islands of a well-controlled geometry that enables us to know precisely the evolution of the surface morphology during film growth. In unpatterned films, we characterize the resulting microstructure using cross-section electron microscopy in order to understand the dependence of the stress on the growth rate and grain size. From these results we are building an understanding of stress evolution in multiple material systems. The eventual product of this work will be to predict the stress in single component and alloy thin films in terms of the processing conditions and materials parameters.

FY 2014 HIGHLIGHTS

In the past year, we have made significant progress in two related series of studies. In the first, we studied stress in films grown on patterned substrates so that the morphology during growth could be known. These studies were performed on both 1-dimensional and 2-dimensional patterned arrays in which the islands grew as half-cylinders and half-spheres, respectively. The difference between the two patterns enabled us to study how the different geometries during island coalescence affect the resulting stress, as well as study the effects of anisotropy in the island array. The results were interpreted in terms of a model that we developed that considers the stress that develops at the boundary between the islands. The island geometry and film growth rate both affect the evolution of the boundary, as predicted by the model. The model was able to explain the results for both types of island arrays for multiple growth rates. For the 1-d array, we were also able to study the effect of the pattern spacing on the stress. The good agreement supports the validity of our model for explaining residual stress. In the second set of studies, we performed systematic experiments to explore the relationship between the stress evolution, the grain size and the growth rate in unpatterned films. We did this by measuring the stress as we grew the film for multiple growth rates. Afterwards, we characterized the grain size by cross-sectional electron microscopy measurements. By knowing the growth rates at different times, we could correlate the grain size at different thickness with the growth rate and resulting stress. These are the first data that clearly separate the effects of growth rate and grain size on stress. Previous studies have not considered how they are inter-related.

Electric-Loading Enhanced Kinetics in Oxide Ceramics: Pore Migration, Sintering and Grain Growth

Institution: Pennsylvania, University of
Point of Contact: I-Wei Chen
Email: iweichen@seas.upenn.edu
Principal Investigator: I-Wei Chen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$600,000 (2014-2017)

PROGRAM SCOPE

The project has reported several novel observations of electric-loading effects on sintering, grain growth and pore/bubble migration in cubic yttria-stabilized zirconia (YSZ) ceramics. Two fundamental atomistic mechanisms, one controlled by surface diffusion of cations, the other caused by supersaturation of oxygen vacancies, have been identified. They led to sintering, without grain growth, of YSZ at unprecedentedly low temperature, and to 10000 times faster microstructure evolutions that can be controlled by electric polarization. These findings may be applied to aid processing of YSZ and other ceramics, as well as assessing the stability and reliability of high temperature energy devices. To further basic understanding of atomic defects and microstructures, the project extends the above research to single crystal studies, electrochemical studies, *in situ* TEM studies, and continuum and computational modeling. Specific topics investigated include: electro-migration of pores/bubbles and second phase particles in YSZ single crystals, measurement of internal electric and oxygen potentials in YSZ electrolyte, field-enhanced grain growth in particle-containing YSZ, *in situ* imaging of bubble migration in YSZ under an electric or oxygen potential bias, boundary value problems of electro-migration, and simulations of defect configurations, energetics and dynamics. By strategic exploration of novel phenomena in phase/microstructure stability and defect kinetics engendered by electric loading on cubic YSZ, this study will expand the potential scope of utilizing electric effects for ceramic synthesis and processing.

More broadly, the fundamental thermodynamic and kinetic information gained from the research will significantly advance our scientific knowledge of a class of oxide ceramics that find myriad energy applications from oxide electrochemical cells, thermal barrier coating, to nuclear fuels and waste storage.

FY 2014 HIGHLIGHTS

We have succeeded in demonstrating electro-migration of dispersed particles of alumina, an oxide second phase, in YSZ ceramics, for the first time. Using two-step sintering, we also obtained dense bulk YSZ ceramics of an unprecedentedly small grain size. We further discovered in such ceramics grain growth kinetics that contradicts the conventional kinetics of exhaustion, such as Hillert's parabolic law. Instead, the grain size initially follows an exponential law, which has never been reported before. These results provide new opportunities to fundamentally understand the kinetic and thermodynamic aspects of defects and structure in this class of technologically important ceramics.

High-Throughput Preparation and Characterization of Vapor-deposited Organic Glasses

Institution: Wisconsin-Madison, University of
Point of Contact: Mark Ediger
Email: ediger@chem.wisc.edu
Principal Investigator: Mark Ediger
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Glasses combine the disordered structure of liquids with the mechanical properties of solids. On macroscopic scales, glasses can be extremely homogeneous, and their properties can be tuned continuously through composition and processing conditions. These are important factors explaining the significant role of glassy materials in developing technologies including organic electronics. In this project, we are working to expand considerably the range over which the properties of organic glasses can be tuned by making use of recent developments in physical vapor deposition (PVD). It has recently been established that PVD can prepare glasses that have much higher density and kinetic stability than can be attained with other methods and that such glasses can exhibit anisotropic packing. We are developing a temperature-gradient stage to prepare a wide variety of highly stable glasses in a single deposition. We perform ellipsometry and wide angle X-ray scattering at ~40 positions along the temperature-gradient. In this way, we efficiently characterize how a 130 K range of substrate temperatures influences the density, anisotropy, and molecular packing of vapor-deposited glasses. We are performing these measurements on glasses made of four molecules, including a model glassformer and three molecules important in organic light emitting devices (OLEDs). The OLED molecules were chosen to explore the effect of molecular shape on the properties of PVD glasses and to understand the potential role of highly stable glasses in these technologies. In particular, the anisotropy of PVD glasses may be advantageous for some applications and it appears that varying the substrate temperature allows access to a wide variety of anisotropic packing arrangements while maintaining high density and high kinetic stability.

FY 2014 HIGHLIGHTS

We have studied glasses of three molecules that have been used to make organic light emitting diodes (OLEDs). We used physical vapor deposition onto a silicon wafer with a 130 K temperature gradient so as to efficiently prepare a wide range of glasses of each compound in a single deposition. All these glasses were then interrogated individually using spectroscopic ellipsometry. Our results for these three molecules show a remarkable dependence of molecular orientation upon substrate temperature and this dependence is qualitatively similar for the three molecules. At the lowest substrate temperature, all three molecules lie down such that their long axes are almost completely in the plane of the substrate; this arrangement is known to be advantageous for emitters in OLEDs as it can increase device efficiency by a factor of 1.5. At a higher substrate temperature, all three molecules show a tendency to stand up such that their long axes are normal to the plane of the substrate. Our high-throughput methodology allows us to differentiate between the effects of molecular shape and substrate temperature for the first time. We find substrate temperature to be the dominant control variable and this suggests that a wide range of molecular orientations might be achieved via physical vapor deposition with almost any organic molecule; this provides a new dimension for optimizing the properties of OLEDs and other organic electronics devices. Computer simulations allow an interpretation of these results in terms of the molecular orientation present at the surface of the equilibrium liquid and allow optimism that molecular orientation in vapor-deposited glasses might ultimately be predicted from computer simulations.

Atomic Layer Controlled Growth of Artificially Engineered Pnictide Superlattices By Design

Institution: Wisconsin-Madison, University of
Point of Contact: Chang-Beom Eom
Email: eom@engr.wisc.edu
Principal Investigator: Chang-Beom Eom
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$110,000 (2014)

Jointly funded by "Experimental Condensed Matter Physics" and "Synthesis and Processing Science"

PROGRAM SCOPE

Since the discovery of superconductivity in iron-based materials significant progress has been made in the fabrication of high quality bulk and epitaxial thin film materials to explore their intrinsic properties and evaluate novel device applications. The superconducting mechanism, structural transitions, magnetic behavior above and below T_c , interfacial phenomena, and critical current and flux-pinning behavior have all been recognized as critical to progress toward understanding the pnictides. Artificial layered pnictide superlattices with atomically sharp heterointerfaces offer unique opportunity towards tailoring superconducting properties and understanding the mechanisms of superconductivity by creating model structures which do not exist in nature. Our main tasks are to create and control pnictide superlattices and heterointerfaces at the atomic level, to understand the relation between structure, magnetism and superconducting properties, and to design and grow novel pnictide superlattices tuned to take advantage of the superconducting structure/property relationships possible in this unique new superconductor. The thrusts of our proposed work are: (1) Atomic-layer-controlled growth of artificially engineered superlattices. (2) Designing interfacial superconductivity at pnictide and FeSe interfaces. (3) Investigation of interaction between superconductivity and magnetism by proximity effect (4) Understanding and control of flux-pinning mechanisms (5) Study of growth mechanisms of

heteroepitaxial superlattices and artificial pinning centers. The proposed work investigates the basic physical processes of novel superconductivity, primarily by looking at its interaction with magnetism on a microscopic scale, and the role these play in the flux pinning process. We also extend these fundamental investigations to explore routes to interfacial superconductivity in these systems.

FY 2014 HIGHLIGHTS

We investigated the superconducting properties of single- and multilayer Co-doped BaFe₂As₂ (Co-Ba122) thin films grown on CaF₂ and (LaAlO₃)_{0.3}(Sr₂AlTaO₃)_{0.7} (LSAT) substrates. We confirmed the significant improvement of the critical temperature in the film on CaF₂ and we demonstrated that the multilayer deposition has no detrimental effect on T_c. We found that deposition on CaF₂ produces much cleaner films compared to films on LSAT, since on CaF₂ the substrate absorbs oxygen preventing the formation of the high density of defects present in the LSAT case. The result of this oxygen reaction is that in the single layer on CaF₂ (CaF-S) the only visible defects are dislocations. Moreover, the different trend of angular dependence of critical current density in CaF-S at intermediate temperature suggests an increasing contribution of point defects with decreasing temperature. The multilayer film on CaF₂ (CaF-M), grown with insertion layers enriched in BaO, does have defects including short nanorods, round particles and flat particles similar in size but with a lower density to those in films on LSAT. Despite the different pinning mechanisms that affect the shape of the angular dependence of J_c, the single layers on both substrates roughly have similar J_c at the same reduced temperature. In contrast the multilayer deposition on CaF₂ is 2-3 times more effective in increasing J_c with respect to the corresponding single layer than in the LSAT case. This results in a record high pinning force (F_p) of 84 and 70 GN/m³ in Ba122 phases (H//ab and H//c, respectively), significantly larger than reported previous values in the Co-Ba122 phase and higher-T_c P-Ba122 phase. Applications interest is strengthened by their notably better in-field performance than in Nb₃Sn.

Using Energetic Gas Jets to Enable New Modes of Focused Electron Beam Induced Deposition

Institution: Georgia Institute of Technology
Point of Contact: Andrei Fedorov
Email: agf@gatech.edu
Principal Investigator: Andrei Fedorov
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$220,000 (2014)

PROGRAM SCOPE

Focused Electron Beam Induced Deposition (FEBID) is an emerging method of directly fabricating three-dimensional nanostructures from a variety of materials. There exists a wide range of potential applications for FEBID, since it is of a relatively low cost, inflicts minimal surface damage, and can achieve high feature resolution as compared to other deposition systems. However, the FEBID penetration as a manufacturing tool remains limited due to low deposition rates, poor deposit purity, and a trade-off between an achievable deposition rate and deposit resolution. A great deal of fundamental science relevant to gas jet assisted EBID is not well understood, such as predicting the adsorption probability of impinging molecules onto the surface and the dissociation probability of adsorbed molecules due to secondary electrons. Gas injection as a method of precursor delivery presents unique opportunities to enhance FEBID performance. In particular, use of energetic jets allows modulation of the local effective surface temperature of the substrate and control precursor sticking to

the surface. We have demonstrated that the energy of an inert gas jet impinging upon the surface is sufficient to raise the effective temperature of the surface, to greatly enhance the pre-adsorbed precursor diffusion rate and, in turn, to significantly improve the deposit growth rate. We propose experiments and simulations that would allow us to develop the first principle sticking probability model(s) for gas-jet FEBID, thus enabling development of comprehensive system design tools. This research will provide a significant benefit to society by developing a nanomanufacturing tool for making topologically complex semiconductor nanostructures and devices. Potentially transformational benefits are expected, impacting a wide range of applications including energy conversion, optoelectronic communication, and 3D nano-electro-mechanical devices for separation and sensing.

FY 2014 HIGHLIGHTS

Complimentary experimental research and modeling have been performed to develop the first principle sticking probability model and relevant process simulations in order to enable comprehensive energetic gas-jet enhanced Focused Electron Beam Induced Deposition (FEBID) simulation tools with minimal empirical inputs. The thermal response of the substrate subjected to the energetic gas-jet impingement has been mapped using a micromachined array of resistor temperature detectors (RTDs), which is the first time such a spatially-resolved experimental data has been obtained in this research field. In concert with the experimental measurements of thermal effect of the gas jet, the comprehensive simulation framework for the gas-jet has been developed to accommodate – for the first time – continuum, transitional, and molecular flow regimes in a unified computational approach based on Direct Monte Carlo Simulations. We have shown that FEBID can be utilized to covalently functionalize graphene with high degrees of control, owing to its intrinsic patterning resolution down to a few nanometers. Controlled chemisorption of carbon atoms or hydrocarbon radicals using FEBID can be effective in modifying the electronic and magnetic properties of graphene. In particular, we assessed the nature of adsorption states of FEBID-produced carbon on graphene as function of the deposit location and suggested a laser-assisted post-deposition process to remove parasitic carbon deposits, using first-principles calculations and complementary Raman experiments. In combination with demonstrated post-deposition “cleaning” process using laser ablation to remove detrimental “halo” carbon deposits with graphene remaining intact, this approach establishes the FEBID as a novel tool for controlled covalent functionalization of graphene with applications to electronic device fabrication and sensing on nanoscale.

Forces, Crystallizations and Assembly in Nanoparticle Suspensions

Institution:	Pennsylvania State University
Point of Contact:	Kristen Fichthorn
Email:	fichthorn@psu.edu
Principal Investigator:	Kristen Fichthorn
Sr. Investigator(s):	Robert Rioux; Pennsylvania State University
Students:	1 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding:	\$250,000 (2014)

PROGRAM SCOPE

In this research, complementary theoretical and experimental methods are used to quantify the binding of structure-directing agents (SDAs) to coinage-metal surfaces and to resolve the mechanisms by which SDAs mediate shape-selective growth. On the theoretical side, first-principles, dispersion-corrected, density-functional theory (DFT) is used to quantify the binding of polymeric and small-molecule SDAs, as

well as solvent, to low Miller-index surfaces of the coinage metals. Force fields have been and are being fit to describe binding in these systems and tested against DFT and experiment. Large-scale molecular dynamics (MD) simulations are being conducted to understand the solution-phase growth and structural transformations of isotropic Ag nanoparticles, as well as structural transformations and aggregative, solution-phase growth mechanisms for coinage-metal nanowires and Ag nanosheets. Additionally, we continue to investigate the growth and assembly of titanium dioxide nanoparticles using empirical force fields. On the experimental side, two experimental platforms - isothermal titration calorimetry (ITC) and in-situ, liquid-phase, high resolution transmission electron microscopy - are being developed to understand the influence of SDAs on anisotropic seeded growth in coinage-metal colloidal syntheses. These studies are quantifying SDA binding energies to various nanostructures and provide a real-time, in-situ view of nanostructure growth.

FY 2014 HIGHLIGHTS

Theoretical studies focused on understanding oriented attachment (OA), where we applied a newly developed reactive force field to demonstrate how water mediates OA of anatase nanocrystals (Nano Lett. 14, 1836, 2014; Chem. Eng. Science 121, 10, 2015). A second thrust focused on understanding the workings of SDAs in the synthesis of noble-metal nanostructures. We developed an empirical force field to describe the interaction of polyvinylpyrrolidone (PVP), polyethylene oxide (PEO), and (poly)ethylene glycol with Ag surfaces (J. Phys. Chem. C 118, 3366, 2014). We wrote two invited reviews on the workings of PVP and PEO as SDAs for Ag nanostructure synthesis (Molecular Simulation 40, 134, 2014; J. Chem. Eng. Data 59, 3113, 2014). We used MD to calculate binding free energies of PVP analog molecules to Ag surfaces and compare the results to experiments (see below). We used MD to demonstrate that 5-fold-twinned noble-metal nanowires have a body-centered orthorhombic structure (J. Phys. Chem. C 118, 18746, 2014). We also completed a study of the binding of PVP to Au surfaces involving DFT and empirical force fields and a manuscript will be submitted on this work in early 2015. Studies with DFT and MD are demonstrating how hexadecylamine is an effective SDA for the formation of {100}-faceted Cu nanostructures. In an effort to quantify the thermodynamics of PVP adsorption to Ag nanostructures, a new method has been developed for conducting isothermal titration calorimetry (ITC) experiments. The details of this method have been submitted to the Journal of the American Chemical Society and a provisional patent has been filed. The advantages of the new method have been detailed in a publication recently submitted to Nature Methods, which demonstrates for the first time, the direct calorimetric measurement of a picomolar (pM) binding system. The new method has been used to analyze the binding energy of small molecules adsorption to Ag nanostructures and the nanoscale cation exchange of Ag with CdSe nanoparticles.

Kinetic and Mechanistic Study of Vapor-Phase Free Radical Polymerization onto Liquid Surfaces

Institution: Southern California, University of
Point of Contact: Malancha Gupta
Email: malanchg@usc.edu
Principal Investigator: Malancha Gupta
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$250,000 (2014-2015)

PROGRAM SCOPE

This proposal aims to experimentally and computationally study the fundamental aspects of a new and exciting technique to deposit polymer particles and films onto liquid surfaces via initiated chemical vapor deposition (iCVD). This is a novel technique pioneered by the PI which is expected to revolutionize materials development by offering new initial conditions for growth as well as additional degrees of freedom afforded by the unconstrained nature of the liquid surface. This technique could lead to a more cost effective, scalable process for fabricating thermally stable films for fuel cell applications as well as nanoparticles for a range of applications in solar cells, photonics, and computer memory devices. In addition, the ability to introduce patterns into the liquid surface, for example standing wave patterns and vortices, could allow for the shape of the resulting particles to be controlled. The molecular origins associated with polymerization on liquid surfaces will be determined by studying how the adsorption and arrangement of the monomer molecules on the surface of the liquid affects the polymer molecular weight and diffusion. In addition, multiscale simulations will be performed to determine the molecular mechanisms involved during polymerization on liquid surfaces. The results of this study will uncover fundamental aspects of the process-structure-property relationships that govern the deposition process. The field of vapor phase deposition of organic and inorganic materials onto liquids is evolving rapidly with a broad range of applications, and it is expected that the conclusions from this study will have broad relevance on the characterization and understanding of the liquid/vapor interface.

FY 2014 HIGHLIGHTS

We are currently investigating nanoparticle formation at the liquid surface as a function of several parameters including liquid viscosity and molecular weight. We are using dynamic light scattering and quartz crystal microbalance measurements to determine how surface tension, molecular weight, viscosity, and absorption affect the nanoparticle size distribution. In order to observe the particle growth directly on the liquid surface, we have developed a method in which the particles are deposited onto liquid poly(dimethyl siloxane) (PDMS) with cross-linker. The PDMS is then cured at room temperature and imaged. This new imaging technique allows us to determine the location of nanoparticle growth relative to the interface and provides us with new information about the spacing between particles on the interface.

New Frontiers in III-Nitride Selective Area Growth: Nanoepitaxy and Lateral Evolution

Institution: Yale University
Point of Contact: Jung Han
Email: jung.han@yale.edu
Principal Investigator: Jung Han
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

Selective area growth (SAG) is a phenomenon in thin-film deposition where the sample surface is masked by a dielectric or refractory layer such that growth takes place only in exposed window regions. The selectivity is introduced due to large disparities in incorporation energetics and kinetics between the mask and window region. This proposal aims to bring the SAG of GaN to a new state of art, so as to unleash the full potential of this wide bandgap semiconductor family in photonics and microelectronics.

The concept of SAG will be extended to a mesoscopic scale and combined with sophisticated lithography and micromachining to create novel geometric configurations and conditions not attainable at present. A major objective is the universal, chip-level, and heterogeneous integration of GaN devices with other substrates and devices (such as CMOS electronics). We propose the application of the evolutionary selection process through confined SAG growth to create mono-crystalline GaN on oxide and other amorphous substrate. A textured nitride thin film, having preferred out-of-plane alignment, is first deposited and then lithographically patterned into the seed for the subsequent lateral overgrowth. The lateral growth in a constricted channel, which can be implemented as either an open groove or a closed tunnel, will induce a lateral orientation selection based on the competition of growth velocities among grains having different in-plane orientations. The consequence of this lateral competition selection is a great reduction in the angular dispersion of in-plane crystallographic alignment and the creation of monocrystalline GaN on arbitrarily-chosen templates.

FY 2014 HIGHLIGHTS

We have shown a full demonstration of the ability to grow GaN on an amorphous SiO₂ surface. Synchrotron micro-focused XRD analysis of evolutionary-section grown GaN on SiO₂ validates the intrinsically high microstructural quality of the GaN produced with this method, and shows its suitability for the production of high-performance GaN-based devices on amorphous surfaces. Analysis of channel confined growth for GaN on amorphous surfaces is expected to enable a scalable and effective method for integration of device quality semiconductor crystals with non-crystalline substrates, and further apply the use of channel confined masks to achieve other desirable growth configurations. And we carried out further investigation of confined lateral overgrowth of GaN tiles about the strain and microstructural properties, as well as the growth mechanism studying. The strain estimated from Raman results was found to be gradually reduced to zero from the center to the edge of tiles. Most of the dislocations in AlN are blocked by SiO₂ floor mask except the region of exposed AlN seed. Dislocations originated from the AlN seed region bend lateral into the GaN tiles. Therefore the density of vertical dislocations propagating into the top surface of GaN is reduced dramatically. The growth mechanism of confined lateral overgrowth (CLO) has been investigated by studying the growth behavior in the rectangular channels. The growth behavior was also simulated by COMSOL with concerning gas-phase diffusion. The experimental thickness profiles of GaN exhibited similar trends as the results from simulation, indicating that the growth behavior of CLO is dominated by gas-phase diffusion and can be predicted by the simulation.

Understanding and Controlling Nanoscale Crystal Growth Using Mechanical Forces

Institution: Massachusetts Institute of Technology
Point of Contact: Anastasio John Hart
Email: ajhart@mit.edu
Principal Investigator: Anastasio John Hart
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2014-2017)

PROGRAM SCOPE

Synthesis of high-quality 2D materials such as graphene requires control not only over the nucleation and growth of each crystal domain, but also over the interactions among populations of domains growing simultaneously. To enable future energy-efficient electronics, membranes, and other

applications of graphene, it is most desirable to produce graphene directly on a functional substrate. Current transfer methods from metallic growth substrates can degrade film quality and introduce harmful residues. In this program we will explore the mechanisms of graphene growth at the interface between a metal film and dielectric or semiconducting substrate (e.g., SiO₂, h-BN). By understanding of the role of film microstructure, mechanical stress, carbon diffusion and precipitation kinetics, and interface properties, we believe it will be possible to establish position-controlled nucleation and growth of interfacial graphene domains that combine into highly uniform graphene films. The program will leverage specialized techniques in our laboratory including *in situ* optical spectroscopy of the substrate along with rapid temperature control, and instruments that can apply and measure controlled stresses in thin films. The program will also extend our multi-scale understanding of nanoscale carbon precipitation and collective self-organization at the mesoscale, which was recently developed in the context of carbon nanotube growth. Overall, this research will establish interfacial growth as a means of fabricating high-quality graphene films directly on non-metal substrates, with potential relevance to other 2D crystal systems.

FY 2014 HIGHLIGHTS

The funding period began on 9/15/2014.

Laser Fabrication of Active Single-Crystal Architecture in Glass

Institution: Lehigh University
Point of Contact: Himanshu Jain
Email: hj00@lehigh.edu
Principal Investigator: Himanshu Jain
Sr. Investigator(s): Volkmar Dierolf; Lehigh University
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014-2015)

PROGRAM SCOPE

Numerous energy devices rely on the availability of suitable single crystals of complex compositions in appropriate form. The conventional thermal processes for fabricating single crystals from the melt are not suitable for many important multi-component systems because either the material decomposes before melting, or undesired phases form by incongruent solidification of the melt. We are addressing this generic challenge of material fabrication by a laser-crystallization process that bypasses melting, yet would allow the control of size, geometry and orientation of the single crystal. As a proof of concept our goal is to fabricate a bend in the single-crystal line and then a 2D planar single crystal, without altering the lattice orientation. Our approach is based on two hypotheses: (i) The crystal growth can be controlled using a dynamic temperature profile which determines rate-controlling local diffusivities and interfacial reaction kinetics. (ii) A laser can produce complex heating profiles that are not possible with any other technique. Consequently, we are determining the heat profile and the dependence of growth on local (anisotropic) temperature gradient. Then appropriate dynamic temperature profile is established to yield specified crystal geometry (shape and size) in a given glass. High resolution spatial light modulator technology, which has become readily available only recently, is to be used to shape precisely and vary dynamically essentially arbitrary beam profiles. The initial crystal growth experiments are to be performed on IR transmitting chalcogenide systems to yield active crystal phases with superior piezoelectric, photoelectric, pyroelectric and pyro-optic properties. The chosen systems allow a systematic variation of network dimensionality, hence growth anisotropy. Successful understanding of

single crystal growth process in these compositions would help establish its broad applicability to various other glass forming systems.

FY 2014 HIGHLIGHTS

We have demonstrated the first unequivocal fabrication of a laser-induced single crystal in a glass via solid \rightarrow solid transformation i.e. without melting. Specifically, Sb_2S_3 crystals are fabricated on the surface of Sb-S-I glass, where temperature and chemical gradients induce single crystal growth and suppress polycrystallinity. Here the nucleation rate in the supercooled liquid state is much slower than the crystal growth rate, which facilitates the formation of single crystal from a given nucleus as the laser is traversed above a threshold speed. Through the control and optimization of laser writing parameters, we have succeeded in forming straight and bent single-crystal lines, and then 'stitched' them to form a 2D single-crystal on the surface of glass. The lattice of the single-crystal line fabricated at or near the surface of Sb-S-I glass rotates gradually along its length. To elucidate the mechanism of this unexpected phenomenon, the crystals were analyzed by scanning X-ray micro-diffraction (microSXRD) at the Advanced Light Source, Lawrence Berkeley Lab. The Laue patterns obtained by this technique reveal that the laser-written crystal is similar to a plastically deformed crystal, comprising of tilt dislocation walls. Apparently, these dislocations are introduced to accommodate the mismatch between the density of the crystal and glass matrix, which in turn cause gradual rotation of the crystal lattice about the axis that is in the plane of crystal surface and normal to the laser writing direction. Preliminary results indicate that the magnitude of rotation per unit length of the crystal line depends on the orientation of the crystal lattice relative to the laser scanning direction, at least for the Sb-S-I system, and there may be a particular orientation for which its value is negligible. Confirmation of this observation in the future will provide conditions for fabricating single-crystal lines of fixed orientation through the whole length.

Group IV Nanomembranes, Nanoribbons, and Quantum Dots: Processing Characterization and Novel Devices

Institution:	Wisconsin-Madison, University of
Point of Contact:	Max Lagally
Email:	lagally@engr.wisc.edu
Principal Investigator:	Max Lagally
Sr. Investigator(s):	Mark Eriksson; Wisconsin-Madison, University of
Students:	4 Postdoctoral Fellow(s), 6 Graduate(s), 3 Undergraduate(s)
Funding:	\$467,188 (2014)

PROGRAM SCOPE

Single-crystal semiconductor sheets present a platform for entirely new science and technology. They may form the basis for devices relevant in energy harvesting, transformation, and conservation. The novelty of thin crystalline sheets lies in the following. 1) They are thin; a factor that brings many new phenomena. The very high interface-to-volume ratio makes surfaces or interfaces, and their chemical and structural properties, very important contributors to unique membrane electrical, thermal, and mechanical behavior. 2) Thin sheets can be strained to a high degree, effectively allowing lattice constant choice. Many of the most fundamental materials properties are influenced by the lattice and distortions of the lattice. 3) They are easily stackable and bondable, introducing the potential for an entirely new set of composite materials that change their properties vertically on the scale of 10s to 100nm. Because of this property, interface effects can be significant, but are readily investigated. Additionally, sheets are compatible with all top-down processing that is conventional in the

semiconductor device industry. The platform of single-crystal semiconductor sheets offers the choice of nano-size in one, two, or three dimensions, as well as the formation of structures with mixed dimensions, but the true advantage is working at the nanoscale in one dimension, while the other two dimensions are at the mesoscale or macroscale. Our work provides excellent prospects for modifying and enhancing materials properties, and new areas of nanomembrane (NM) processing that can act as technology drivers.

FY 2014 HIGHLIGHTS

Research has focussed on composites of thin nanomembranes, some of crystalline/crystalline combinations, some on crystal/polymer combinations. An example of the first is graphene on Ge, with outstanding, record values of charge transport measured in graphene due to interface effects. An example of the latter is Si NMs on PDMS, creating novel microstructures that are useful in bioengineering or fluidics sensing. Other combinations include SiN_x thin films on a free-standing Si NM, to explore mechanical properties associated with film formation, and thin SiGe NM single crystals to serve as seeds for strained-Si two-dimensional electron gases (s-Si 2DEGs). 13 papers were published in 2014 with partial or exclusive support from this grant.

Hydrogen Caged in Carbon-Exploration of Novel Carbon-Hydrogen Interactions

Institution: Pennsylvania State University
Point of Contact: Angela Lueking
Email: Adl11@psu.edu
Principal Investigator: Angela Lueking
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our research includes four complementary projects. The first two utilize Diels Alder condensation reactions to attempt to trap hydrogen in carbon cages via 'wrapping' and/or polymerization of carbon around available hydrogen, focusing on extreme pressures of model compounds in a diamond anvil cell. The third project probes hydrogen penetration into known and well-characterized carbon materials under extreme conditions; in the past year this has focused on correlation of spectral features and perturbations in model carbon structures and gas diffusivity. The fourth modeling project probed candidate carbon structures that may form in the three experimental projects. In addition to these four original project lines, we added a fifth line of research concerning the formation of carbon-hydrogen interactions when hydrogen is provided via an adjacent transition metal catalyst.

FY 2014 HIGHLIGHTS

Gas confinement via repulsive interactions is intended to design molecular-level nanostructures that act as compressed gas storage tanks. Under extreme conditions of pressure, hydrogen solubility in carbon materials is expected to increase and carbon is expected to restructure to minimize volume via a mixed sp²/sp³ hydrogenated state. High pressure polymerization of triptycene, a molecule with internal free volume, led to an amorphous hydrogenated carbon with 40% sp³ C-H content and retention of bridgeheads and rigidity. We have also probed near-ambient temperature confinement of N₂ and H₂ in model carbon geometries with spectroscopy and gas diffusivity measurements, with alteration of pore

geometry via synthesis and post-synthesis techniques. Defected carbon nanoshells did not retain gas at room temperature, even after deposition of amorphous carbon at the defects. A high binding energy (0.16 eV) interaction between N₂ and a porous polymer was observed at room temperature that was a function of pore dimension, which led us to revisit how spectra may be used as a means to characterize pore geometry in carbon materials, enabling rapid characterization of microgram quantities of sample. We are validating the technique for slit and cylindrical carbon geometries as a function of temperature, chemical potential, and gas density and correlating the results to gas diffusivity. We have also explored gas entrapment in flexible metal-organic frameworks and noted an unusual non-Fickian response behavior.

Quasiepitaxial Growth of Organic Crystalline Thin-Films

Institution: Michigan State University
Point of Contact: Richard Lunt
Email: rlunt@egr.msu.edu
Principal Investigator: Richard Lunt
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$152,000 (2014)

PROGRAM SCOPE

The presence of excitons in organic semiconductors at room temperature distinguish them from traditional semiconductors, providing exceptional opportunities for manipulating energy in a range of structures from light emitting diodes, lasers, transparent photovoltaics, and optical switches. However, control over crystalline order, orientation, and defect formation is crucial to the fabrication and optimization of these excitonic organic electronics. The overarching goal of this project is to understand and explore bottom-up vapor-deposition routes to the growth of large-area organic single crystalline like films with controlled thickness through a combination of organic-organic interactions. The specific aims are to 1) map growth modes from the vapor phase for archetypal homo-epitaxial and hetero-quasiepitaxial systems, monitored with both real-time and *in situ* diffraction techniques; 2) elucidate predictive energetic design rules for multilayer sustained quasi-epitaxial ordering; and 3) model and understand energetically driven quasiepitaxial relationships. This understanding will enable a new class of organic electronics with unique excitonic tunability and will be used as a platform to study organic quantum wells, exciton confinement, and determine upper limits for energy transport.

FY 2014 HIGHLIGHTS

We have now realized the growth of the first set of heteroquasiepitaxial multilayer organic thin film crystals. These crystals are composed of incommensurate organic semiconductors with sustained azimuthal ordering and controlled orientation grown from the bottom up. By probing a range of molecular pairings with in-situ and real-time diffraction, we have confirmed that one of the driving forces behind this growth is the requirement of surface energy matching of the lowest energy crystalline planes, which is completely distinct from the requirements of lattice matching for inorganic epitaxial growth. This insight is helping to provide a more universal understanding of the key requirements for such remarkable growth that has been historically inaccessible. In addition we have extended our molecular dynamics simulations of surface diffusion to understand the kinetic dynamics of a full molecular series across a range of surfaces. Combined, these results demonstrate the starting criteria

for manipulating the bottom up growth of multilayer organic thin-film crystals that is now being used as a platform to characterize energy transport in unique crystalline organic ensembles.

Non-Equilibrium Effects in the Processing of Materials Using Plasmas

Institution: California-Riverside, University of
Point of Contact: Lorenzo Mangolini
Email: lmangolini@engr.ucr.edu
Principal Investigator: Lorenzo Mangolini
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$100,000 (2014)

PROGRAM SCOPE

The scope of this project is to investigate the interaction between nanoparticles and non-thermal plasmas. Dusty plasmas are emerging as a powerful and versatile tool for nanopowders synthesis, with several demonstration of successful production of semiconductor, metallic and even ceramic nanoparticles. While significant effort has already been given to plasma-induced chemical nucleation of dust and to the electrostatic charging of particles in plasmas, it is unclear how a non-thermal process can produce high-quality crystalline powder even for the case of high-melting point materials. This project addresses this issue. The main goal is to measure the temperature of nanoparticles as they are dispersed in a partially ionized gas. This can be achieved using several strategies, but this particular project relies on the use of in-situ FTIR to probe the nanoparticle surface as they are in direct contact with the non-thermal plasma. An IR beam is sent through the discharge as it is nucleating and growing nanoparticles. Under consideration is the case of a silane-containing plasma, which leads to the formation of silicon nanoparticles. By monitoring the stability of different surface moieties as the particles interact with the discharge it is possible to extract the nanoparticle temperature. Ultimately this project will provide a more detailed description of the interaction between particles and plasmas, focusing in particular on the complexity of the plasma chemistry and on its influence on the heating of nanoparticles during processing. This in turn will clarify what is the real potential of non-thermal plasma techniques for nanopowders synthesis and processing.

FY 2014 HIGHLIGHTS

This project led to two publications in 2014. The first one [1] summarizes an experimental study on the kinetics of phase change for ultrafine silicon powder. A second publication [2] discusses the kinetics of crystallization of silicon particles when exposed to a plasma instead of to a thermal source such as a furnace. Nanoparticles were grown in a non-thermal plasma and sampled at different positions in the reactor using an extraction orifice). The structural evolution is monitored as a function of residence time in the plasma. In-situ FTIR is used to monitor the nucleation process and the nanoparticle surface. It is found that particles are first nucleated with an amorphous phase and then annealed by the plasma to reach a crystalline structure. By using the crystallization rate determined in [1] it is possible to calculate the necessary temperature to which the particles should be heated to observe a phase transformation. This is found to be 1100K. Consistently with this measurement, the nanoparticle surface is bare as they are in the plasma, likely because of rapid thermal desorption. This work was presented at the AVS 61st meeting in Baltimore (invited talk). 1. Lopez, T. and L. Mangolini, 2014, *Nanoscale*, 6(3): p. 1286-1294. 2. Lopez, T. and L. Mangolini, 2014, *Journal of Vacuum Science & Technology B*, 32(6): 061802-1 to 8.

Thermochemistry of Oxides with Electrochemical and Energy Applications

Institution: California-Davis, University of
Point of Contact: Alexandra Navrotsky
Email: anavrotsky@ucdavis.edu
Principal Investigator: Alexandra Navrotsky
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

This project represents a renewal, continuation, and redirection of a program emphasizing the thermodynamics of materials relevant to energy. The major objectives are: (a) to advance and use unique calorimetric capabilities to determine the energetics of oxide materials relevant to energy applications, with an emphasis on new materials for batteries and fuel cells, (b) to understand, in terms of both macroscopic energetics and microscopic structure and bonding, the interplay of defect chemistry, oxidation-reduction, and size effects at the nanoscale in determining the properties of oxides. In addition to completing work on ionic conductors and continuing to pioneer calorimetric studies of refractory materials above 1500 °C, this project will emphasize mixed ionic - electronic conducting materials containing transition metals of variable valence, especially perovskites ($A_xRE_{1-x}M_yM'_{1-y}O_3$ (A = alkaline earth, RE = rare earth, M and M' = Mn, Fe, Co) and lithium containing rocksalt, spinel, olivine, and fluorosulfate phases with M = Mn, Fe, Co, Ni. In addition, thermochemical studies of purely ionic conductors (Bi_2O_3 - based fluorite structured electrolytes, co-doped rare earth ceria, apatites) will be continued. The major and unique technique employed is high temperature oxide melt solution calorimetry, with careful attention to materials synthesis and characterization. Direct *in situ* studies of refractory oxides above 1500 °C by levitation melting and crystallization, synchrotron – based diffraction, and improved differential scanning calorimetry will probe structure and phase transitions in refractory oxides.

FY 2014 HIGHLIGHTS

We have made progress on several fronts. Salih Buyukkilic has completed his Ph.D. and is starting a job at Intel. The second half of his thesis work involved the high temperature thermochemical and conductivity behavior of neodymia and samaria singly and co-doped ceria. We have shown definitively that the correlation between maximum heat of mixing and highest ionic conductivity holds up to 700 °C, with the composition of the maximum shifting to higher dopant concentration, consistent with increasing defect dissociation at higher temperature. This work is being prepared for publication. S. Mahboobeh Hosseini, working on apatites, completed her Ph.D. and is now employed by Chevron. An additional paper is published and another is under review. Tien Tran, postdoc, is now teaching at the University of the Pacific. A paper showing the effect of order-disorder on the thermodynamics of doped bismuth oxide has been published. Our work on battery materials is our exciting new focus. We have shown that $LiCoO_2$ has low surface energy and low hydration energy and argue that these features are important in aiding ion and electron transfer across the electrode/electrolyte interface. The results support theoretical calculation by Meng's group. Our work is recently published in *Angewandte Chemie* (Maram *et al.* 2013). In addition, we have finished work on a set of hydroxysulfate ionic conductors from Tarascon's group in France. The paper is in the final revision stages for publication. Selected Publications include: 'Energetic Effects of Substitution of La-Nd and Si-Ge Oxyapatite-Type Materials' S. M. Hosseini and A. Navrotsky, *J. Am. Ceram. Soc.*, 96, 3915-3919 (2013). "Energetics of Disordered and Ordered Rare

Earth Oxide-Stabilized Bismuth Oxide Ionic Conductors” T. Tran and A. Navrotsky, Phys. Chem. Chem. Phys., 16, 2331-2337 (2014).

A Fundamental Study of Inorganic Type II Clathrate Open-Framework Materials

Institution: Florida State University
Point of Contact: George Nolas
Email: gnolas@usf.edu
Principal Investigator: George Nolas
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The goal of this project is to investigate the intrinsic properties of intermetallic clathrates in order to develop fundamental structure-property relationships that expand the knowledge base of the unique properties that these materials possess. The intellectual merit of investigating these materials is very closely tied with their novel structure and the corresponding physical properties they exhibit. This work is intended to lead to a clearer understanding of the unique properties that define the suitability of these materials for energy-related applications. New processing and crystal growth techniques are also of interest due to the fact that for many materials of technological interest, as well as materials that probe fundamental new physical phenomena, the preparation of high-purity compositions, or high-quality single crystals, by traditional techniques is very challenging. This research has allowed for strong collaborations with other DOE-funded experts and their research groups (e.g. Prof. Carolyn Koh at the Colorado School of Mines) as well as international researchers in the field (e.g. Prof. Dr. Yuri Grin, Director, Max Planck Institute for the Physical Chemistry of Solids).

FY 2014 HIGHLIGHTS

Intermetallic clathrates continue to be of scientific and technological interest, however, the synthesis of phase pure clathrates, new compositions in particular, is extremely challenging especially when the component elements possess significantly different melting points and/or vapor pressures. New synthetic approaches are therefore a major part of this research project. We employed two new methods for crystal growth developed under this DOE project, spark plasma sintering (SPS) and kinetically controlled thermal decomposition (KCTD), in investigating intermetallic clathrates of different compositions as well as new “open-framework” materials, some for the first time. For example, $K_8Ge_xSi_{46-x}$ with varying Ge content (x) and $Na_8Al_ySi_{46-y}$ with varying Al content (y) were synthesized for the first time. The former was synthesized employing KCTD and the later SPS. Optical and transport properties investigations revealed that $Na_8Al_8Si_{46}$ is a semiconductor with properties that may be of interest for thermoelectrics applications. In expanding on the use of SPS for materials synthesis, single crystals of a new ternary type-II clathrate, $K_6Na_{16}Si_{136}$, as well as $Rb_8Na_{16}Si_{136}$ and $Cs_8Na_{16}Si_{136}$ clathrates were synthesized by using a mixture of NaSi and AlCl (A = K, Rb and Cs) as the precursor for ion-exchange/electrochemical redox reactions by SPS. This novel synthetic approach indicates that SPS can be employed in topochemical ion exchange reactions, thus allowing for the rapid synthesis of single crystals of multinary intermetallic phases that cannot be accessible by traditional crystal growth techniques. In addition, a novel solution oxidation approach employing ionic liquids was employed in the synthesis of clathrates. Three uniquely different synthetic and crystal growth techniques were therefore developed under this project.

Fundamentals of Spark-Plasma Sintering: Material Processing for Energy Applications

Institution: San Diego State University
Point of Contact: Eugene Olevsky
Email: eolevsky@mail.sdsu.edu
Principal Investigator: Eugene Olevsky
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$253,000 (2014-2015)

PROGRAM SCOPE

The program is focused on the development of a multi-scale theory of spark-plasma sintering (SPS) of powder components. SPS is a rapidly emerging powder consolidation technique capable of producing highly dense materials with a significant potential for grain size retention. Potentially, SPS has many significant advantages over the conventional powder processing methods, including the lower process temperature, the shorter holding time, dramatically improved properties of sintered products, low manufacturing costs, and environmental friendliness. Practical implementations of the SPS' bright potential, however, are limited by the lack of theoretical concepts enabling the process predictiveness and optimization. The project introduces important mechanisms of both thermal and non-thermal nature in a novel generic micro-macro modeling framework for the description of spark-plasma sintering. The modeling activities are supported by unique experiments on the de-convolution of the heating rate-driven and electromagnetic field-imposed effects at various scale levels. The developed concepts are implemented in a novel multi-scale modeling framework describing spark-plasma sintering for the optimization of the fabrication of functional porous structures of nuclear fuel for modular multiplier reactors. Thereby, the main applied aspects of the project are concerned with exploring the previously non-investigated applications of spark-plasma sintering to the fabrication of structurally strong porous materials, which are of great interest for nuclear fuel and other energy-related applications. The collaborative component of the proposed program involves interactions between San Diego State University and General Atomics - one of the world's leading resources for the high-technology systems development.

FY 2014 HIGHLIGHTS

During the reported period the following major research results have been obtained: (I) By solving a number of problems to determine the micro-nonuniform temperature distribution in resistance heating of a copper powder with spherical particles, it was shown that the contact temperature may be substantially different from the average macroscopic temperature of the sample, up to melting of the contact upon slight increase in macro-temperature. (II) Inter-particle neck growth kinetics of vanadium carbide powder during initial stages of conventional and spark-plasma sintering has been investigated. The neck sizes derived from scanning electron microscopy observations were utilized in the inverse regression of the surface diffusion equation and led to the calculation of the value of the surface diffusion activation energy for the vanadium carbide powder. (III) The SPS overheating phenomenon was analyzed by varying the geometry of the tooling that exhibits the problem, namely by modeling various tooling configurations involving sequences of disk-shape spacers with step-wise increasing radii. The analysis was conducted to obtain a more suitable SPS tooling configuration with the avoidance of the overheating as a final aim. (IV) Fe, Ti powders and their mixtures were subjected to electric discharges in a hydrocarbon liquid. The obtained powder mixtures were consolidated by spark plasma sintering. The densification behavior, microstructure, phase composition and mechanical properties of the processed

powder samples were investigated. The developed fabrication approach represents a novel technological route for metal-ceramic powder composites' fabrication where the electromagnetic field assistance is employed at both powder synthesis and powder consolidation stages. The research results have been published in a number of refereed journals including Scripta Materialia, Intern. Journal of Refractory Metals and Hard Materials, Adv. Engineering Materials, and Materials.

Plasmonic Control of Radiation and Absorption Processes in Semiconductor Quantum Dots

Institution: Boston University
Point of Contact: Roberto Paiella
Email: rpaiella@bu.edu
Principal Investigator: Roberto Paiella
Sr. Investigator(s): Theodore Moustakas; Boston University
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$170,000 (2014)

PROGRAM SCOPE

This project is focused on the control of radiation and absorption processes in semiconductor photonic materials through the use of metallic nanoantennas. By virtue of their strongly confined plasmonic resonances, these nanostructures can concentrate incident radiation into sub-wavelength "hot spots" of highly enhanced field intensity, thereby increasing optical absorption by suitably positioned nanoscale absorbers. By reciprocity, the same nanoparticles (NPs) can also dramatically increase the spontaneous emission rate of radiating dipoles located within their hot spots. In this case, the far-field properties of the emitted light (e.g., polarization and directionality) are also determined by the nature of the plasmonic excitations involved in the radiation process. The NPs can therefore be used to enhance the light-emission efficiency of the underlying active material and at the same time control the output radiation far-field pattern. The study of these phenomena can address a number of basic questions related to the optical properties of metallic nanostructures, while at the same time pave the way to new device concepts, e.g., for sensing, optoelectronics, and photovoltaics. The specific semiconductor samples employed in this project involve quantum structures based on the InGaN materials system. While earlier work has focused on quantum wells, the use of highly localized quantum dots (QDs) is currently being pursued, which will allow us to directly probe the giant optical-field enhancements produced by metallic NPs in their hot spots. InGaN QDs are also promising for the demonstration of high-efficiency photovoltaic energy conversion based on the intermediate-band device concept – a potentially transformative application which could benefit strongly from the proposed plasmonic interactions. Thus, another important goal of this research is the demonstration of plasmon-enhanced light absorption via both interband and intraband transitions in InGaN QDs.

FY 2014 HIGHLIGHTS

The research activities carried out during FY 2014 have mostly focused on the development of high-quality InGaN QD samples with small dimensions (to enable fully three-dimensional quantum confinement) and high In content (to red-shift the bandgap energy into the green spectral region and beyond). Both of these conditions are particularly important for the intermediate-band photovoltaic application just described. The QD samples were grown using epitaxial self-assembly techniques based on the Stranski-Krastanov growth mode, and characterized using x-ray diffraction, AFM, SEM, and optical measurements. The results of these studies indicate that the QD optical properties are suitable to the investigation of the proposed plasmonic interactions. In particular, photoluminescence as well as

absorption due to transitions between quantum confined states in the QDs were observed. Regarding the metallic nanostructure development, a particularly significant outcome has been the demonstration of plasmonic beaming with simultaneously enhanced output light intensity. In prior work within this project, metallic nanoantenna arrays on InGaN quantum-well samples were developed to produce highly collimated radiation beams emerging from the sample surface along predefined geometrically tunable directions. At the same time, however, the total radiated power (i.e., integrated over all directions) was found to be somewhat reduced by the presence of the beaming nanostructures, due to optical losses in the metallic ground plane supporting the nanoantenna array. During the current reporting period, the array geometry has been modified to overcome this drawback, leading to the initial demonstration of plasmon-enhanced light emission combined with plasmonic beam shaping.

New Oxide Materials for an Ultra High Temperature Environment

Institution: Wisconsin-Madison, University of
Point of Contact: John Perepezko
Email: perepezk@engr.wisc.edu
Principal Investigator: John Perepezko
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The development of ceramics that provide a robust performance in an aggressive high temperature environment is a continuing challenge. The available ceramics such as zirconates, sialons, diborides or carbides satisfy some of the requirements such as high melting temperature, but they also exhibit limitations such as a high oxidation rate or surface decomposition especially in the presence of water vapor. What is needed for enhanced high temperature capability are new oxide materials. From the existing experience we are pursuing a new strategy that involves internal modification control of the outer surface of diborides to promote enhanced oxidation resistance. The internal modification focuses upon the development of a new oxide type based upon HfTaO ($n\text{HfO}_2 \cdot \text{Ta}_2\text{O}_5$, $5 \leq n \leq 7$) and ZrTaO superstructures which lowers the oxidation rate. The oxide superstructures are metastable in the binary Hf-O and Zr-O systems, but experiments confirm that they can be stabilized by Ta additions. The primary objective is to establish an understanding of the synthesis and performance of a new oxide materials class based upon HfTaO and ZrTaO superstructures. This includes: (1) synthesis of (Hf, Ta)_{B₂} multicomponent borides and the use of Hf-Ta alloys and the diboride as precursors to synthesize the HfTaO superstructures by high temperature oxidation; (2) evaluation of the phase stability at high temperature up to 2500°C and measurement of selected thermodynamic properties (i.e. C_p and α) by a differential scanning calorimeter (DSC) and high temperature XRD; (3) quantitative assessment of the oxidation resistance of the multicomponent borides and oxide superstructures by Thermal gravimetric analysis (TGA), measurement of weight change and oxide thickness to identify the oxidation mechanisms and synthesis kinetics of the multicomponent oxide superstructures. In addition to the primary objective, we also intend to evaluate the potential of the superstructures to develop low thermal conductivity.

FY 2014 HIGHLIGHTS

We have synthesized pure HfTaO oxides superstructures by fully oxidizing Hf-27Ta and Hf-35Ta alloy precursors. We have discovered a novel synthesis mechanism for the formation of the HfTaO

superstructures. During exposure to oxygen at high temperature (e.g. 1500°C) the initial homogeneous BCC solid solution dissolves oxygen. Next, the BCC phase with oxygen in solution undergoes a phase separation reaction to yield two BCC phases: a Hf-rich phase and a Ta-rich phase with both phases containing oxygen in solution. With continued exposure the oxygen content in the BCC phases increases to the level necessary to initiate the formation of monoclinic HfO₂ and orthorhombic Ta₂O₅. Lastly, the monoclinic HfO₂ is converted to a cubic structure and with further reaction the HfTaO orthorhombic superstructure is established at the outer surface region. To determine if this reaction pathway occurs in other systems we have examined the oxidation of a Zr-20Nb alloy and have confirmed a similar reaction sequence leading to the synthesis of ZrNbO superstructures. We also found that the Hf-27Ta alloy exhibits parabolic kinetics with a parabolic rate constant that is over 20 times lower than that for Hf at 1200°C. By using the pure HfTaO superstructures, we demonstrated that the HfTaO oxide superstructures are stable up to over 1800°C in air. The heat capacity of HfTaO at 1650°C was measured as 63.85 J•mol⁻¹•K⁻¹, which is much smaller the value of ZrO₂ (81.1 J•mol⁻¹•K⁻¹); thus, the HfTaO superstructure may have a lower thermal conductivity than ZrO₂. We have also successfully synthesized (Hf,Ta)B₂ borides by reaction synthesis. The formation enthalpies of HfB₂ and TaB₂ are (-328.9 kJ/mole) and (-209.2kJ/mole) respectively. Upon heating a well-mixed and compacted sample of elemental powders, the initiation of diboride formation is rapid and the adiabatic temperature rise is in excess of the diboride melting temperatures to enable formation of the diboride solid solution.

Phase Transformations and Equilibria in Complex Half-Heusler/Full-Heusler Nanocomposites

Institution: Michigan, University of
 Point of Contact: (Pierre) Ferdinand Poudeu-Poudeu
 Email: ppoudeup@umich.edu
 Principal Investigator: (Pierre) Ferdinand Poudeu-Poudeu
 Sr. Investigator(s): Ctirad Uher; Michigan, University of
 Anton Van der Ven; California-Santa Barbara, University of
 Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 5 Undergraduate(s)
 Funding: \$340,000 (2014)

PROGRAM SCOPE

This project focuses on experimental and theoretical investigations of the mechanisms of phase formation and transformations in various half-Heusler/ full-Heusler systems. The resulting HH_(1-x)/FH_(x) nanocomposites are structural characterized using a combination of X-ray diffraction and transmission electron microscopy. Finally, the mechanism by which FH nanostructures regulate electronic and thermal charge transport in the synthesized nanocomposites is investigated using a combination of transport and microstructural data.

FY 2014 HIGHLIGHTS

During the past four quarters of the project, we focused our attention on the synthesis, structural characterization, and evaluation of the thermal and electronic transport in p-type Ti_{0.5}Hf_{0.5}Co_{1+x}Sb_{0.9}Sn_{0.1} and n-type Ti_{0.1}Zr_{0.9}Ni_{1+x}Sn_{0.975}Sb_{0.025} nanocomposites. In addition, we have investigated the effect of synthesis and processing methods on the microstructure and electronic transport of bulk nanostructured half-Heusler phases and also obtained preliminary results on the theoretical investigation of the formation of full-Heusler precipitates in TiNiSn half-Heusler matrix. We show that *in situ* growth of coherent nanometer-scale full-Heusler (fH) quantum dots (fH-QDs) within the p-type Ti_{0.5}Hf_{0.5}CoSb_{0.9}Sn_{0.1} half-Heusler (hH) matrix induces a drastic decrease of the effective hole density

within the hH/fH-QD nanocomposites at 300K followed by a sharp increase with rising temperature. This behavior is associated with the formation of staggered heterojunctions with a valence band (VB) offset energy, ΔE at the hH/fH phase boundaries. The energy barrier (ΔE) discriminates existing holes with respect to their energy by trapping low energy (LE) holes, while promoting the transport of high energy (HE) holes through the VB of the fH-QDs. This “hole culling” results in surprisingly large increases in the mobility and the effective mass of HE holes contributing to electronic conduction. The simultaneous reduction in the density and the increase in the effective mass of holes resulted in large enhancements of the thermopower whereas; the increase in the mobility minimizes the drop in the electrical conductivity. Poudeu*, Full-Heusler nanostructures Boost Thermopower and Hole Mobility in Bulk p-type Half-Heuslers, *Nanoscale* 2013, 5, 9419-9427.

Improved Electrochemical Performance of Strained Lattice Electrolytes via Modulated Doping

Institution: Delaware, University of
Point of Contact: Ajay Prasad
Email: prasad@udel.edu
Principal Investigator: Ajay Prasad
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Solid electrolytes, found in batteries, fuel cells, and chemical sensors, are highly (and increasingly) important energy technology components. Nevertheless, the rigid atomic framework of solids provides for relatively few materials with high ionic conductivity, particularly at low temperatures. For example, solid oxide fuel cells typically must be operated at ≥ 800 °C in order to obtain sufficient oxygen ion conduction through the electrolyte. These temperatures necessitate the use of expensive components and limit device lifetimes, making them economically unfeasible at this time. Recently, the use of nanostructured multilayers has been proposed as a means to obtain vastly improved solid state ionic conduction. Unfortunately, the experimental evidence advocating these techniques has often been controversial. In addition, nearly all of the multilayers demonstrated have used layer materials wherein one of the layers was a poor ion conductor. In this project, we have sputter deposited nanostructured, pseudo-homoepitaxial multilayers of oxygen ion conductors. Impedance spectroscopy has been used to determine the effects of the spacing and magnitude of compositional (and therefore lattice parameter) modulation on the ionic conductivity. In addition, ionic analogues of the high electron mobility transistor (HEMT) were formed by modulation of the dopant and host atom concentrations, thereby forming high ionic mobility electrolyte layers in close proximity to layers with high dopant (and thus defect) concentration. Important discoveries made in this project include the ability to use heterogeneously distributed dopants to improve oxygen ion conduction in cerium oxide electrolytes and quantification of the linear strain effect on oxygen vacancy mobility, among others. Oxygen ion conductors, with application to SOFCs, were used in this study; however, the concepts and methods discovered are believed to carry over to other ionic conduction systems.

FY 2014 HIGHLIGHTS

This project previously found that 100 nm or thicker yttria-stabilized zirconia (YSZ) films exhibited lattice parameters and oxygen ion conductivities similar to bulk samples, but that lattice strain and increased

ion conductivity resulted as the thickness decreased to 6 nm. This project year found that these thinnest films exhibit a second significant conduction mechanism. Specifically, we showed for the first time that in humid environments, proton conduction along the free surface of ultrathin YSZ can become comparable to oxygen ion conduction through the volume, even > 200 °C. Building on prior project year's discovery that alternating nanolayers of pure Y₂O₃ and pure CeO₂ yields ion conduction in space charge regions at the interface, the effects of dopant type were examined during this project year. The Gouy-Chapman model previously implemented to describe space charge region conduction had to be generalized, as it could not account for significant differences in conductivities as the Y₂O₃ was replaced with Gd₂O₃ and La₂O₃. Promisingly, we showed for the first time that heterodoped ceria can support a low activation energy of conduction despite high overall dopant concentration, improving the low temperature conductivity relative to other dopant strategies. Finally, nanostructured multilayers of ceria-zirconia interleaved with either doped ceria or YSZ were fabricated and characterized. The multilayers with doped ceria showed strain was effectively created, with the ceria compressed by up to 2.2% and with concomitant ionic conductivity reductions by a factor of as much as 3. This project thus provides some of the most unambiguous evidence of a strain-ionic conductivity relationship to date. Multilayers with YSZ exhibited non-elastic accommodation of the lattice mismatch, and no change in conductivity was observed. The past year's project work has resulted in 8 peer reviewed papers and the PhD conferral on both supported students.

New Optoplasmonic Materials for Next Generation Energy Systems

Institution: Boston University
Point of Contact: Bjoern Reinhard
Email: bmr@bu.edu
Principal Investigator: Bjoern Reinhard
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

This project develops new classes of optoplasmonic materials that amalgamate the advantages of conventional photonic and plasmonic electromagnetic materials. Optoplasmonic materials provide unique opportunities for enhanced light capture and energy transfer/storage through the availability of delocalized photonic-plasmonic modes. These opportunities can be translated into custom-designed optoplasmonic materials for a variety of applications, including enhanced light absorption and generation of carriers in semiconductors, enhanced light processing and transfer, and controlling cooperative interactions of atomic and molecular systems. However, a precise understanding of the, as yet unknown, electromagnetic coupling mechanisms underlying the near- and far-field optical properties of these mixed metal-dielectric materials is required to achieve these goals. The overarching theme of this project is the development of this understanding for morphologically well-defined networks and extended two-dimensional arrays of noble metal nanoparticles and dielectric resonators. Electromagnetic interactions between the photonic (dielectric particles) and plasmonic (noble metal nanoparticles) building blocks in the resulting multi-scale structures can be manipulated to create a collective photonic-plasmonic response which is more than just the simple summation of the properties of the individual components. Rationally designed optoplasmonic materials hold the potential to pave the road to entirely new device functionalities. Optoplasmonic materials with custom tailored optical responses that can localize, enhance, and transfer the incident light with high spatial control could, for instance, enhance light conversion efficiencies across the entire visible range and beyond. We focus in

this project on the development of reliable fabrication approaches to implement and test these novel materials and then elucidate their physical working principles.

FY 2014 HIGHLIGHTS

We have developed new colloidal assembly techniques that facilitate the integration of electromagnetically strongly coupled plasmonic clusters and colloidal high refractive index materials (e.g. TiO₂ nanoparticles) into optoplasmonic hetero-nanoparticle arrays. The developed fabrication tools provide control over interparticle separations from a few to hundreds of nanometers, which provides important degrees of freedom for tuning near- and far-field optical responses as well as tailoring the optical phase landscape. We were able to demonstrate – experimentally as well as through electromagnetic simulations – that these new materials give rise to a cascaded electromagnetic field enhancement when delocalized photonic array resonances couple to localized surface plasmon resonances of the plasmonic nanoparticle clusters. Importantly, the photonic-plasmonic mode coupling did not only affect the electromagnetic hot-spots located in the metal nanoparticle clusters, but also achieved a general increase of field intensity throughout the array. The generation of an increased electromagnetic field enhancement in the entire array is an important step towards the engineering of homogeneously “hot” surfaces for enhancing light-matter interactions in a large volume of the ambient medium. In a subsequent step of this work we have refined our fabrication strategies to allow the combination of gold nanoparticles with high refractive index silicon nanoresonators. The coupling of plasmonic antenna and high refractive index silicon allows a coupling of electronic and magnetic resonances and we were able to show that metal-silicon hybrid resonators achieve a dramatic radiative rate enhancement with defined spatial emission properties. We have also demonstrated an on-chip photon transfer over several microns in networks of optoplasmonic structures made of whispering gallery mode resonators (dielectric microspheres) containing plasmonic antennas in their equatorial plane.

Using Interfaces to Create Strongly-Coupled Magnetic-Ferroelectrics via Atomic-Scale Heteroepitaxy

Institution: Cornell University
Point of Contact: Darrell Schlom
Email: schlom@cornell.edu
Principal Investigator: Darrell Schlom
Sr. Investigator(s): Craig Fennie; Cornell University
David Muller; Cornell University
Students: 4 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$680,000 (2014)

Jointly funded by “Electron and Scanning Probe Microscopies” and “Synthesis and Processing Science”

PROGRAM SCOPE

Our objective is to create a ferromagnetic ferroelectric that can be deterministically switched between symmetry equivalent states using an electric field. The electric-field switching of a magnetization between 180° symmetry equivalent states has not been demonstrated in any material. The required coupling between ferroelectric and ferromagnetic domains allowing such switching is a missing feature in most multiferroics and is key to advancing the field both scientifically and technologically. Starting at the level of electrons and atoms our goal is to rationally design complex oxide heterostructures and interface-materials with this targeted emergent behavior. Using a combination of symmetry arguments and first-principles calculations to explore the connection between structural distortions and

ferroelectricity in the perovskite family of materials, we have predicted electrical control of magnetism in the hexagonal rare earth ferrites. These realizations are created with atomic-layer precision, microscopically interrogated to see if there are competing mechanisms to the intended realization, and finally their macroscopic properties are measured. Here we will develop the scientific ideas and experimental tools necessary to apply this design paradigm to the creation of multiferroics with unprecedented coupling between ferroelectric and magnetic order parameters.

FY 2014 HIGHLIGHTS

We have studied, both theoretically and experimentally, the properties of metastable hexagonal rare-earth ferrites with the $YMnO_3$ structure. In the hexagonal rare-earth manganites ($RMnO_3$), improper ferroelectricity (trimerization) leads to a network of coupled structural and magnetic vortices that induce domain wall magnetoelectricity and magnetization (M), neither of which, however, occurs in the bulk of these materials. It is relegated to the domain walls. Through a combination of first-principles calculations, group-theoretic techniques, and microscopic spin models, we have shown how the trimerization not only induces a polarization (P), but also a bulk M and bulk magnetoelectric effect. This results in the existence of a bulk linear magnetoelectric vortex structure or a bulk magnetoelectric coupling such that if P reverses so does M. We determined the intrinsic properties of the metastable hexagonal polymorph of $LuFeO_3$. We find that hexagonal $LuFeO_3$ is a canted antiferromagnet with $T_N=147$ K and a saturation magnetization, $M_s=0.018 \mu_B/Fe$. We have combined $LuFe_2O_4$ which is ferrimagnetic below 240 K, although it is not ferroelectric, with hexagonal $LuFeO_3$ that is a robust high-temperature ferroelectric with a closely related structure. The resulting precisely engineered $(LuFeO_3)_n(LuFe_2O_4)_m$ superlattices are strong ferrimagnet-ferroelectrics with the highest-known simultaneous transition temperatures. Using scanning transmission electron microscopy imaging and spectroscopy we have mapped the structure, chemistry, and polarization of these artificial multiferroics. Our results show that the superlattices have a higher ferrimagnetic ordering temperature (T_C) than either of the end members, $LuFe_2O_4$ and $LuFeO_3$, from which they are created. T_C increases to nearly room temperature with simultaneous ferroelectricity, suggesting the tantalizing prospect of the existence of the world's first single-phase room-temperature ferrimagnetic ferroelectric.

Discovery and Crystal Growth of New Oxide Phases from Metal Fluxes

Institution: Florida State University
Point of Contact: Theo Siegrist
Email: siegrist@eng.fsu.edu
Principal Investigator: Theo Siegrist
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

Discovery and growth of crystalline materials is one of the key areas in materials research. New materials, and engineering of their properties, have produced tremendous progress. The search for new materials with novel properties remains an ongoing activity. Of the many oxide single crystal growth methods, flux growth has proven to be an excellent method for exploratory synthesis work that also will yield crystals large enough for structural and physical characterization. Using metal fluxes to grow oxide phases produces a unique crystal growth environment, where oxygen is now a minority constituent. The low melting point of certain metal fluxes in use allows low temperature synthesis, and gives access to

potentially metastable and hard to crystallize phases. We are investigating single crystal oxide growth from alkaline earth metal fluxes, where the sizable oxygen solubility as well as good solubility of lanthanides is used to discover new phases. The reactivity of the flux can be tailored to provide reducing conditions for oxide growth by using alkaline earth mixtures, or the flux material can also be incorporated into the oxide. In particular, the low temperature eutectic mixtures of magnesium with calcium, strontium and barium provide control not only over crystal growth temperatures, but also the reactivity of the flux and its power to reduce lanthanide oxides. Furthermore, alkaline earth metal fluxes have simultaneous solubility for oxides, halides, hydrides, and chalcogenides; therefore new phases are expected to form under unusual conditions.

FY 2014 HIGHLIGHTS

The arrangement of lanthanide ions in the $BaLn_2O_4$ family of compounds ($Ln=La$ to Lu , Y) produces two trigonal ladders. The magnetic interactions of the lanthanide ions is thus expected to be frustrated, since the distances and angles in the Ln ladders are close to a regular triangle. The whole family of compounds was synthesized for the first time in single crystal form, allowing a detailed investigation of the structural changes induced by different sizes of the lanthanide ions. The magnetic properties of the series were further investigated, and geometric frustration has been observed. In the case of the prototypical $BaGd_2O_4$, the expected antiferromagnetic ordering temperature is around 10K, whereas the actual transition is at 2.7K. The two phases that indicate a high degree of frustration are $BaCe_2O_4$ and $BaYb_2O_4$. The former has one electron in the f-shell, whereas the latter has one hole in the f-shell. Structurally, the two ladders differ more in $BaCe_2O_4$ than in $BaYb_2O_4$, making $BaYb_2O_4$ more frustrated than $BaCe_2O_4$. Additionally, crystal field effects are observed in both compounds. A simple new phase has been discovered, Ba_2TeO , and Roxy-telluride, showing that a barium metal flux can have simultaneous solubility for oxygen as well as tellurium. The structure is a semiconductor, with a band gap of the order of 3eV, as measured by optical transmission, and confirmed by DFT calculations. The structure combines elements of the NaCl-type $BaTe$ and BaO structures: two layers of $BaTe$ alternate with one layer of Ba_2O_2 , forming a tetragonal layer structure. The in-plane compressive stress on the Ba_2O_2 layer results in the oxygen atoms moving out of the plane, giving a puckered Ba_2O_2 layer that is related to the inverse PbO -type structure. Testing of the barium flux for antimony and bismuth solubility, two new phases were discovered: $SmMg_2Bi_2$ and $SmMg_2Sb_2$. These compounds crystallize in the hexagonal Mg_3Sb_2 -type and may be potential thermoelectric materials.

Epitaxial Electrodeposition of Metal Oxide Thin Films and Superlattices for Energy Conversion and Storage

Institution: Missouri University of Science
Point of Contact: Jay Switzer
Email: Jswitzer@mst.edu
Principal Investigator: Jay Switzer
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$187,000 (2014)

PROGRAM SCOPE

Although the electroplating of metals is a mature technology, the electrodeposition of metal oxide ceramics is still in its infancy. The metal oxide films and nanostructures are electrodeposited by driving chemical reactions at electrode surfaces. It is a bottom-up processing methods in which solids are

assembled from molecules and ions in solution- much like biomineralization The focus of the project is the electrodeposition of metal oxide semiconductors, catalysts, and pseudocapacitor materials for energy conversion and storage. Specific topics we plan to explore are (i) electrodeposition of crystalline cobalt oxide- a potent oxygen evolution reaction, (ii) electrochemical reduction of epitaxial metal oxides to epitaxial metals and alloys, (iii) electrodeposition of nanostructured metal oxides for pseudocapacitors, and (iv) electrodeposited plasmonic nanostructures for photovoltaics. The research strongly emphasizes the basic science behind the electrodeposition of epitaxial and nanostructured metal oxides.

FY 2014 HIGHLIGHTS

Germanium is a group IV semiconductor with superior electronic properties compared with silicon, such as larger carrier mobilities and smaller effective masses. It is also a candidate anode material for lithium-ion batteries. This year, we introduced a one-step method to electrodeposit dense arrays of germanium nanowires onto indium tin oxide (ITO) substrates from aqueous solution. The electrochemical reduction of ITO produces In nanoparticles that act as a reduction site for aqueous Ge(IV) species, and as a solvent for the crystallization of germanium nanowires. Nanowires deposited at 95 °C have an average diameter of 100 nm, whereas those deposited at room temperature have an average diameter of 35 nm. Both optical absorption and Raman spectroscopy suggest that the electrodeposited germanium is degenerate. The high conductivity of the wires should make them ideal for lithium-ion battery applications. The results were published in ACS Nano. We also electrodeposited Co/CoOOH islands on n-Si to produce a photoanode for the photoelectrochemical splitting of water into hydrogen and oxygen. The n-Si/SiO_x/Co/CoOOH photoanode functions as a solid-state metal-insulator semiconductor (MIS) photovoltaic cell with spatially nonuniform barrier heights in series with a low overpotential water-splitting electrochemical cell. The results are under consideration for publication in Nature Materials.

Enhanced Materials Based on Submonolayer Type-II Quantum Dots

Institution: New York-City College, City University of
Point of Contact: Maria Tamargo

Sr. Investigator(s): Igor Kuskovsky; New York-Queens College, City University of
Ismail Noyan; Columbia University
Carlos Meriles; New York-City College, City University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$209,000 (2014)

PROGRAM SCOPE

During the past few years we have investigated a nanostructured material known as sub-monolayer type-II QDs, made from wide bandgap II-VI semiconductors. Our goal is to understand and exploit their tunable optical and electrical properties, by taking advantage of the type-II band alignment and quantum confinement effects. Type-II ZnTe quantum dots (QDs) in a ZnSe host are particularly interesting because of their large valence band and conduction band offsets. In the current award we aim to develop enhanced materials based on these sub-monolayer type-II QDs, with emphasis on materials that may be advantageous for photovoltaic and spintronics applications. We also propose to expand the structural characterization of these materials by refining our X-ray diffraction methodologies. Last year we reported extensive work with ZnTe/ZnCdSe type II QDs materials that have

ideal properties for the development of intermediate band solar cells (IBSC). We also began a systematic approach to define the structural properties of these QDS, such as their size and their distribution, and began to investigate spin dynamics of these type II QDS. The past year we 1) developed new ways to analyze and model high resolution X-ray diffraction (HRXRD) techniques to extract structural details of sub-monolayer type II QD structures, 2) developed a model and made experimental validation of an approach to measure in-plane dimensions of the QDs and developed a model to calculate the dependence of QD size and density on the molecular beam epitaxy (MBE) growth conditions, 3) measured the linear polarization of the photoluminescence (PL) and confirmed the predictions obtained from HRXRD of anisotropic shape of the QDs, 4) made temperature dependent time resolved Kerr rotation (TRKR) studies to explore the spin dynamics of these materials, and 5) initiated studies of the growth of the so called "inverted" structure, in which the QDs are ZnSe and the matrix is ZnTe, which results in a material in which electrons are localized rather than holes.

FY 2014 HIGHLIGHTS

We previously reported high resolution X-ray diffraction (HRXRD) studies using a 1D model, in which the quantum dot (QD) layer was considered as a continuous layer, limiting the information that could be obtained. We have now used out-of-plane diffuse scattering and in-plane 3D mapping to obtain detailed structural information about the QDs. By performing small angle reciprocal space map around a reflectivity satellite, a 'fish bone' structure was observed, and related to the vertical correlation of QDs. 3D mapping presents a strong anisotropy in the diffuse scattering related to the QD shape. A QD elongation is seen in the $\langle 110 \rangle$ directions, consistent with anisotropy in the adatom mobility in the ZnSe surface. The shape of the QDs predicted by HRXRD should produce an optical anisotropy. To investigate this, we analyzed the linearly polarized PL emission. The collected PL intensity was found to be changing as we varied the analyzer angle, with the PL linearly polarized along the [110] axis of the sample, consistent with the anisotropy observed by HRXRD. The results obtained from PL and magneto-PL, HRXRD and secondary ion mass spectrometry data were combined to evaluate the QD density. We obtained the dependence of average QD volume and density on the Te flux and number of Te cycles, and show that these are the key parameters to control the QD dimension and distribution. The previously estimated radius of the stacked QDs was based on the assumption that the hole is strongly confined at the center of the dot. However, within the QD plane the Coulomb interaction between electron and hole should be much stronger than the quantization due to kinetic motion, and the trajectory of the hole is as important as that of electron. We have modified our model and applied a lateral tightly-bound exciton approach that takes into account the lateral wavefunction of the hole. The angular motions of the hole and the electron are strongly correlated, forming a well-defined dipole.

Directed Assembly of Rod-Coil Block Copolymers By Combined External Fields

Institution: Colorado State University
Point of Contact: David (Qiang) Wang
Email: q.wang@colostate.edu
Principal Investigator: David (Qiang) Wang
Sr. Investigator(s): David Dandy; Colorado State University
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The overall goal of this project is to understand, predict, and ultimately control the self-assembled nanostructures of rod-coil (RC) block copolymers in bulk, under thin-film confinement and with applied magnetic field. Photovoltaic (PV) energy obtained using conjugated (semiconducting) polymers is very attractive due to its cheap materials, low processing cost, and ease of large-scale manufacture. Control of the polymer morphology and structure at the nanoscale is critically important for optimizing the efficiency of polymer optoelectronic devices. The underlying hypothesis of this research is that such control can be achieved with magnetic-field directed assembly in thin films of RC block copolymers containing conjugated rod blocks. Using judiciously designed models and carefully selected methods, including 3D real-space parallel self-consistent field (SCF) calculations with high accuracy and newly proposed fast off-lattice Monte Carlo (FOMC) simulations with soft potentials that allow particle overlapping, we will examine in detail the effects of key factors (rod block length and volume fraction, RC incompatibility, orientational interaction between rod blocks, bending rigidity of rod blocks, and system fluctuations/correlations) on the self-assembled morphology of RC diblock copolymers (DBC) in bulk, as well as the effects of external conditions (surface preference, film thickness, substrate topology, and applied magnetic field strength) for obtaining the optimal structures of bulk heterojunction in RC DBC thin films optimal for PV cells. This research will allow knowledge-based rational design of these nanomaterials, instead of trial-and-error experiments in a large parameter space, which will advance their integration into a range of technologically important applications, including the fabrication of polymer-based PV cells, light-emitting diodes, field-effect transistors, and chemical and biological sensors.

FY 2014 HIGHLIGHTS

Based on the computationally efficient soft-core spherocylinder model for the orientational interaction between rod blocks previously developed and validated in this project, we have performed FOMC simulations to study the self-assembled morphology of RC DBCs in bulk as a function of rod block length and volume fraction, RC incompatibility, and orientational interaction between rod blocks. We have also developed efficient algorithms for the corresponding 3D real-space parallel SCF calculations based on the same model system used in our FOMC simulations, and examined the effects of system fluctuations/correlations by direct comparisons between FOMC and SCF results. These lead to two manuscripts being prepared for publication. We are currently working on the effects of external conditions on the morphology in RC DBC thin films.

Surface-Reaction-Limited Pulsed Chemical Vapor Deposition for Growing Nanowires Inside Highly-Confining Spaces

Institution: Wisconsin-Madison, University of
Point of Contact: Xudong Wang
Email: xudong@engr.wisc.edu
Principal Investigator: Xudong Wang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$210,000 (2013-2014)

PROGRAM SCOPE

The objective of this proposed research is to obtain in-depth understanding of the nanoscale crystal growth behavior in a surface-reaction-limited pulsed chemical vapor deposition (SPCVD) process, and thereby achieve well-controlled syntheses of three-dimensional (3D) nanowire (NW) arrays inside highly-confined spaces. In order to obtain in-depth understanding of the entire SPCVD process and eventually develop it into a versatile, highly controllable, and large-scale NW manufacturing technology, we propose an experiment-based project to study the nucleation and anisotropic crystal growth mechanisms of titanium dioxide (TiO_2) and extend it to the growth of other functional materials. The following four aspects will be investigated: (1) Study the atomic recombination and restructuring on TiO_2 crystal surfaces, and understand how a continuous polycrystalline atomic layer deposition (ALD) film is evolved into discrete NW arrays. (2) The window of this precursor-concentration-independent growth will be determined in order to perform valid SPCVD growth inside various 3D-confined spaces. (3) Understand how to apply SPCVD to other material systems including oxides (ZnO , In_2O_3 , SnO_2 , V_2O_5) and nitrides (GaN , AlN). (4) The pulsed precursor supply during SPCVD offers an opportunity to introduce impurity atoms (dopants) into the NW lattice. The doping mechanisms, dopant concentration control, and corresponding optical and electronic properties will be studied. This project will provide in-depth, experimentally grounded understanding of the nucleation and anisotropic crystal growth mechanisms of the SPCVD process. The outcome of this project will be a powerful NW synthesis technique that can uniformly grow NW arrays of controlled composition and morphology inside 3D-confined and submicron-sized spaces, thus enabling the creation of a variety of new functional nanomaterial architectures for the applications of electrochemical and photovoltaic electrodes, sensor elements, and catalysts.

FY 2014 HIGHLIGHTS

Our accomplishments during the report period include three aspects: (1) Observation of the Ostwald-Lussac Law in high-temperature atomic layer deposition (ALD). Through atomistic electron microscopy study of surface-reaction-limited pulsed chemical vapor deposition (SPCVD) TiO_2 nanostructures at designed growth cycles, we found that the evolution of TiO_2 nanostructures in ALD follows a path from amorphous layers to amorphous particles to metastable crystallites and ultimately to stable crystalline forms. Such a phase evolution is a manifestation of the Ostwald-Lussac Law, which governs the advent sequence and amount ratio of different phases in high-temperature TiO_2 ALD nanostructures. This discovery provides a new understanding of morphology and property variation, and phase non-uniformity in ALD thin films and nanostructures. (2) Observation of vapor-solid Kirkendall effect in ZnO-to- TiO_2 nanostructure conversion. Following our previous research on SPCVD of TiO_2 NRs on Si NWs, we explored the application of SPCVD of TiO_2 NRs on ZnO NWs. By introducing TiCl_4 vapor pulses to ZnO NW templates, we obtained TiO_2 nanotubes with well-preserved dimensions and morphology. This process involved the cation exchange reaction between TiCl_4 vapor and ZnO solid and the diffusion of reactants and products in their vapor or solid phases, which was a manifestation of the Kirkendall effect. This discovery offers a new route for hierarchical functional nanomaterial assembly and application. (3) Development of highly-efficient capillary photoelectrochemical (PEC) solar-fuel generation. 3D fibrous TiO_2 nanotube architecture was synthesized by ALD of TiO_2 films over cellulose nanofiber templates. In this design, capillary force could drive the electrolyte to the active area quickly and continuously. It mimics the mass transport process in natural photosynthesis, where the interaction between light and reaction sites is no longer limited by the volume, surface and depth of electrolyte.

Boron-Based Nanostructures, Stability, Functionality and Synthetic Routes

Institution: Rice University, William Marsh
Point of Contact: Boris Yakobson
Email: biy@rice.edu
Principal Investigator: Boris Yakobson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$510,000 (2014-2017)

PROGRAM SCOPE

This project goal is to advance our theoretical understanding of the boron assembly into nanoscale structures, initially ignited by the prediction of B_{80} fullerene. Theoretical modeling and assessment of possible structures and their properties, has then expanded towards the emerging area of two-dimensional (2D) materials and 1D nanowires. The project focus has been mainly on two important examples, representing in certain way two extreme cases: pure elemental B as most subtle and not yet synthesized in the laboratories, and h-BN-hexagonal boron nitride, a.k.a. 'white graphene'--a very stable compound with the array of useful properties available for experiments. In the meantime, a spectacular confirmation of pure boron Buckyball (B_{40} in recent report by the US-China collaborative team), has brought these exotic clusters back to focus. Extending the search to a broader spectrum of 2D boron-rich compounds whose synthesis can be rationalized, and properties can be explored in detail, constitutes the overall scope. Based on the first-principles computations, both synthesis and property characterization of several boron-rich nanostructures, including two-dimensional crystals of B_{12} , as well as novel layers of BC_3 , BSi, B_2O_3 , and B_xS_y composition, remain important lines of work.

FY 2014 HIGHLIGHTS

Motivated by experimental identification of B_{40} , recent comprehensive computational analysis revealed (i) mapping of B_{40} topological structure onto formal 2D-precursor monoatomic sheet; (ii) its instability with respect to dimerization and fusion; (iii) how it can be well isolated/preserved inside the inert carbon nanotubes or as adsorbed on graphene layer. Another class of pure-boron nanostructures are 1D linear chains, where density functional theory computations establish the possibility of a metastable (stable under tension) monoatomic chain $*B*B*B*B*$ (similar to C-chain carbyne!) and a free-standing more stable double-zigzag B-chain (with B_3 triangles serving as units). Electronic and mechanical properties, as well as chemical reactivity, establish the identity of these novel 1D-materials of boron. Among the boron compounds, one particularly important and recently synthesized is BN|C (coplanar BN with graphene) hybrid. Details of the optimal grain boundary interface structures are formulated in terms of tilt angle, lattice mismatch strain and deviation angle from the bisector line (reminiscent of Snell's law in optics), in good agreement with comprehensive numerical analyses. The ground state structures of the grain boundaries manifest as a series of laterally misaligned bisector segments, which are verified by intensive first-principle calculations. These findings not only provide a general guidance for exploring boundaries in various hybrid 2D materials but also serve as an important stepping stone for understanding mechanical and electronic behaviors in the boron-doped graphene and other hybrids.

Mapping the Synthetic Routes for 2-Dimensional Materials

Institution: Rice University, William Marsh
Point of Contact: Boris Yakobson
Email: biy@rice.edu
Principal Investigator: Boris Yakobson
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$510,000 (2014-2017)

PROGRAM SCOPE

This project is motivated by three concurrent factors: (i) an intensified worldwide interest in two-dimensional (2D) materials, (ii) our laboratory's general approach to modeling the growth of graphene; (iii) emergent findings—including some in our own work—of specific functionalities among 2D materials, relevant to DOE interests, such as potential battery electrodes, catalytic activity, tunable energy band gaps for electronics, interfaces in heterogeneous systems for photovoltaics, etc. This raises broader compelling questions about the ways of making such monoatomic layers. The exfoliation from natural bulk precursors (3D bulk→2D layer) is not scalable. On the other hand, their synthesis—often called 'growth' due to visible change in size and shape—through chemical vapor deposition (CVD) involves complex gas-solid chemistry, which may work empirically, but its theoretical understanding and sentient design remain in infancy. This project will develop the state of the art multiscale models of 2D-layers on substrates, atomistic mechanisms of their nucleation (when the 2D island may or may not be preferred over the 3D cluster) and subsequent growth. Methods, from the first principles density functional theory to the nucleation and growth theories, organized in the nanoreactor mass-flow diagram, will be connected to larger-scale models (Monte Carlo, phase field, level sets). The focus on already established materials of interest, graphene (C), boron nitrogen (h-BN), transition metal disulfides like MoS₂, along with the emergent or even hypothetical borophene (B), phosphorene (P), stanene (Sn), and silicene (Si). Impact of this project, even if only successful for a subset of examples, could be enormous, leading to efficient synthesis of materials with novel desired properties. It will impact fundamental studies in this field, as well as permit various applications in devices, energy utility and production, of commercial and defense significance.

FY 2014 HIGHLIGHTS

The deep gap states created by defects in semiconductors typically deteriorate the performance of (opto)electronic devices. This has limited the applications of two-dimensional (2D) metal dichalcogenides (MX₂) and underscored the need for a new 2D semiconductor without defect-induced deep gap states. Comprehensive analysis has demonstrated that one 2D monoelemental semiconductor is a promising candidate. This is exemplified by first principles study of 2D phosphorus (P), a recently fabricated high-mobility semiconductor. Most of the defects, including intrinsic point defects and grain boundaries, are electronically inactive, thanks to the homoelemental bonding, which is not preferred in heteroelemental system such as MX₂. Unlike MX₂, the edges of which create deep gap states and cannot be eliminated by passivation, the edge states of 2D P can be removed from the band gap by hydrogen termination. It is further found that both the type and the concentration of charge carriers in 2D P can be tuned by doping with foreign atoms. This study sheds light on the role of defects in the electronic structure of materials, and how they can be made more energy efficient while also better performing in the devices.

Atomic Layer Deposition (ALD) of Metal and Metal Oxide Films: A Surface Science Study

Institution: California-Riverside, University of
Point of Contact: Francisco Zaera
Email: zaera@ucr.edu
Principal Investigator: Francisco Zaera
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$200,000 (2014)

PROGRAM SCOPE

The main objective of this research project has been to advance the fundamental knowledge of the surface chemistry of ALD precursors needed for the design and optimization of film deposition processes. A modern surface-science approach is being used to both elucidate the mechanisms of the reactions of the precursors on the surface and characterize the composition and morphology of the growing films. Special emphasis has been placed on: (1) Identifying the primary reactions that may lead to the deposition of clean films; (2) Identifying the secondary reactions that may help the ALD process, by, for instance, helping with the reduction (or oxidation) of the metal atom; (3) Identifying the secondary reactions that may lead to the deposition of impurities in the growing films; (4) Determining the kinetic parameters of the relevant surface reactions in order to define the optimum conditions for film deposition and to minimize impurity deposition; (5) Characterizing the nature of the resulting films, with focus on their stoichiometry and on the oxidation states of the elements; and (6) Using the information obtained to propose better precursors for given ALD processes. The depositions of two specific types of thin films relevant to microelectronics manufacturing are being studied here: (1) Transition metal films, Cu in particular, for electrical interconnects; and (2) Transition metal oxides and nitrides for diffusion barriers.

FY 2014 HIGHLIGHTS

The surface chemistry of bis[(N,N'-di-sec-butyl acetamidinate)Cu], the basis for our initial studies on Cu(110), was extended to investigate the differences in deposition with active metal surfaces such as Ni(110). A series of thermal stepwise conversions were identified, starting with the partial dissociative adsorption of the copper acetamidinate dimers into a mixture of monomers and dimers on the surface. An early dissociation of a C–N bond leads to the production of N-sec-butylacetamide, which is detected in the temperature program desorption (TPD) experiments in three temperature regimes, the last one centered around 480 K. Butene, and a small amount of butane, is also detected above approximately 500 K, and hydrogen production, an indication of dehydrogenation of surface fragments, is observed at 460, 550 and 670 K. All this chemistry shares common steps with that previously reported on Ni(110), but occurs at higher temperatures. The chemistry of second generation of acetamidinate precursors was also tested, tetrakis[Cu(I)-N-sec-butyl-iminopyrrolidinate] and bis[Cu(I)-N,N-dimethyl-N',N'-di-iso-propyl-guanidinate], on Ni(110). It was found that both precursors, which exist as tetramers and dimers in the solid phase, respectively, undergo dissociative adsorption at temperatures below 200 K to produce adsorbed monomers on the surface. A beta-hydride elimination step leads to the release of some of the ligands in dehydrogenated form at 300 K. The remaining adsorbates undergo similar decomposition between 350 K and 600 K as the copper atoms are reduced from a Cu(I) oxidation state to metallic Cu(0). Ethene and acetonitrile are produced from the Cu(I)-iminopyrrolidinate, and propene from the Cu(I)-guanidinate, and HCN from both. These results suggest a common behavior in the surface

reactions of these families of ALD precursors. Finally, we have also published several invited to write reviews on the subject of ALD.

EARLY CAREER: Utilizing Molecular Self-Assembly to Tailor Electrical Properties of Si Nanomembranes

Institution: Michigan State University
Point of Contact: PengPeng Zhang
Email: zhang@pa.msu.edu
Principal Investigator: PengPeng Zhang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The program is focused on understanding the various interfacial phenomena, including self-assembly of organic molecules, charge injection, distribution, and separation at the organic–inorganic hetero-interface that control electronic behavior. Interfacing organic molecules with semiconductors, in particular, with semiconducting nanostructures where materials transport properties are sensitive to the surface and interface conditions such as surface states, surface charges, defects, traps, and dipole layers, offers a great opportunity to unravel the mechanistic basis of electronic interactions at hetero-interfaces. It can also potentially provide a nondestructive method for doping nanoscale semiconductors with molecular-scale precision. Moreover, this work will explore the possibility and develop strategies to grow highly ordered and tunable organic molecular thin films which have been proven to be a significant challenge due to the delicate balance required between the interactions governing the molecular growth, i.e., the molecule-substrate and molecule-molecule interactions. Scientifically, the aim is to promote the understanding and control of hetero-interfaces between organic and inorganic materials. Technologically, the hetero-interfaces are crucial in the development of organic electronics, molecular electronics, molecular and biological sensors, and energy converting devices.

FY 2014 HIGHLIGHTS

(1) Achieve the growth of highly ordered organic molecular thin films in both the in-plane and out-of-plane directions on the deactivated Si(111)-B surface. Recently, we reported the multilayered growth of zinc phthalocyanine (ZnPc) on the Si(111)-B surface. We find that access to the anisotropic step-flow growth mode provides a means to accomplish long-range in-plane molecular ordering. Meanwhile, the titled orientation of the ZnPc molecules allows for the out-of-plane π - π stacking, leading to the formation of a stable molecular structure with the same molecular packing to coverage of 40 monolayers. (2) Explore the effects of Ehrlich-Schwoebel barrier (ESB) and grain boundary crossing barrier on the growth dynamics of organic thin films. It is known that energetics and kinetics both play important roles in controlling the thin film morphology. In the ZnPc growth on the Si(111)-B surface, we find that the Ehrlich-Schwoebel barrier (ESB) associated with the ZnPc step edges is negligible, while the formation of molecular domain boundaries provides an activation barrier and additional nucleation sites. By increasing the substrate temperature, the grain boundary density is significantly reduced, resulting in a well-controlled surface morphology.

Giant Electrocaloric Effect in Ferroelectric Polymers with Tailored Polar-Nanostructures

Institution: Pennsylvania State University
Point of Contact: Qiming Zhang

Email: qxz1@psu.edu
Principal Investigator: Qiming Zhang
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 4 Graduate(s), 1 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Basic molecular and nanostructural considerations, experimental results, and phenomenological theory all suggest the existence of giant electrocaloric effect (ECE) in the normal ferroelectric and defect modified polyvinylidene fluoride (PVDF) based polymers. The research works supported by this DOE program confirmed this hypothesis and demonstrated that indeed giant ECE can be obtained in the normal ferroelectric P(VDF-TrFE) (TrFE: trifluoroethylene) copolymer and relaxor ferroelectric polymers. In the DOE program, we showed that in P(VDF-TrFE) 55/45 mol% copolymer, an isothermal entropy change $\Delta S > 50$ J/kgK and adiabatic temperature change $\Delta T > 12$ °C can be induced at ferroelectric-paraelectric transition (FE-PE). Moreover, by defects modification which converts the normal ferroelectric into a relaxor ferroelectric, we demonstrated a $\Delta T \sim 20$ °C and $\Delta S \sim 100$ J/kgK near room temperature in the high energy electron irradiated P(VDF-TrFE) 68/32 mol% copolymer. In this DOE program, a specially designed high resolution calorimeter was developed which directly measures ECE in polymer films. This new calorimeter at Penn State allows us to expand our study of ECE to ferroelectric polymers with first order FE-PE transition and to defects modified ferroelectric polymers, both of which can't be studied using the indirect method, i.e., the Maxwell relations. In this DOE program, we also showed that the defects modification in ferroelectric materials has the promise of further enhancing ECE. Proper defects modifications can significantly reduce the polar correlation and increase the number of polar entities beyond that allowed by the macroscopic symmetry of the crystal structures, both of which will result in larger entropy change between the dipolar-ordered and disordered states.

FY 2014 HIGHLIGHTS

During this time period, we systematically studied nanocomposite EC materials. One objective of this study is to answer the question of how to significantly improve the EC response at low electric field in the relaxor polymer in particular and in square law dielectrics in general by material synthesis. Here we synthesized a class of novel nanocomposites which establish a built-in material DC bias field in the relaxor ferroelectric polymers, and consequently to significantly improve EC response at low electric fields. We show that in a polymer blend (nanocomposite) with a properly controlled normal ferroelectric in nano-phase dispersion in the relaxor polymer matrix, the charge neutrality in the blends can generate an internal biasing field, leading to more than 40% enhancement in the ECE at low electric field. Inorganic/organic nanocomposites, due to the large interfacial areas and large contrast in many material properties, provide an ideal material system to study ECE and to probe synthesis approaches to markedly enhance the ECE. Here, we investigate nano-composites with inorganic ferroelectric nanofillers, which possess much higher dielectric constant than that of the polymer, and BN nano-sheets, which possess high thermal conductivity (> 500 W/mK) as an highly insulation material, to study how the ECE and thermal conductivity can be tailored and enhanced. Experimental results indicate that these ferroelectric nanofillers, through interfacial effect, can lead to significant enhancement of ECE (more than 100% enhancement) in the nanocomposites. Furthermore, by incorporating small vol% of BN nano-sheets, both the thermal conductivity and the dielectric strength are improved. This material system opens up a totally new avenue of developing EC materials and provides an interesting material system to developing scientific understanding on the multiferroic effects and interfacial effects.

In Situ Visualization and Theoretical Modeling of Early Stages of Oxidation of Metals and Alloys

Institution: New York-Binghamton, State University of
Point of Contact: Guangwen Zhou
Email: gzhou@binghamton.edu
Principal Investigator: Guangwen Zhou
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Acquiring the ability to manipulate the microscopic processes governing the surface oxidation via either controlling the reaction environment or modifying the materials has huge technological implications. The work proposed therefore encompasses an atomic-scale study of the reaction ranging from the initial stage of oxygen surface chemisorption to the subsequent stages of nucleation and growth of bulk oxide. These studies exploit the unique in-situ capabilities of microscopy and spectroscopy techniques to dynamically measure the surface structure and surface chemistry of Cu, Cu-Au, and NiAl alloys under a wide range of oxidation conditions. Three research goals are pursued through this program: 1) Tune oxygen chemisorption induced surface phase transitions via oxygen pressure and temperature; 2) Tune the crossover from on-surface oxygen chemisorption to subsurface oxygen incorporation; 3) Tailor the growth morphologies of oxide nanoislands via metal/oxide interfacial strain. The in-situ experiments are coordinated closely by a number of theoretical modeling techniques ranging from the first-principles calculations to continuum elastic theory for developing direct insight into the reaction mechanism, including adsorption sites, diffusion path, reaction barrier, and surface/interface effects. The study allows for identifying how the interplay between thermodynamics and kinetics determines the final structure, composition, and oxidation mechanism, and also provides the baseline for tailoring the structures and composition of materials to steer the reaction toward the desired direction.

FY 2014 HIGHLIGHTS

A detailed understanding of the initial oxidation processes of surfaces has always been complicated by overwhelming inhomogeneities due to high density of defects. Atomic steps are present on virtually any crystalline material in any environment and serve as natural sources and sinks of substrate atoms owing to the reduced coordination of atoms at step sites. Through the use of a combination of *in situ* microscopy tools and theoretical modeling, we have addressed several outstanding issues in oxidation induced surface dynamics as a result of mass transfer from and to steps: 1) Using *in situ* STM, we were able to follow the nucleation and growth of -Cu-O- added-row reconstruction with the coordinated retraction of surface steps of the Cu(110) substrate, which provides direct evidence that surface steps are the source of Cu adatoms for the Cu(110)-(2x1)-O restructuring. 2) Using *in situ* aberration-corrected environmental TEM, we visualized oxide film growth at atomic resolution during the oxidation of stepped Cu surfaces. We observed that the presence of surface steps leads to the decomposition of the oxide overlayer at the growth front, thereby resulting in oscillatory oxide film growth that proceeds in tandem with the propagation of the surface step. 3) Using in-situ low-energy electron microscopy (LEEM) that spatially and temporally resolves oxide film growth during the oxidation of NiAl(100), we demonstrated that surface steps are impermeable to oxide film growth. The advancement of the oxide occurs exclusively on the same terrace and requires the coordinated migration of surface steps. The

resulting piling up of surface steps ahead of the oxide growth front progressively impedes the oxide growth.

DOE National Laboratories

Molecular Beam Epitaxy of Superconducting Oxides

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Ivan Bozovic
Sr. Investigator(s): Anthony Bollinger; Brookhaven National Laboratory
Jie Wu; Brookhaven National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,284,000 (2014)

PROGRAM SCOPE

The mechanism of high-temperature superconductivity (HTS) is arguably still the most important open problem in Condensed Matter Physics. Some of the most basic questions - what is the role of dimensionality in the HTS phenomenon, what are the spin and the charge of free carriers, what is the nature of superconducting transition, and what is the 'glue' (boson excitations) responsible for electron pairing - are still being debated. The research project relies on a unique molecular beam epitaxy (MBE) system for atomic-layer ('digital') synthesis of complex oxides. We fabricate single-crystal films of various cuprates and other complex oxides (nickelates, bismuthates, etc.), as well as multilayers and superlattices with atomically perfect interfaces. We manufacture heterostructures as well as HTS nanowires, nanorings and nanodots, and perform on them a series of experiments – some in-house and others in collaboration with leading experimental groups elsewhere – that were not previously possible. These experiments are aimed at providing conclusive answers to at least some of the above questions, and significantly impact research on HTS and more broadly on strongly-correlated materials. Correlated electron materials, transition-metal oxides, and HTS in particular are the main thrust of research at CMPMS Department and BES Directorate at BNL. Atomic-layer-by-layer MBE technique to synthesize perfect films and interfaces and to exploit epitaxial effects, and the identification of essential interactions giving rise to HTS, have been singled out as a Priority Research Direction in the latest BES Workshop on Superconductivity.

FY 2014 HIGHLIGHTS

The MBE laboratory, including a clean room, is fully functional at the peak performance. In FY 2014 we have performed over 200 synthesis experiments, most of which produced atomically smooth superconducting films. Every film was characterized by reflection high-energy electron diffraction (RHEED), atomic force microscopy (AFM), and transport and/or mutual inductance measurements, and selected ones also by x-ray diffraction (XRD). Many were patterned into micro- or nano-sized devices and were subject to detailed study of their physical properties and behavior, resulting in a number of new observations and results. These were reported in nine journal papers published in FY 2014, including two in Nature Materials and one in Nature Nanotechnology; one more was accepted for publication in Nature Physics (where it was published in December 2014). FY 2014 Recognition, Honors, and Awards: I. Bozovic was elected to the Academia Europea (the European Academy of Humanities, Letters and Sciences) in recognition of his lifetime achievements. He is a Foreign (Honorary) Member of

the Serbian National Academy of Sciences, Fellow of APS and SPIE, and a Member of the Editorial Board of Journal of Superconductivity, Journal of Nanophysics Letters, and ISRN Condensed Matter Physics. He won the prestigious award for Materials Synthesis from the Gordon and Betty Moore Foundation, one of only twelve that have been awarded nationwide and the only one awarded to a full-time employee of a National Laboratory. He was also elected an Adjunct Professor in the Applied Physics Department, Yale University. In FY 2014, he has been a Chair or Member of The International Advisory Boards of 10 international conferences. He received 22 official invitations to give invited talks at international conferences in FY 2014. Two invited talks were given by A. T. Bollinger and J. Wu, respectively.

Electronic, Magnetic and Optical Properties of Doped Metal Oxide Epitaxial Films and interfaces

Institution: Pacific Northwest National Laboratory
Point of Contact: Louis Terminello
Email: Louis.Terminello@pnl.gov
Principal Investigator: Scott Chambers
Sr. Investigator(s): Peter Sushko; Pacific Northwest National Laboratory
Tiffany Kaspar; Pacific Northwest National Laboratory
Tim Droubay; Pacific Northwest National Laboratory
Yingge Du; Pacific Northwest National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$879,000 (2014)

PROGRAM SCOPE

We explore fundamental phenomena related to electron-hole pair creation, propagation, and lifetime, collective defect interaction, and carrier spin polarization in complex oxide epitaxial films, heterojunctions and superlattices. Understanding these phenomena paves the way for effective and scientifically informed use of oxides in photovoltaics, photo- and thermo-electrochemical, and spintronic device technologies. These materials are synthesized with state-of-the-art control and purity for the purpose of understanding the intricate relationships that exist between composition, structure and functional properties using molecular beam epitaxy in conjunction with a state-of-the-art atom beam flux monitoring technology developed in this program. The resulting material systems are characterized using a variety of methods aimed at accurately determining composition, global and local structure and the kinds and quantities of defects present. Electronic, optical, magnetic and magnetoelectronic properties are measured and interpreted in light of realistic, as opposed to idealized, models of the material system. Deep insight is gained by coupling experiment with classical and quantum mechanical modeling efforts. A key goal is an in-depth understanding of not only how defects influence properties, but also how defects can be harnessed and controlled for useful purposes. The specific scientific themes being investigated include: (i) tailoring electronic and optical properties through alloying, superlattice formation, and strain for the purpose of efficient visible light harvesting, (ii) exploring collective defect phenomena to generate novel and useful mesoscale structures, and, (iii) using ferromagnetic complex oxides for spin injection into non-magnetic semiconductors in simple spintronic devices.

FY 2014 HIGHLIGHTS

We discovered that the semiconducting phase, SrCrO_{2.8} (R-SCO), contains planes of ordered oxygen vacancies which allow O²⁻ to rapidly diffuse through the material at low temperature, a property of considerable importance in solid oxide fuel cells. These O-deficient planes act as fast diffusion paths for O anions, leading to relatively low-temperature (~250°C) in-air oxidation of R-SCO to SrCrO_{3.6} (P-SCO).

Fast O^{2-} diffusion at low temperature is highly desirable for solid oxide fuel cells in that the overall efficiency of the cell is greatly enhanced by being able to diffuse O^{2-} through the cathode at low temperature, whereas $\sim 800^\circ\text{C}$ is required with materials currently in use. Through the use of *ab initio* modeling, we were able to gain mechanistic understanding of O^{2-} diffusion in R-SCO, leading to the low-temperature oxidation of R-SCO to P-SCO. We have investigated the evolution of the structural and electronic properties of $\text{La}_{1-x}\text{Sr}_x\text{CrO}_3$ ($0 \leq x \leq 1$) epitaxial films deposited by molecular beam epitaxy. LaCrO_3 is an antiferromagnetic insulator whereas SrCrO_3 is a metal. Substituting Sr^{2+} for La^{3+} in LaCrO_3 effectively dopes holes into the top of valence band, leading to Cr^{4+} ($3d^2$) local electron configurations. Core-level and valence-band features monotonically shift to lower binding energy with increasing x , indicating downward movement of the Fermi level toward the valence band maximum. The material becomes a p-type semiconductor at lower doping levels and an insulator-to-metal transition is observed at $x \geq 0.65$. Valence band x-ray photoemission spectroscopy reveals diminution of electronic state density at the Cr $3d$ t_{2g} -derived top of the valence band while O K-edge x-ray absorption spectroscopy shows the development of a new unoccupied state above the Fermi level as holes are doped into LaCrO_3 . These results indicate a pronounced redistribution of electronic density of states upon hole doping, a result that is also obtained by density functional theory with a Hubbard U correction.

EARLY CAREER: In-Situ Monitoring of Dynamic Phenomena During Solidification

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor
Email: ttaylor@lanl.gov
Principal Investigator: Amy Clarke
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Solidification is experienced by all metals and is critical to the manufacture of components, from cast aluminum alloy engine blocks to the growth of single crystal superalloy turbine blades. Solidification is multiscale, ranging from the microscopic scale, where solid-liquid interface stability dictates solidification pattern and structural development, to the macroscopic scale, where casting mold filling, intended heat-transfer, and solidification progression are crucial. We experimentally visualize the dynamics of controlled metal solidification from the microscopic to the macroscopic scale by imaging with electrons, x-rays, and protons. Our movies are used to inform and develop multiscale computational models of metal solidification, enabling predictive capability. We have performed x-ray imaging of controlled growth and microscopic structural development in aluminum-copper alloys during solidification and the first quantitative phase-field simulation comparison, proton imaging of casting mold filling at the macroscopic scale and modeling informed by experiments, and dynamic transmission electron microscopy of nanocrystalline aluminum-silicon alloy films to study rapid solidification relevant for processes such as additive manufacturing. We are also pursuing three-dimensional visualization of morphologically complex solidification structures and complementary experiments and modeling of the properties and performance of solidification structures. Experimental and computational visualization of solidification, coupled with controlled processing, will result in the development and deployment of manufacturing technologies for creating advanced metals with designed structures, properties, and performance.

FY 2014 HIGHLIGHTS

- The first quantitative phase-field simulation comparison with x-ray imaging of metal alloy microstructural evolution during solidification.
- X-ray imaging of metal alloys during controlled solidification at the Advanced Photon Source at Argonne National Laboratory, November 2013 and August 2014
- Casting mold filling modeling informed by proton imaging experiments.
- Proton imaging of casting mold filling with pRad (proton radiography) at the Los Alamos Neutron Science Center (LANSCE) at Los Alamos National Laboratory, October 2013 and November 2014
- Dynamic transmission electron microscopy of metal alloys during rapid solidification at Lawrence Livermore National Laboratory, July 2014
- “Controlled grain boundary grooving experiments toward fundamental understanding of hot tearing in metal alloys”, Advanced Photon Source Argonne National Laboratory, awarded 36 (8 hr) shifts, 2014-2016
- “Multiscale prediction and control of metallic alloys during solidification”, Proton Radiography (pRad) LANL, awarded 1 week of beamtime, November 2014.

Growth Mechanisms and Controlled Synthesis of Nanomaterials

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: David Geohegan
Sr. Investigator(s): Gyula Eres; Oak Ridge National Laboratory
Alex Poretzky; Oak Ridge National Laboratory
Gerd Duscher; Oak Ridge National Laboratory
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 2 Undergraduate(s)
Funding: \$1,031,000 (2014)

PROGRAM SCOPE

The goal of the research program is to understand the link between the growth mechanisms and the resulting structure of nanoscale materials. The development of real-time, *in situ* methods to probe and induce chemical and physical transformations away from thermodynamic equilibrium is emphasized in order to controllably synthesize nanomaterials with metastable structures and enhanced properties. The approach relies on correlating the real-time diagnostic measurements with predictive theoretical methods and characterization by imaging, spectroscopy, and atomic-resolution analytical electron microscopy. Specific aims of the program are: (1) To understand the special role of nonequilibrium growth environments in the capture of metastable structures with novel nanoscale properties through the development of new synthesis and processing approaches incorporating *in situ* diagnostics. (2) To reveal the kinetic pathways and ultrasmall “building blocks” involved in the growth of nanostructures through the development of real-time measurement techniques. (3) To understand the atomistic interactions governing the design and synthesis of nanostructures with specific configurations and functionalities through predictive theory and associated experiments. Key synthesis and processing science challenges are addressed for major nanomaterials classes that are important to DOE's energy mission. Novel two dimensional materials (e.g., monolayers or few-layers of graphene, metal chalcogenides) are of key interest because alone or stacked into heterostructures, quantum confinement and interfacial interactions in these materials results in a wide range of emergent electronic, optical, and thermal phenomena quite different than their bulk counterparts. In addition, the hierarchical assembly of novel oxide, metal, and carbon nanoparticle architectures are of key interest for catalytic, photocatalytic and photovoltaic applications where interfacial phenomena can drive new functionality.

FY 2014 HIGHLIGHTS

Time-resolved *in situ* spectroscopy and imaging diagnostics of two-dimensional material growth processes were developed to measure the nucleation and growth kinetics of graphene, and develop models that allow its predictable synthesis. Graphene growth by chemical vapor deposition (CVD) on nickel revealed the competition between isothermal surface- and bulk-nucleation and growth, while growth on copper revealed the crucial role of suppressing nucleation and cooperative island growth to enable the synthesis of large-area (mm-scale) single-crystal graphene grains that are essential for emerging applications. Novel synthesis and processing methods were explored to synthesize 2D metal chalcogenide (2DMC) monolayers, few layers, and nanosheets (e.g., GaSe, MoSe₂, WS₂, WSe₂). The first use of pulsed laser deposition (PLD) to synthesize crystalline 2DMC nanosheets revealed how ultrasmall, stoichiometric GaSe or MoSe₂ nanoparticles form and serve as “building blocks”. A new “digital transfer growth” technique utilized these PLD-deposited ultrasmall nanoparticles as precursors, evaporated and confined between two plates to overcome boundary layer effects found in CVD, and allow the patterned growth of large 2D crystals. Finally, atomistic energetics of monolayer 2DMC epitaxial growth and subsequent layer homoepitaxy were understood through the epitaxial growth and computational modeling of GaSe monolayer crystals on graphene suspended on TEM grids. Controlled synthesis and PLD of ultrasmall TiO₂ nanoparticles was studied by *in situ* diagnostics and atomic-resolution electron microscopy to understand how these ‘amorphous’ “building blocks” assemble to form novel mesoporous architectures of nanoparticles, nanorods, and thin films with interesting metastable phases such as TiO₂ (B) at different temperatures. The synthesis and directed deposition of metal nanoparticles by femtosecond ablation of ultrathin films was also understood through experiment and computational modeling.

Structure and Dynamics in Condensed Systems

Students: 7 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$2,132,000 (2014)

PROGRAM SCOPE

The research project entails bringing simulation methods together with theory and critical experiments to investigate structural selection dynamics in highly driven systems. Building on our past efforts aimed at understanding the structure and properties of highly undercooled liquids and glasses, the structural dynamics of solidification and devitrification, and the fundamental behavior of interfaces, we are developing a research program that is focused on the multi-scale structural dynamics of metallic liquids,

glasses, and crystalline phases under far-from-equilibrium conditions. By exploring this realm of material dynamics in earnest, we aim to open vast untapped domains of materials structures and physical behaviors, with an equally broad scope of potential functionality in magnetic, electric, elastic, thermal, and optical properties, and the critical coupled-response behaviors that may be strongly influenced by using far-from-equilibrium conditions to influence phase selection, crystallographic orientation, polycrystalline scale and texture, multiphase architectures, interface structure, solute distribution, and defect concentrations.

FY 2014 HIGHLIGHTS

We continued efforts in the past year to adapt the Adaptive Genetic Algorithm in collaboration with “Exploratory Development of Theoretical Methods” FWP to solve, in concert with advanced diffraction methods, the atomic structure of experimentally identified metastable phases. In FY 2013 we worked out the framework for the algorithm and began to identify previously unsolved nanoscale phases. In FY 2014 we have begun to routinely solve a number of metastable complex crystals which formed during the devitrification process in the Al-Sm system. The efficient genetic algorithm can simultaneously search a wide range of compositions for unknown crystalline phases while comparing the diffraction patterns of the calculated compounds to the experimental data.

Structural Origins of Electrochemical and Mechanical Properties in Pre-Formed Solid Electrolyte Interphases

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Chengdu Liang
Sr. Investigator(s): Nancy Dudney; Oak Ridge National Laboratory
Ke An; Oak Ridge National Laboratory
Miaofang Chi; Oak Ridge National Laboratory
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$631,000 (2014)

PROGRAM SCOPE

The conduction of ions in solids and at interfaces is the key phenomenon for electrochemical energy storage and conversion. This program derives a thorough understanding of the transport of ions through concerted efforts of advanced synthesis, analytical microscopy, and neutron scattering. The goal of this project is to correlate the electrochemical and mechanical properties of solid electrolytes and solid electrolyte interphases (SEIs) to their atomic, nanoscale, and dynamic structures. The project focuses on two structurally distinct material systems: (1) crystalline oxides and sulfides, and (2) amorphous lithium phosphorous oxynitride (Lipon). New solid electrolytes have been designed based on crystalline oxide and sulfide materials. The research identifies the conduction mechanisms of solid electrolytes. The knowledge of the conduction mechanism guides the material discoveries of solid ion conductors with tailored electrochemical and mechanical properties for energy storage. Amorphous Lipon is the basis of pre-formed SEIs for high-energy batteries. Thin films of Lipon have been deposited in model battery systems to understand the function of a pre-formed SEI in conventional batteries that use liquid electrolytes. The Lipon thin film electrolyte has also been used to investigate the transport phenomenon of the all-solid state batteries that hold the promise of the next generation of high-energy, safe batteries.

FY 2014 HIGHLIGHTS

In FY 2014 this project focused on the development of solid electrolytes and pre-formed SEIs. The accomplishments can be classified as follows: (1) Implemented the concept of pre-formed SEIs to achieve excellent cyclability of high voltage batteries and high capacity batteries using conventional liquid electrolytes. In these systems, a thin film of Lipon has been deposited as a pre-formed SEI. (2) Established the new concept of bifunctional electrolyte to extend the energy storage capacity of Li-CF_x primary batteries. The solid electrolyte Li₃PS₄ was discovered as a cathode material that can be activated through a catalytic process. (3) Advanced the understanding of the structure-properties relationship of solid electrolytes. The Hard and Soft (Lewis) Acids and Bases theory was used to mitigate the air sensitivity issues of sulfide-based solid electrolytes. The space-charge effect was found to enhance the conductivity of composite electrolytes of sulfides and oxides. Aliovalent substitution was used as the approach for probing the structural dependence of ion conduction in sulfide-based solid electrolytes. The origin of grain boundary resistance of perovskite Li-ion-conducting solid electrolytes was revealed through high-resolution transmission electron microscopy. (4) We developed an *in situ* neutron scattering method for the direct observation of the phase evolution of (La_{0.8}Sr_{0.2})_{0.95}MnO_(3-δ)(LSM) and (Y₂O₃)_x(ZrO₂)_(1-x) (xYSZ, x = 3, 6, 8 and 10) for oxide conducting system.

Molecularly Organized Nanostructural Materials

Institution: Pacific Northwest National Laboratory
Point of Contact: Louis Terminello
Email: Louis.Terminello@pnl.gov
Principal Investigator: Jun Liu
Sr. Investigator(s): Yongsoon Shin; Pacific Northwest National Laboratory
Praveen Thallapally; Pacific Northwest National Laboratory
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$631,000 (2014)

PROGRAM SCOPE

Self-assembled materials with controlled nanostructures and functions have great potential for energy storage and conversion. Although many different approaches have been reported, there is a fundamental gap in the understanding of the underlining principles, in particular, the understanding and control of competing driving forces for crystal growth and three-dimensional self-assembly. The overall goal of this project is to investigate molecularly-directed crystallization and self-assembly phenomena at the interfaces for synthesizing nanostructured materials with controlled micro- and nanoporosity, desired stable crystalline phases, and tailored multicomponent three-dimensional architectures. The project focuses on well-defined experimental systems, such as two-dimensional graphene building blocks, and explores the surface chemistry in order to develop new approaches to assemble complex materials using nanoscale building blocks. The project places a strong emphasis on extensive molecular and mesoscale computer modeling to elucidate fundamental mechanisms of interfacial binding, nucleation and self-assembly and guide materials synthesis efforts. Innovative *in situ* transmission electron microscopy techniques will also be developed to obtain real-time kinetic information of nucleation, crystal growth and structural evolution. The electron and ion transport properties are measured by both microscopic and molecular spectroscopic methods, and correlated with the structure and surface chemistry of the materials. A multiscale model combining density functional theory and phase-field theory will be used to understand the coupling between resident charge transport

properties and the attendant structure-property relationships. The research consists of four subtasks: 1. Molecular interactions at the interfaces 2. Fundamentals of nucleation and growth 3. Three-dimensional assembly of functional materials 4. Charge transport and structure-property relationships.

FY 2014 HIGHLIGHTS

The project focused on the understanding of surface defects. A fluorination process is developed to semi-quantitatively probe the defects and functional groups on graphene surface (ChemSsuChem 2014). The fluorine content was modulated to investigate the different functional groups such as C-F, CF₂, O-CF₂ and (C=O)F during the fluorination process. The results of the Density function theory (DFT) and nuclear magnetic resonance (NMR) studies show that the lattice vacancies, without oxygen containing groups, provide most of the reactive sites to react with F. Functionalized graphene sheets (FGS) also contain COOH, hydroxyl or epoxy groups that contribute to the reaction products with a higher F content. We also studied hard carbon surface chemistry and solid electrolyte interphase (SEI) formation for Na ion storage (Advanced Materials, 2014). The SEI formation in Na ion chemistry is similar to that observed in more familiar Li ion systems. Electrolyte additives significantly suppress the SEI formation. Proper design of carbon surface helps other energy storage mechanisms. For example, lithium-sulfur (Li-S) batteries have recently attracted wide attention due to the high gravimetric energy density. Continuous dissolution and capacity fading during cycling remains a large challenge. A new design was developed using graphite in a hybrid anode to control undesirable surface reactions on the anode (Nature Comm. 2014). The lithiated graphite placed in front of the lithium metal functions as an active solid electrolyte interface (SEI) layer to control the electrochemical reaction while minimizing the deleterious side reactions on the surface and bulk lithium metal. Excellent electrochemical performance has been observed. Many other nanostructured electrode materials have been developed including Bi nanotubes as anode for high capacity Mg ion storage (Nano Letters 2014) and stable cathode materials (Chem. Mat., 2014).

Novel Materials Preparation and Processing Methodologies

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov
Principal Investigator: Thomas Lograsso
Sr. Investigator(s): Iver Anderson; Ames Laboratory
Larry Jones; Ames Laboratory
Yong Liu; Ames Laboratory
R. William McCallum; Ames Laboratory
Qingfeng Xing; Ames Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,583,000 (2014)

PROGRAM SCOPE

The growth, control and modification of novel materials in single crystal and polycrystalline form, represent a national core competency that is essential for scientific advancement within and across traditional disciplinary boundaries, and are critical components of the Basic Energy Sciences' mission. In support of this mission, the Novel Materials Preparation and Processing Methodologies FWP focuses on developing synthesis protocols for energy-relevant materials that contain volatile, reactive or toxic components such as the rare earth (RE) metals, Mg-based and RE containing thermoelectric alloys and

Fe-As based superconductors. The objective of Novel Materials is to advance the ability to synthesize and characterize high purity, high quality materials, primarily in single crystal form; to quantify and control processing-structure-property relationships between chemical inhomogeneities and structural defects and functionality of highly responsive materials; to develop unique capabilities and processing knowledge in the preparation, purification, and fabrication of metallic elements and alloys. Single crystals are often required to achieve scientific understanding of the origin of various phenomena, whether from intrinsic or extrinsic origins, to elucidate its properties as well as to evaluate a material's full functionality.

FY 2014 HIGHLIGHTS

We developed an inverted-temperature-gradient method to grow large and high-quality single crystals of $Ba_{1-x}K_xFe_2As_2$. When setting the upper zone as the cold zone, upon cooling the nucleation initiates from the surface layer of the liquid melt. The crystallization, proceeding from the top of a liquid melt, helps to expel impurity phases during crystal growth compared to the growth inside the flux. High vapor pressure of K and As elements at the soaking temperature is also an important factor in the growth of single crystals of $Ba_{1-x}K_xFe_2As_2$. By allowing crystallization of the free surface first, evaporative losses are minimized eliminating large macro-segregation along the crystal and ensuring control of target compositions. High soaking temperature, fast cooling rate, and an adjusted temperature window of the growth are necessary to obtain single crystals of heavily K-doped crystals ($0.65 < x < 0.92$) with a sharp transition. In the efforts on studying solidification behaviors and phase space of potential thermoelectric materials made of earth-abundant and non-toxic elements, Mg-Si based materials have been selected. The phase space of pseudo binary Mg_2Si - Mg_2Sn system has been elucidated. A method to prepare single crystalline diffusion couples of air-sensitive materials by hot-pressing has been established. Utilizing the high pressure Bridgman furnace we have for the first time synthesized single crystals of Zn-bearing Fe-Ga alloys. We have grown bcc Fe-Ga-Zn single crystals up to 4.6% Zn in a Bridgman furnace under elevated pressure (15 Bar) in order to overcome the high vapor pressure of Zn and obtain homogeneous crystals. Single-crystal measurements of magnetostriction and elastic constants allow for the direct comparison of the magnetoelastic coupling constants of Fe-Ga-Zn with other magnetoelastic alloys. The partial substitution of Ga with Zn yields comparable values for the magnetoelastic coupling factor, $-b_1$, to those of the binary Fe-Ga alloys.

Exploratory Materials Synthesis and Characterization

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Cedomir Petrovic
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$569,000 (2014)

PROGRAM SCOPE

The Exploratory Materials Synthesis and Characterization (EMSC) program concentrates on exploratory synthesis and characterization of the new model materials of current interest in condensed matter physics. In addition, we often focus on advanced synthesis of known materials in order to enable important physical and structural investigations. In our focus are correlated electron systems in energy related materials. Most often materials are synthesized in the single crystal form since many

observables of interest are tensor quantities and since this allows for the investigation of physical properties that are free of grain boundary influences. We use a range of techniques suitable for exploratory synthesis: arc melting and solid state reactions, solution methods, high temperature intermetallic, oxide, chalcogenide or salt fluxes, chemical vapor transport and deposition. Automated physical and structural characterization is the essential component of the lab. Quite often the same methods are used to probe and perturb crystal structure, transport, thermodynamic and magnetic properties, sometimes at the extreme conditions. We are regular users of NHMFL Tallahassee and HZDR Dresden. We also use EXAFS beamlines at NSLS and we are constantly engaged in the buildup of our synthesis and characterization capabilities. We currently pursue several interpenetrating directions: Quantum criticality in heavy fermions and charge density wave materials, Metal – Insulator transitions (MIT) in nearly magnetic materials, Dirac states in bulk crystals and facility development. This program includes training of the next generation of scientists. Students from neighboring universities (Brown, Columbia, Johns Hopkins, and Stony Brook) were or are being educated in materials physics, arts and crafts of crystal growth, materials synthesis and characterization.

FY 2014 HIGHLIGHTS

(1) Exploratory synthesis and characterization of novel materials. We reported electrical and thermal transport properties of the BaMn_2Bi_2 crystals. The resistivity of the antiferromagnetic BaMn_2Bi_2 shows a metal-semiconductor (insulator) transition at 80K with decreasing temperature. Correspondingly, the thermopower S shows a peak at the same temperature, approaching $150 \mu\text{V/K}$. With increasing temperature, S decreases to about $125 \mu\text{V/K}$ at the room temperature but the magnetic field enhances the peak value to $210 \mu\text{V/K}$. The Hall resistivity reveals an abrupt change of the carrier density close to the metal-semiconductor transition temperature. The origin of high Seebeck coefficient is in the sharp change in the carrier density and the metal-semiconductor (insulator) transition which is related the strongly correlated effect. Kefeng Wang and C. Petrovic, Appl. Phys. Lett. 103, 192104 (2) Advanced materials synthesis and crystal growth. Crystals made at EMSC BNL enabled imaging Cooper pairing of heavy fermions in CeCoIn_5 ; collaboration with Seamus Davis (BNL) and Dirk Morr groups (University of Illinois). The results provided direct evidence for a magnetic f-electron-mediated Cooper pairing mechanism of heavy-fermion superconductivity in CeCoIn_5 . It should be noted that many other important experimental results from diverse techniques were explained within this framework. J. S. Van Dyke, F. Massee, M. P. Allan, J. C. Seamus Davis, C. Petrovic and D. Morr, Proc. Natl. Acad. Sci. U. S. A. 32, 11663 (2014).

Fundamental Studies of Synthesis of Nanomaterials: A Joint Challenge for Plasma and Materials Science

Michael Keidar; George Washington University
Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$1,300,000 (2014)

PROGRAM SCOPE

This research project explores the fundamental physics of nanomaterial synthesis by plasma with the goals to understand, predict, and ultimately control the synthesis processes, including plasma generation and nucleation and growth of nanoparticles and nanostructures. The research focuses on three key areas: (1) characterization of the plasma properties relevant to synthesis of nanomaterials; (2) development and utilization of in-situ diagnostics of nanoparticles and nanostructures; and (3) understanding plasma-mediated synthesis for various nanomaterials, including development, validation, and integration of codes for multiscale modeling of nanomaterial synthesis. The emphasis is on carbon, boron nitride, and hybrid B-C-N nanostructures. A comprehensive set of in-situ plasma and nanoparticle diagnostics will be developed and employed to provide the dataset needed to validate and further develop theoretical models of plasma and nanostructure growth.

FY 2014 HIGHLIGHTS

This project was funded in August 1, 2014. Since then, we made a good progress in terms of initiation and coordination of research efforts in three main research directions, including modeling, diagnostic development and plasma synthesis experiments. In particular, we initiated characterization of electrode evaporation-deposition processes in the carbon arc using weighting procedures and applying optical emission spectroscopy, high speed imaging and IR imaging, segmented electrodes. On the diagnostic development, we are completing designs of the proposed *in situ* laser diagnostics of nanoparticles. In support of these efforts, we are working on modeling of laser-induced effects on nanoparticles in the presence of the plasma. Candidates for the two diagnostic and one theory post doc positions were interviewed. The selected candidates were recently hired.

Surface Structures Far-From-Equilibrium

Institution: Ames Laboratory
Point of Contact: Duane Johnson

Pat Thiel; Ames Laboratory
Cai-Zhuang Wang; Ames Laboratory
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$561,000 (2014)

PROGRAM SCOPE

The emergence of novel properties in nanostructures can be related to various factors, important ones being electron confinement and lower atom coordination. The goals of this FWP are two-fold, first to grow epitaxially controllable nanostructures and second to use their novel, selectable properties on several technologically important problems. Achieving these goals it is also essential to find ways to tune atomistic processes (diffusion, adsorption) and use them to grow perfect nanoscale patterns easily and in short times. Such studies have been carried out in several specific systems. Understanding metal growth on graphene, graphite and other carbon coated substrates is one of the areas of interest because graphene based devices require stable metal contacts of low electrical resistance. Novel

graphene properties can emerge after metal intercalation. Robust ways were found to speed up adatom diffusion, from the electric field generated in regions of different workfunction on metal islands or when 2-dimensional metallic overlayers become extremely mobile after compressed to densities higher than their crystalline densities. Understanding the growth mechanism for defect-free nanowires with high and tunable aspect ratios on carbon coated surfaces is relevant for magnetic and optoelectronic applications.

FY 2014 HIGHLIGHTS

In FY 2014 the team elucidated the difference in workfunction between adjacent terraces on a Pb(111) mesa grown over stepped Si surface generates a lateral electric field that changes stochastic to biased diffusion of Mg adatoms with the Mg adatoms populating terraces of low workfunction. In collaboration with two outside groups the “Devil’s Staircase” (DS) phases in Pb/Si(111) were used to test how robust is 1-layer superconductivity using high resolution spectroscopy with millikelvin STM and to show very fast pattern formation between the DS phases at low temperature after deposition of C₆₀ fullerenes.

Theoretical Condensed Matter Physics

Theory of Computation for Semiconductor Catalysis of Solar Water Splitting

Institution: New York-Stony Brook, State University of
Point of Contact: Philip Allen
Email: philip.allen@stonybrook.edu
Principal Investigator: Philip Allen
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

The aim is to improve theoretical understanding of processes by which solar energy can be captured at catalytic interfaces (e.g., the semiconducting GaN/water interface) to drive the reaction $2 \text{H}_2\text{O} \rightarrow 2 \text{H}_2 + \text{O}_2$. Computation (primarily density functional theory) provides the method to simulate processes and to interact with experiment. This work also trains physics graduate students working at the interface between physics and chemistry. A primary material for study is the wurtzite-structure alloy of GaN with ZnO, apparently stable over the full concentration range x of $\text{Ga}_{1-x}\text{Zn}_x\text{N}_{1-x}\text{O}_x$. The predicted bond-length relaxations and strong short-range concentration correlations are being tested experimentally. We develop theories of optical and dc conductivity of the bulk alloy. We study the structure and thermodynamics of the clean and the wet surfaces of this alloy. We ask how alloying affects the photo-absorption spectrum and carrier mobility. We study bulk and surface carrier traps and their importance for photo-catalysis. We are generalizing the USPEX (Universal Structure Predictor: Evolutionary Xtallography) genetic structure-predicting algorithms in order to predict thermodynamically relevant surface and interface structures. We study the perovskite-structure polar materials of the $\text{CaTiO}_3/\text{SrTiO}_3/\text{BaTiO}_3$ family. Their interfaces with water offer new ways to tune the photochemistry.

FY 2014 HIGHLIGHTS

Progress is occurring on four projects. (1) The clean non-polar (10-10) surface of GaN in contact with water is an important model system for surface chemistry. The first monolayer of water largely splits into Ga-OH and N-H surface species. The reactivity of these species when GaN is photo-excited is being studied. (2) Crystal structure prediction computer codes have been modified to assist in surface structure prediction. A surprising new candidate structure of the polar (0001) surface of ZnO in the presence of hydrogen is predicted. (3) Atom relaxation of large supercells representing characteristic configurations of GaN/ZnO alloys has been simplified. This enables “pre-relaxed” configurations to initiate the final expensive density-functional relaxation. (4) The oxidation of water on the SrTiO_3 (100) surface has been quantified.

Electron Interaction Effects in Nanosystems

PROGRAM SCOPE

The research program aims to develop a theory of electron transport in nanosystems with strongly correlated carriers. The work is organized around the following themes. (i) Theory of electron transport beyond the Fermi- and Luttinger- liquid paradigms. Charge carriers in high mobility semiconductor nanostructures often form strongly correlated liquids in which the energy of Coulomb repulsion U exceeds the Fermi energy, ϵ_F . In this case there is a wide and largely unexplored interval of temperatures, $\epsilon_F < T < U$, in which the Fermi-liquid (or Luttinger liquid in one-dimension) description is inapplicable but the liquid remains strongly correlated. Part of the research program focuses on development of a theory of electron transport in one- and two- dimensional high mobility systems in the regime where the Luttinger- or Fermi- liquid description becomes insufficient or inadequate. This work will advance our understanding of electron transport in semiconductor nanostructures with strong Coulomb repulsion between the charge carriers. (ii) Transport phenomena in non-centrosymmetric media. Another part of the research program aims to develop theory of transport phenomena in non-centrosymmetric (and/or time reversal non-invariant) conductors and superconductors. This includes 1) theory of linear and circular photogalvanic effect and the Kerr effects in chiral magnets and superconductors, 2) photogalvanic effect in monolayers of transition metal dichalcogenides, and 3) theory of spin and charge transport in normal metal/p-wave superconductor structures with the chiral $p_x + ip_y$ symmetry of the order parameter.

FY 2014 HIGHLIGHTS

(1) Equilibration of spin-degenerate one-dimensional electron liquid in the Wigner crystal regime: We developed a theory of equilibration of one-dimensional electron liquids at strong interactions, Phys. Rev. B 90, 035148 (2014). (2) Theory of Coulomb drag (CD) in the hydrodynamic regime: We developed a theory of CD in clean double layers with strongly correlated carriers. If the equilibration length of the electron liquid is shorter than the interlayer spacing CD arises from hydrodynamic density fluctuations. We expressed CD resistivity in terms of kinetic coefficients of the electron fluid. Our results are nonperturbative in interaction strength and do not assume Fermi-liquid behavior of the electron liquid. Phys. Rev. B 89, 121104(R)(2014). (3) Theory of disordered unconventional superconductors: Unconventional superconductors are easily driven to the normal state by disorder. In the vicinity of the normal-metal-superconductor transition the superconducting state consists of superconducting islands connected by Josephson links. Kivelson and Spivak showed that for d-wave superconductors the Josephson junction model reduces to the Mattis model. We extended the theory to p-wave materials. The Mattis model is the leading approximation in the inter-island distance. We studied corrections to the Mattis model and stability of the superconducting phase with respect to perturbations to the Mattis model Hamiltonian. arXiv:1405.7090, accepted to JETP. (4) Aharonov-Bohm (AB) oscillations in singly-connected disordered conductors: We showed that AB oscillations exist even in singly-connected disordered conductors. They arise from quantum interference of a special class of diffusive electron trajectories that graze the sample boundary. The manuscript, arXiv:1412.5209, has been submitted to Phys. Rev. Lett.

Theory of Fluctuating and Critical Quantum Matter

Institution: California-Santa Barbara, University of
Point of Contact: Leon Balents
Email: balents@physics.ucsb.edu
Principal Investigator: Leon Balents
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$315,000 (2014-2016)

PROGRAM SCOPE

The project centers on the theory of phenomena in electronic materials involving strong quantum fluctuations, which arise due to frustration, exotic interactions (especially those originating from spin-orbit coupling), and proximity to quantum critical points. The projects are divided roughly into two areas: phases of frustrated quantum magnets, and quantum critical points in itinerant systems with frustrated or exotic interactions. All components are connected both to specific experiments and materials, and to general issues at the forefront of the theory of correlated quantum matter. The research will guide theory and experiment in the search for exotic highly entangled quantum phases such as quantum spin liquids and spin nematics. A microscopic understanding of frustrated Kondo lattice systems and doped iridates will be developed, and the appropriate field theories for recently discovered and newly proposed quantum critical points will be formulated. We will extend and develop methodology from model building to numerics, to field theory methods. The work will provide specific predictions for materials and experiments to observe new physics at the frontiers of condensed matter physics.

FY 2014 HIGHLIGHTS

One of the major focuses of the research supported by this grant has been on novel types of quantum criticality. We discovered an intriguing example in the pyrochlore iridates: a quantum phase transition from paramagnetism to antiferromagnetism, in the presence of nodal fermions. We showed how this transition fits naturally into the experimentally observed sequence of rare earth iridates, and is consistent with observations of magnetism and transport in these materials. We derived a universal quantum field theory description for the transition, and solved it using renormalization group methods. The results provide a singular example of a critical magnetic order parameter strongly coupled to electronic quasiparticles, for which a fully controlled theory exists. We are currently working to extend this theory to include the effects of doping, and to describe electrical transport in a more quantitative fashion. A separate effort has been to continue our study of spin-orbit liquids, including a collaboration with an experimental group in Augsburg on the optical properties of such systems. Our theory, formulated earlier under DOE support, predicted this spin orbital liquid and a proximate quantum critical point. Now we discovered some direct evidence for the criticality in optical excitations, and performed new theoretical calculations to compare with the measured spectra. Lastly, we are working on a new theory of frustrated ferromagnets, which explains how these types of materials support metamagnetism, chirality, and multipolar order. We have made considerable progress in formulating a new theory for these systems, deriving it for relevant microscopic models, and solving it in some of the most relevant limits. This effort is being aided by development of a new DMRG (Density Matrix Renormalization Group) code, which is now close to completion. We expect to report first results from these efforts in the coming year.

Electronic Structure, Spectroscopy and Correlation Effects in Novel Materials

Institution: Northeastern University
Point of Contact: Arun Bansil
Email: bansil@neu.Edu
Principal Investigator: Arun Bansil
Sr. Investigator(s): Robert Markiewicz; Northeastern University
Students: 2 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$810,000 (2014-2016)

PROGRAM SCOPE

This project is targeted on modeling and understanding electronic structure, spectroscopies, and correlation effects in novel materials of current interest. We are pursuing techniques for realistic treatment of electronic spectra of a wide variety of materials, which serve as a prelude to formulating and implementing methodologies for making direct connection with various spectroscopies. This project is concerned specifically with, angle resolved photoemission (ARPES), resonant inelastic x-ray scattering (RIXS), scanning tunneling microscopy/spectroscopy (STM/STS), magnetic and non-magnetic Compton scattering, and positron annihilation spectroscopy related issues. Specific systems being investigated are cuprates and Fe-based superconductors, topological materials, 2D spin-orbit coupling driven thin films beyond graphene, nanocrystals, and Li-battery materials. Our goal is to exploit the strengths of various spectroscopies to piece together a complete picture of electronic states, enabling direct and sharpened confrontations with theoretical models, and help advance the reach of various spectroscopies. With current and planned high-resolution beamlines at various DOE supported facilities, tremendous amounts of data are becoming available, launching a new era for probing the huge phase space of experiments as a function of temperature, magnetic field, doping and substitutions in the normal and the superconducting state. It will be difficult to effectively utilize this powerful instrumentation without parallel theoretical efforts of the sort being pursued here to develop sophisticated modeling methodologies, including key effects of strong correlations, electron-phonon coupling, and various nanoscale heterogeneities. The proposed program will help fill this critical gap by continued development of increasingly sophisticated theoretical tools for analyzing and interpreting the most important highly resolved spectroscopies in wide current use today.

FY 2014 HIGHLIGHTS

(I) Topological Insulators (TIs): Progress made includes: (1) Analysis of scanning tunneling spectra to unveil the orbital texture of $Pb_{1-x}Sn_xSe$ topological crystalline insulator; (2) We investigated the delicate relationship between quantum tunneling and Fermi surface (FS) spin polarization in ultrathin Bi_2Se_3 films, suggesting that the polarization current can be tuned to zero in thin insulating films to provide a basis for a future spin-switch nanodevice; (3) We showed that the surface of $Sr_3Ir_2O_7$ near a metal-Mott insulator transition exhibits weak metallicity, shedding light on transport phenomena in iridate-based devices. (II) 2D atomically thin layered materials: Various 'beyond graphene' 2D materials were studied, and their potential in new devices for manipulating spins was explored in silicene/germanene nanoribbons. In considering effects of strains/substrates we showed that tensile strain can convert freestanding bilayers of group IV and V elements into TI phases, and hydrogenation has a similar effect on tin films. (III) FS reconstruction in the pseudogap state of Bi2201: We found evidence for the appearance of a FS in the antinodal region near optimal doping, far from the point of pseudogap collapse, which could also support anomalous 'FS-free superconductivity'. (IV) Core hole effects in RIXS and $S(q,\omega)$: We introduced a numerically soluble model in which electrons are noninteracting except for

a Hubbard-like attraction to a static core hole. The one-boson contribution in the resulting spectrum can be understood as $S(q,\omega)$ dressed by matrix element effects, which divide the spectrum into well- and poorly-screened components, and display a remarkable relation to the x-ray edge singularity. (V) Gutzwiller calculations of competing orders in cuprates: We investigated magnetic and charge instabilities within the Gutzwiller approximation RPA (GA+RPA), finding evidence for phonon-coupled charge density waves, and a secondary nematic order, pinned by disorder effects.

Quantum Phases in Nanosystems: Dissipation, Interactions, and Non-Equilibrium Phenomena

Institution: Duke University
Point of Contact: Harold Baranger

Principal Investigator: Harold Baranger
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$120,000 (2014)

PROGRAM SCOPE

This project concerns the intersection of three major themes of contemporary condensed matter physics: First, open quantum systems (a quantum system interacting with an environment) are receiving increasing attention because of processes of societal relevance such as photosynthesis and energy capture. Second, quantum simulation of strongly interacting systems is being widely pursued as a way of producing exotic states of matter. Third, non-equilibrium quantum systems are becoming more appreciated for the qualitatively new phenomena produced. This project focuses on how dissipative nanoscale systems can elucidate these three themes by making use of the amazing control that is experimentally possible. The building block in this theoretical work is a quantum dot coupled to a dissipative electromagnetic environment. Several experimental groups are pursuing this platform, including our collaborator G. Finkelstein here at Duke. We have recently shown that this system can emulate resonant tunneling in an interacting one-dimensional system, revealing a quantum phase transition. We demonstrate that it can be described by a Majorana fermion model and thereby account for the experimentally observed conductance at the quantum critical point. The plan for the present project is to further explore possibilities for producing exotic quantum states and phenomena by using quantum dots coupled to dissipative electromagnetic environments. This work contributes a thorough understanding of a well-controlled open quantum system with strong correlation effects and exotic states of matter. Such an understanding impacts the larger question of how and when such phenomena occur, and so whether they may be relevant for open quantum systems involved in energy capture. The impact of environmental dissipation on quantum behavior is a key issue for nanoscale systems, which are often at the juncture where microscopic quantum objects and macroscopic environments meet.

FY 2014 HIGHLIGHTS

Accomplishments regarding: (1) entanglement within an environment coupled to a two-level system, (2) quantum phase transitions in a dissipative resonant level. Unveiling Environmental Entanglement in Strongly Dissipative Qubits: The coupling of a qubit to a macroscopic reservoir plays a fundamental role in understanding the transition from the quantum to the classical world. Considering a harmonic environment, we use both intuitive arguments and numerical many-body quantum tomography to study the complete wavefunction for intense qubit-environment interaction. The resulting strongly-correlated many-body ground state is built from quantum superpositions of adiabatic (polaron-like) and non-

adiabatic (antipolaron-like) contributions of the environment. The emerging Schrodinger cat environmental wavefunctions are described quantitatively via simple variational coherent states. In contrast to qubit-environment entanglement, we show that entanglement among the modes in the reservoir is crucial to stabilize qubit superpositions in regimes where standard theories predict an effectively classical spin. Dissipative Resonant Level: We study tunneling through a resonant level connected to two dissipative bosonic baths: one is the resistive environment of the source and drain leads, while the second comes from coupling to potential fluctuations on a resistive gate. We show that several quantum phase transitions (QPT) occur and obtain the phase diagram. For strong dissipation, a BKT-type (Berezinsky-Kosterlitz-Thouless) QPT separates strong-coupling and weak-coupling (charge localized) phases. In the source-drain symmetric case, all relevant backscattering processes disappear at strong coupling, leading to perfect transmission at zero temperature. In fact, a QPT occurs as a function of the coupling asymmetry: the two phases are (i) the system is cut into two pieces (zero transmission), or (ii) it is a single connected piece with perfect transmission, except for a disconnected fractional degree of freedom.

Properties of Multiferroic Nanostructures from First Principles

Institution: Arkansas, University of
Point of Contact: Laurent Bellaiche
Email: laurent@uark.edu
Principal Investigator: Laurent Bellaiche
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$10,000 (2014)

PROGRAM SCOPE

Objectives: This project will build a research program aimed at (1) investigating complex phenomena in multiferroic nanostructures; and (2) designing new low-dimensional multiferroic materials with optimal or original properties. Description: The research objectives will be achieved through the development and use of the following *ab initio* numerical tools: (i) accurate first-principles techniques; (ii) effective Hamiltonian approaches that extend the reach of first-principles calculations by realistically mimicking complex (static and dynamical) properties of multiferroic nanostructures at finite temperature; and (iii) the inverse method that allows an efficient design of materials with improved properties. Collaborations with internationally-known experimental groups will also be strengthened. The proposed cooperative activities will allow a careful side-by-side comparison between predictions and measurements, which is important to fully understand the systems to be investigated and to validate the numerical tools to be developed. This research program will also be integrated into the educational experiences of postdoctoral and graduate students. Many compounds and effects are going to be studied. Potential impact: A broad and deep knowledge of complex phenomena, multiferroics and nanoscience will be gained thanks to the techniques to be developed, and the variety of systems/effects to be investigated. In addition to build a network that will be the basis for future collaboration and exchange of students between the involved institutions, the collaborative efforts have also the potential to result in the realization of devices with enhanced and/or new functionalities, and that will improve energy efficiency and storage.

Theoretical Investigations of Nano Bio Structures

Institution: North Carolina State University
Point of Contact: Jerry Bernholc
Email: bernholc@ncsu.edu
Principal Investigator: Jerry Bernholc
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$110,000 (2014)

PROGRAM SCOPE

This proposal addresses fundamental issues in nanoscale science and technology, namely the design of nanostructured materials and devices with desired, novel characteristics. The research projects will focus on several broad areas: (i) carbon nanotube-based molecular sensors, (ii) molecular self-assembly on metal surfaces, and (iii) Li ion transport and incorporation in battery structures. These projects build on the work accomplished during the prior proposal periods, which included substantial advances to real-space electronic structure methodology and investigations of (i) novel nanoelectronic devices; (ii) copper-induced misfolding in Parkinson's disease and the action of copper-containing nitride reductase, and (iii) transition rates in cis-trans isomerization of polyproline peptides. Our newly developed capabilities enable fully quantum-mechanical simulations of solvated systems through a Quantum Mechanics (QM)/approximate-QM methodology at much reduced cost, multi-terminal non-equilibrium Green's function investigations of realistic device structures, and calculations of transition rates in rare events through non-equilibrium steered molecular dynamics. Our improved real-space multigrid method is capable of simulating the dynamics of systems containing thousands of atoms on DOE's leadership-class massively parallel super-computers.

FY 2014 HIGHLIGHTS

DNA is perhaps the world's most controllable nanowire, able to be grown in a precisely defined sequence with extremely few errors. If it can be made to conduct, it would have significant potential for applications in nanoscale sensors and electronics. However, experimental measurements of DNA conductivity span a very broad range, from highly conducting to fully insulating. We use *ab initio* techniques combined with molecular dynamics simulations to investigate B-DNA connected to carbon nanotubes via alkane linkers. The fully solvated system contains up to 78,000 atoms and is equilibrated at room temperature using molecular mechanics. For each system, 20 representative snapshots, containing up to 1,800 atoms, are extracted for quantum transport calculations. The quantum calculations include the DNA, the linkers, the first solvation shell with counterions, and the nanotube electrodes. We show that: (i) thermally-induced changes in DNA conformation lead to many orders of magnitude differences in instantaneous conductivity; (ii) coherent transport occurs over much longer distances than commonly assumed, leading to weak dependence of conductivity on length; (iii) while solvation in water and the positions of counterions can alter the conductivity by an order of magnitude, conformational changes are clearly the dominant effect. Furthermore, although mismatched base pairs can lower the conductivity significantly for specific DNA conformations, thermally-induced conformational fluctuations wash out this effect. Assuming exponential scaling of the current with the length, $I(L) = I_0 \exp^{-\beta L}$, β is found to be 0.18 \AA^{-1} for B-DNA. It is thus a promising nanowire candidate for nanoelectronic applications, since other molecular wires have β values between 1 and 0.2. In particular, immobilizing a partially dried poly(G)-poly(C) B-DNA on a substrate would lead to consistent conductive properties and thus be preferable for applications.

Internal Geometry, Stability and Design of Quantum Hall States

Institution: Princeton University
Point of Contact: Ravindra Bhatt
Email: ravin@princeton.edu
Principal Investigator: Ravindra Bhatt
Sr. Investigator(s): F. Duncan Haldane; Princeton University
Edward Rezayi; California State University-Los Angeles
Kun Yang; Florida State University
Students: 2 Postdoctoral Fellow(s), 6 Graduate(s), 0 Undergraduate(s)
Funding: \$475,000 (2014)

PROGRAM SCOPE

We seek to build upon our recent discovery of a previously unrecognized shear deformation degree of freedom possessed by incompressible fractional quantum Hall (FQH) states, and understand its implications under various circumstances. These include multi-component anisotropic systems, inhomogeneous systems and systems in confined geometries with boundaries (e.g. quantum dots), as well as Fermi liquid states of composite fermions. We plan to extend our investigations to other anisotropic systems, and to seek systems with new, interesting phase diagrams in the FQH regime, with an eye to optimizing the stability of various phases. These include materials with various band dispersions, with different experimental geometries and sub-band structure, and systems with complex edge structures. We also propose to extend our study to cold atom based systems, which offer the possibility of tuning interactions over a wide range, and thus the hope to study new FQH phases, tuning through different phases, and new methods for probing various phases. In parallel, we will perform controlled, systematic numerical studies with the aim of achieving a fuller, quantitative understanding of

the nature and stability of the more fragile FQH states, which are candidates for topological quantum computation. Such FQH phases require reliable studies on larger sizes than is possible with exact diagonalization. We have used both the Density Matrix Renormalization Group method as well as Matrix Product State schemes in various geometries, to identify optimal geometries for various problems, and extend the size of systems that can be studied for reliable extrapolation to the thermodynamic limit. We further plan to use a real-space entanglement method to study the topology and entanglement spectrum of various FQH states.

FY 2014 HIGHLIGHTS

The past fiscal year saw the completion of several projects. In two related works, we probed the nature of quasiparticle excitations – the first exposed the internal structure of a $\nu = 1/3$ quasielectron as a composite of a charge $2e/3$ quasiparticle and a $-e/3$ quasihole; the second showed that there is a large spatial difference between quasiholes at $\nu = 1/3$ and $\nu = 7/3$. Haldane's geometrical description was generalized for anisotropic (gapless) composite fermion liquid states, which yields excellent agreement with tilted field measurements at $\nu = 1/2$ by Shayegan's group. In parallel, a comprehensive numerical study in tilted magnetic fields (and its relation to effects of band mass anisotropy) was completed, allowing direct contact with experiments of Eisenstein and Shayegan. A systematic study of FQH states in the (special) zeroth Landau level in Graphene was carried out, whose predictions are being borne out in recent experiments. Our study of reconstruction at the edge of quantum Hall phases was extended to FQH fillings $\nu = 1/3, 2/5, 2/3$ and $5/2$; in all cases but the $5/2$, edge reconstruction is driven by softening of edge spin waves in the absence of Zeeman splitting, and is prevented by Zeeman splitting. For $\nu = 5/2$, however, the edge instability is triggered by softening of the charge mode, and spin plays no role. A new study of quantum entanglement spectra of the composite Fermi liquid at $\nu = 1/2$ was carried out, using toroidal geometry and Monte-Carlo sampling. Scaling with size was found to be similar to the free Fermi case, but with twice the coefficient, suggesting a more complicated scenario. The concept of quantum entanglement was also used to study a different many-body system, namely the phenomenon of many-body localization (MBL) in the presence of large disorder. Several new results were found in this developing field, e.g. area law for entanglement entropy, and signatures of MBL in the presence of coupling to a bath present in experimental situations.

Near-Field Electrodynamics of Carbon Nanostructures

Institution: North Carolina Central University
Point of Contact: Igor Bondarev
Email: ibondarev@nccu.edu
Principal Investigator: Igor Bondarev
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014-2016)

PROGRAM SCOPE

The objective of this research is to advance the frontiers of fundamental knowledge on near-field electrodynamic processes in complex carbon nanostructures. The project seeks to explore how one can use near-fields of low-energy collective interband plasmon excitations of individual constituent carbon nanotubes to tailor optoelectronic properties of (i) double wall carbon nanotube systems and (ii) hybrid quantum systems of molecular-array/metal-atomic-wire encapsulating carbon nanotubes. Clear understanding of the properties of collective electron excitations, and how individual constituents of

complex systems communicate with one another in the near-field, and what it does to the properties of the entire complex hybrid system, is a natural prerequisite for advances ranging from new applications, such as coherent light emission, enhanced electromagnetic absorption, scattering and conversion of ambient electromagnetic radiation, to the development of new concepts for future generation carbon based plasmonic nanomaterials engineering. This research will open up new directions for fundamental nanoplasmonics and near-field optics research, currently focused mostly on metallic nanoparticles, to include a new area of nanotube plasmonics.

FY 2014 HIGHLIGHTS

(1) Exciton Bose-Einstein Condensation (BEC) in Carbon Nanotubes: We demonstrate the possibility for the exciton BEC in individual small-diameter (~1–2 nm) semiconducting carbon nanotubes. The effect occurs under the exciton-interband-plasmon coupling controlled by an external electrostatic field applied perpendicular to the nanotube axis. The effect offers a testing ground for fundamentals of condensed matter physics in one dimension and opens up perspectives to develop a tunable coherent polarized light source with carbon nanotubes. [Physical Review B 89, 045414 (2014)] (2) Bipartite Entanglement in Hybrid Carbon Nanotube Systems: We study theoretically a pair of spatially separated extrinsic atomic type species (extrinsic atoms, ions, molecules, or semiconductor quantum dots) near a metallic carbon nanotube, that are coupled both directly via the inter-atomic dipole-dipole interactions and indirectly by means of the virtual exchange by resonance plasmon excitations on the nanotube surface. We analyze how the optical preparation of the system by using strong laser pulses affects the formation and evolution of the bipartite atomic entanglement. We find generic scenarios for the entanglement evolution and formulate practical recommendations on how to optimize and control the robust bipartite atomic entanglement in hybrid carbon nanotube systems. [Chemical Physics 413, 123 (2013); J. Chem. Phys. 140, 064301 (2014)] (3) Plasmon Enhanced Raman Scattering Near a Carbon Nanotube: Quantum electrodynamics theory of the resonance Raman scattering is developed for an atom in a close proximity to a carbon nanotube. The theory predicts a dramatic enhancement of the Raman intensity in the strong atomic coupling regime to nanotube plasmon near-fields. The effect can be used in designing efficient nanotube based optical sensing substrates for single atom detection, precision spontaneous emission control, and manipulation. [Optics Express, submitted (arXiv1407.5142)]

Correlated Electrons in Reduced Dimensions

Institution: Florida State University
Point of Contact: Nicholas Bonesteel
Email: bonestee@magnet.fsu.edu
Principal Investigator: Nicholas Bonesteel
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The combination of strong correlations and reduced dimensionality can lead to the formation of exotic states of matter for which conventional “textbook” methods of condensed matter physics breakdown. An example of such states are those with so-called topological order, a type of quantum order not characterized by any local order parameter but rather by global properties, (e.g., ground state degeneracies on topologically nontrivial surfaces, fractionalized quasiparticle excitations with exotic quantum statistics, etc.). One goal of this project is to better understand topological order, and, in

particular, the intimate connection it has with the theory of fault-tolerant quantum computation. This widely appreciated connection has motivated much of the recent work which attempts to physically realize topologically ordered states with non-Abelian anyon excitations, as well as ideas for how one could essentially simulate topological order on a “conventional” quantum computer and thus have the computer inherit the built in protection of these states from decoherence, (the so-called “surface code” approach --- currently the leading candidate for realizing fault-tolerant quantum computation). The project is also focused on understanding the properties of metals with sharp Fermi surfaces but without well-defined Landau quasiparticles (and thus, again, a class of states which lies outside of standard condensed matter physics). The question of how the breakdown of Fermi liquid theory affects the quantum phase transitions which can occur in these systems, e.g., BCS (Bardeen-Cooper-Schrieffer) pairing, excitonic condensation, is actively being studied, with work focusing on the composite fermion “metal” description of the compressible $\nu=1/2$ quantum Hall state, for which the Halperin-Lee-Read theory provides a powerful theoretical framework for studying at least one flavor of non-Fermi liquid behavior.

FY 2014 HIGHLIGHTS

A two-dimensional electron gas (2DEG) in a magnetic field with Landau level filling fraction $\nu=1/2$ can enter a compressible state in which composite fermions (CFs) --- emergent excitations consisting of electrons bound to two flux quanta --- form a “metal” with a sharp Fermi surface. In bilayer systems made up of two parallel 2DEGs we studied the transition from two decoupled $\nu=1/2$ CF metals (large layer spacing) to a recently proposed interlayer coherent CF state (intermediate layer spacing). In this latter state, interlayer Coulomb repulsion leads to excitonic condensation of CFs which are then free to tunnel coherently between layers. We found this tunneling is suppressed by the layer-dependent Aharonov-Bohm phases CFs experience as they propagate through the fluctuating gauge fields in the system. This suppression leads to (1) an increase in the critical interlayer repulsion needed to drive the transition and (2) a discontinuous jump in the energy gaps to out-of-phase excitations (those involving currents with opposite signs in the two layers) at the transition. Reason (1) may account for the fact that the interlayer coherent state has not yet been observed experimentally; and reason (2) suggests that if such a transition were to be observed, the detection of a discontinuous jump in the out-of-phase energy gaps would provide indirect experimental evidence for the presence of gauge fluctuations in the system. [Phys. Rev. B 89, 085109 (2014); Editors’ Suggestion]. Voltage pulses which rapidly switch on and off the exchange interaction between two electrons have proven a useful resource for manipulating spin states in multi-quantum dot systems. We have recently obtained a new class of pulse sequences which can be used to entangle two two-level systems encoded using six electron spins. Our sequences are obtained analytically, and shed significant light on the structure of the numerically obtained sequences found previously. [Phys. Rev. B 89, 085109 (2014)].

Strongly Correlated Electrons: Ground States, Excited States, and Transport

Institution: California-Irvine, University of
Point of Contact: Kieron Burke
Email: kieron@uci.edu
Principal Investigator: Kieron Burke
Sr. Investigator(s): Roberto Car; Princeton University
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$630,000 (2014-2016)

PROGRAM SCOPE

The aim of the present project is simple. Prof Roberto Car will develop and test a new ground-state method, denoted OP-NOFT (Occupation Probabilities - Natural Orbital Functional Theory), on molecules and solids. Simultaneously, Burke's group will develop a one-dimensional version, and benchmark it against DMRG (Density Matrix Renormalization Group) calculations, which provide essentially exact solutions. Burke's group will use their scattering methodology to extract conductances from sequences of excited-state energies of exact finite-size molecular calculations in 1D using DMRG. These exact conductances will be compared to Kohn-Sham conductances, found by inverting the KS equations for the OP-NOFT ground-state density. Once it is found where these agree (which should be the typical case for zero-temperature, weak-bias systems dominated by a single channel), both groups will collaborate on performing full chemically realistic calculations in 3D. OP-NOFT has the potential to become a standard method in quantum chemistry. It can break bonds correctly, with a much lower computational cost than traditional alternatives and much higher accuracy than standard DFT treatments. Its ability to accurately include strong static correlation makes it ideal for dealing with the inaccuracies of DFT transport calculations for organic molecules.

FY 2014 HIGHLIGHTS

The Burke group has two major projects is being written up for this period. The first is a large study of the relation between density functional theory and lattice models, using the asymmetric Hubbard dimer as an explicit example. This 35-page paper will be submitted to reviews of modern physics, and will serve as a starting point for all future work involving strong correlation. In this case, OP-NOFT yields an exact solution. This work involves the graduate student, plus an international collaboration with a many-body theorist in Oviedo, Spain, Jaime Ferrer Rodriguez. The second is an important demonstration that Coulomb blockade physics can be extracted from a non-local ground-state density functional calculation, without invoking time-dependent density functional theory. This provides a very different view of how DFT describes the underlying physics, counter to many suggestions in the literature. This work is in collaboration with Zhenfei Liu at Lawrence Berkeley National Lab. Two projects were conducted by Car: (1) The OP-NOFT theory was generalized beyond zero seniority (doubly occupied natural orbitals only). A paper is under review at the Proceedings of the National Academy of Science, in collaboration with Morrel H. Cohen (Princeton and Rutgers) and Ralph Gebauer (ICTP, Trieste (Italy)). Rob A. DiStasio, a postdoc at Princeton, is applying this to the homogeneous electron gas. (2) The concept of fragile Mott insulators (FMI) was extended to ring-shaped molecules with repulsive Hubbard interaction threaded by a half-quantum of magnetic flux. The FMI is an insulating ground state that cannot be adiabatically connected to a single Slater determinant. Electron correlations produce a rich phase diagram in these simple molecular systems. Lukas Muechler, a graduate student at Princeton is the author of a Physical Review B paper, in collaboration with Joseph Maciejko (University of Alberta, Edmonton) and Titus Neupert (Princeton Center for Theoretical Science).

PROGRAM SCOPE

The research in this program involves theoretical investigations of electronic, optical and mechanical properties of graphene and its derivatives, such as bi-layer graphene, graphene heterostructures, strained graphene, as well as graphene on various surfaces. One line of research has been development of theoretical models that support graphene's large array of possible technological applications. For example one of our goals has been the understanding of surface plasmons and spin relaxation mechanisms in graphene, related to novel optoelectronics and spintronics applications. Our current research focus is on understanding the role of correlations in graphene under mechanical deformations, such as strain. The main goal is to describe the mutual interplay between strain and electron-electron interactions which could lead to the formation of novel electronic phases with strongly modified electronic, magnetic and optical properties. This direction of research contributes to deeper understanding of interactions in graphene - a subject at the forefront of research on graphene and its derivatives.

FY 2014 HIGHLIGHTS

The main accomplishments in the past year have been in the following areas: 1.) We have discovered that uniaxial strain deformations can have a major effect on van der Waals interactions between graphene sheets. In particular strong, order of magnitude enhancement of the vdW interaction is possible under strain. The van der Waals interaction is also very sensitive to the electron-electron interaction strength, and the renormalization of the Coulomb interactions can in fact lead to modification of the conventional distance dependence of the dispersion forces - an effect unique to graphene. These results can open up a whole new direction in the field of van der Waals heterostructures. 2.) We have investigated the phase diagram of the Anderson impurity model describing localized magnetic states, due to electron correlation, on adatoms in strained graphene. Detailed predictions were made for the values of the Hubbard U and strain necessary to generate magnetic moments. We have studied the influence of uniaxial strain on the ferromagnetic exchange instability in graphene and have found that itinerant magnetism can occur at much smaller (strain-dependent) value of the electron-electron interactions, relative to the unstrained isotropic graphene. This can lead to magnetism, with rather large magnetization, in strongly anisotropic graphene-based systems. 3.) We have studied graphene on Hexagonal Boron Nitride where, due to incommensuration effects with the substrate, graphene can develop gapped low energy modes that spatially conform into a triangular superlattice of quantum rings. In the presence of these modes, we have shown that Coulomb interactions can lead to spontaneous formation of chiral loop currents in bulk and to macroscopic spin-valley order at zero temperature. Thus we have made the first prediction for an exotic many-body state in graphene on Boron Nitride which can possibly lead to unconventional experimental realization of valley order.

PROGRAM SCOPE

The characterization of interacting topological phases of matter is one of the major goals of the BES supported work. The recently discovered prospect of realizing fractional quantum Hall (FQH) states with the inclusion of short-range interactions in lattice models featuring fractionally filled, topologically non-trivial bands has garnered considerable interest. Apart from a paradigmatic extension of the FQH effect to lattices, these states, called fractional Chern insulators (FCI), arise without an externally applied magnetic field. Because the energy scales are those dictated by interactions and hoppings over lattice distances, the FCIs are an important conceptual step towards realizations of fractionalized states at high temperatures. In addition to the investigation of interacting topological states of matter, the BES supported work is also directed at advancing our fundamental understanding of periodically driven, non-equilibrium quantum systems. Non-equilibrium quantum systems stand at a natural frontier of physics that is only beginning to be probed by theory and experiment. Particularly exciting is the possibility of attaining material properties that are unreachable at equilibrium. We are investigating fundamental aspects of non-equilibrium condensed matter theory, most notably we want to understand the nature of the steady states in systems that are driven by an AC electric field while in contact with a thermal reservoir. The presence of dissipation due to the bath is characteristic of solid state systems, and is to be contrasted with the case of artificial structures built on optical lattices, where the systems are well isolated from their environment.

FY 2014 HIGHLIGHTS

We studied analytically a systematic way to construct two-dimensional topological states starting from one-dimensional quantum wires that are coupled together by electron tunneling. In this construction, non-chiral Luttinger liquids are placed in a periodic array of coupled wires. We also analyzed manifestations of topological order in time-reversal-symmetric fractional topological liquids where the edge modes on boundaries are fully gapped by appropriate backscattering terms. In the absence of gapless edge modes, we showed that there is a ground state degeneracy for systems defined on planar surfaces with holes. We also investigated the possibility of measuring the topological ground state degeneracy with calorimetry. Many of the highlights of the BES supported work on interacting topological phases of matter were presented in an article prepared for the proceedings of the Nobel symposium on “New forms of matter: topological insulators and superconductors” that took place in June 2014 in Stockholm, Sweden. The PI presented an invited talk at this symposium with the results of this DOE supported research. Within the scope of the research on non-equilibrium quantum systems, we unveiled a new route to superconductivity that relies on establishing a non-equilibrium population of carriers via optical pumping. Specifically, we showed that optically pumped semiconductors can exhibit superconductivity. We computed the finite superconducting gap and argued that the mechanism can be induced through both attractive and repulsive interactions and is robust to high temperatures.

Quantum Embedding for Correlated Electronic Structure in Large Systems and the Condensed Phase

Institution:	Princeton University
Point of Contact:	Garnet Chan
Email:	gkc1000@gmail.com
Principal Investigator:	Garnet Chan
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$155,000 (2014)

PROGRAM SCOPE

The main objective of the work is to explore, extend, and establish a new technique for bulk materials simulation: density matrix embedding theory (DMET). DMET is a theoretical framework to map bulk problems of correlated electrons, phonons, spin, and spectra into finite correlated problems, which may then be solved accurately using standard techniques. The research has the twin goals of expanding the DMET formalism to new situations (e.g. spin systems, topologically ordered states, long-range interactions, finite temperature, and real-time dynamics) as well as applying DMET to solve long-standing correlated electron materials problems involving quantum magnetism and high temperature superconductivity.

FY 2014 HIGHLIGHTS

This year, we have extended DMET in several directions. These include: calculation of spectral/dynamical quantities; mixed fermion-boson systems (to treat electron-phonon coupling); and incorporating DMET into quantum-classical treatments (i.e. QM/MM). We have further been pushing DMET to more and more challenging applications. We applied DMET to resolve the issue of the intermediate phase of the Hubbard honeycomb model, the source of much controversy. DMET with large clusters definitively show that (i) there is no spin-liquid phase (ii) at intermediate couplings the system is close to a special hexagonal cluster order. More ambitiously, we have also been using DMET with large clusters extrapolated to the thermodynamic limit to produce a definitive ground-state phase diagram of the 2D Hubbard model on a square lattice, with rigorous error bars. The 2D Hubbard model is the fundamental model of high T_c superconductivity, and understanding its ground-state behaviour is a long-standing challenge. Using DMET, we have been able to compute the ground-state phase diagram to very high accuracy, better than $0.006t$ across the whole phase diagram, well below the superconducting T_c . Many basic questions about the ground-state diagram (such as even the presence of superconductivity) have long been contentious. Our converged phase diagram demonstrates that there is robust superconductivity in the ground-state, as well as rich competing magnetic, charge, and pair density wave phenomena which emerges at large interaction strength. The invention of DMET was specifically mentioned in the National Academy of Sciences Award for Initiatives in Research; and many groups have also started exploring this technique in this year.

Scalable Computational Tools for Discovery and Design: Excited State Phenomena in Energy Materials

Institution: Texas-Austin, University of
Point of Contact: James Chelikowsky

Jeffrey Neaton; Lawrence Berkeley National Laboratory
Chao Yang; Lawrence Berkeley National Laboratory
Students: 3 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$711,495 (2014)

PROGRAM SCOPE

The objective of this project is to develop and implement new methods and theories to elucidate and predict excited electronic state phenomena in energy related materials. Understanding excited state phenomena requires knowledge of both the ground state properties and the related many-electron interactions with excited states, which may involve structural and orbital relaxations. As such, quantitative predictions for excited state phenomena are at the leading edge of current theories for the electronic structure of materials. Advanced algorithms and many-body perturbation theory will be used to predict quasiparticle excitations and lifetimes, optical spectra, excited-state energy surfaces, transport properties, and other excited-state properties/processes. Excited-state properties will be addressed in an interacting Green's functions formalism within many-body perturbation theory. Quasiparticle spectra will be computed within the GW approximation for the electron self-energy, and two-particle optical excitations will be calculated within a Bethe-Salpeter equation approach, including electron-hole interactions. Ground-state properties will be addressed with pseudopotentials within density functional theory. A solution of the Kohn-Sham problem for large scale systems will be implemented within real space using newly developed "parallel" eigensolvers. Science applications will focus on molecular organic assemblies and transition-metal oxides, which are examples of two important classes of materials that promise low-cost, sustainable solar energy conversion. Although structurally distinct, these materials classes share common chemical attributes: highly-localized, sometimes strongly-correlated electronic states and, in some instances, appreciable noncovalent interactions. Additionally, interfaces (both metal-semiconductor and organic-organic) are crucial to energy conversion, and in many cases, their impact on device function is not well understood.

FY 2014 HIGHLIGHTS

Significant advances in algorithms and efficacious coding were achieved for both ground state and excited state codes. With respect to the ground state code, new eigensolvers were implemented to compute eigenvalues within an energy window. This approach adds an additional level of parallelism and allows one to address a key bottleneck: The diagonalization of a large, dense matrix. A new procedure for expediting matrix-vector multiplications was developed that will have wide spread applications. Continued work on interfacing excited state and ground state codes were executed. Materials applications were also carried out. Data mining techniques for predicting the properties of materials were developed. New methods for computing coulombic interactions of charged defects in nanoscale materials were implemented. Studies in fundamental defects, i.e. the oxygen vacancy in strontium titanate compounds were carried out, and surface/interfacial properties of these compounds with respect to highly correlated phenomena were explored.

Theory of Functionalized Nanostructures

Institution: Texas-Austin, University of
Point of Contact: James Chelikowsky
Email: jrc@ices.utexas.edu
Principal Investigator: James Chelikowsky
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The theme of this research program is to develop and implement theoretical methods for predicting and understanding the properties of functionalized matter at the nanoscale. The nanostructures of interest are those composed of electronic materials, e.g., semiconductors like Si or ZnO. Within the nano regime, phenomena occur that are characteristic of neither the atomic limit nor the macroscopic limit. Such phenomena can have direct consequences for characterizing properties of materials. To capitalize properly on predicting such phenomena in this transition (nano) regime, a deeper understanding of the electronic, optical, and magnetic properties of matter will be required. Areas of research encompassed by this work include (1) the electronic and structural properties of dopants relevant for the functionalization of nanostructures (nanocrystals, nanowires, and nanofilms), including both magnetic and non-magnetic dopants; and (2) the evolution of bulk-like electronic, magnetic, and structural properties from the nano to macro scale. The proposed areas of research will enhance our understanding of nanomaterials and the role of quantum confinement and dimensionality at the nanoscale.

FY 2014 HIGHLIGHTS

Research within this program focused on two applications during this time period. One application involved the development of a new model for predicting the properties of charged defects in nanostructures. In particular, an “effective capacitance” model was developed for computing the electronic properties of charged defects in crystals and nanostructures. This model avoids many of the complexities occurring when supercell geometries are employed. Such geometries result in long range coulomb forces involving divergent terms, which often require artificial compensating background charge densities to achieve converged energies. The capacitance model avoids compensating backgrounds. It was employed to determine when heavily doped nanowires become metallic. The other application involved examining the role of dopants on vibrational modes in the Raman spectra of P-doped Si nanocrystals. Raman spectra is a convenient probe to determine the bonding characteristics of materials, e.g., the existence of particular chemical bonds. The P-Si bond does not significantly change the vibrational modes of the nanocrystal, but does break symmetry and strongly alters the Raman spectra. As a consequence, Raman measurements can be used to assess the bond site geometry of doped nanocrystals.

A Computational Approach to Complex Junctions and Interfaces

Institution:	Florida, University of
Point of Contact:	Hai-Ping Cheng
Email:	cheng@phys.ufl.edu
Principal Investigator:	Hai-Ping Cheng
Sr. Investigator(s):	James Fry; Florida, University of
Students:	1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding:	\$180,000 (2014)

PROGRAM SCOPE

The focus of our DOE BES funded program is to understand physical processes at interfaces and across nanojunctions via state-of-the-art, large-scale computation and simulation. Theoretical treatment for electronic degrees of freedom in our investigations is mainly at the level of density functional theory with generalized gradient approximations. Various theories, methods and techniques including

scattering theory, non-equilibrium green functions, the density matrix method, Boltzmann transport theory, classical molecular dynamics, and van der Waals corrections etc. will be used to calculate physical and chemical quantities needed for addressing problems and issues. We study problems in a number of complex interfaces and junctions including a) electron transport through metal-azobenzene-molecule-metal junctions, where the molecule can transform between trans and cis configurations in response to light excitation; b) bonding, atom diffusion, and magnetization in systems containing the tris(8-hydroxy-quinolino)aluminum (Alq3) molecule on magnetic surfaces and between two magnetic leads, for its role as insulator spacer in magnetic tunneling junctions; c) electron dynamics coupled with structural relaxation and phonon-electron interaction after photo-excitation in carbon nanotubes and graphene that are functionalized by adsorbed organic molecule, because understanding such processes may provide hints of mechanisms for photon-electron current conversion; and finally d) interfacial electronic and magnetic properties. One common theme unifying these systems is that interfacial structure has critical effects on properties, and our investigations based on first-principles can provide guidance, not only interpretation, for experiments. Our effort also includes major development of theoretical methods for studying electron transport.

FY 2014 HIGHLIGHTS

We have shown that the conformational dependence of the Coulomb charging energy of a nanocluster leads to a giant electroresistance, where charging induced conformational distortion changes the blockade voltage. The intricate interplay between charging and conformation change is demonstrated in a nanocluster Zn_3O_4 by combining a first-principles calculation with a temperature-dependent transport model. The predicted hysteretic Coulomb blockade staircase in the current-voltage curve adds another dimension to the rich phenomena of tunneling electroresistance. The new mechanism provides a better controlled and repeatable platform to study conformational electroresistance. We have completed the development of a hybrid approach for electron transport. We applied the method to study conductance cross Ag-silicence-Ag junctions and Ni-hBN-Ni junctions, two systems that can be realized in laboratory. When the number of layers of an insulator 2D crystal is small, the calculated transmission coefficient per channel is a fraction of 1, the Landauer equation is no longer adequate. Our hybrid scheme that combines NEGF (Non-Equilibrium Green's Function) techniques, scattering theory, and semi-classical Boltzmann transport theory to compute the conductance of well conducting junctions. We have found a quantitative limit for transmission coefficient below which the Landauer method and the Boltzmann equation agree. We have also implemented the GW method in a newly developed all-electron band structure code, EXCITING+ (also called modified ELK). We used the new GW code to study a group of semiconductors.

Disorder, Dynamics, and Transport in Quantum Magnets

Institution: California-Irvine, University of
Point of Contact: Sasha Chernyshev

Principal Investigator: Sasha Chernyshev
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$110,000 (2014)

PROGRAM SCOPE

Within the current project we perform a set of interrelated theoretical studies with the goal of deepening our understanding of the dynamical and transport phenomena in quantum magnets, in particular the phenomena induced or influenced by disorder. Fundamentally, spin dynamics and magneto-thermal transport are widely open fields of study with the problems of mutual interactions of spin and phonon excitations, role of the dimensionality of spin system, and effects of disorder being largely unexplored. The experimental discoveries of a variety of unusually strong field-dependent phenomena and of the signatures of quasi-ballistic transport in a number of materials contribute to the excitement in this area and call for theoretical explanation. We expect our studies to advance basic knowledge of the physical properties of a diverse group of materials and yield predictions of new phenomena in them.

FY 2014 HIGHLIGHTS

We have recently made a significant progress in theoretical understanding of the quantum effects in kagome-lattice antiferromagnets and provided deep insight into the quantum order-by-disorder mechanism, which is important for the broad class of frustrated systems. We have also challenged general expectation that quantum fluctuations simply follow thermal ones in selecting the ground state and presented a rare example of the situation when quantum order-by-disorder defies this trend and yields the ground state that is different from one favored by thermal fluctuations. We have demonstrated that the order selection is generated by topologically non-trivial tunneling processes, making loops around elementary hexagons. We have proposed a tentative phase diagram of the model and suggested further theoretical studies. This recent progress also paves the way for the future studies of the unusual spin dynamics and calculations of the dynamical structure factor of the realistic kagome-lattice antiferromagnets such as iron-jarosite.

First Principles Investigation of Complex Materials Properties

Institution: Georgia Institute of Technology
Point of Contact: Mei-Yin Chou
Email: meiyin.chou@physics.gatech.edu
Principal Investigator: Mei-Yin Chou
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$155,000 (2014)

PROGRAM SCOPE

This project concentrates on studying complex materials properties using first-principles electronic-structure methods. The computational tools that we will employ include density functional theory (DFT) within the local-density or generalized gradient approximation (LDA or GGA), the pseudopotential method with a plane-wave basis, quantum Monte Carlo (QMC) methods for systems with considerable electron correlation, density-functional perturbation theory (DFPT) for the vibrational properties, and nonequilibrium Green's function methods for electron transport. Our goal is to unambiguously explain the phenomena observed in the experiment and to reliably predict new materials properties. Recently, we have focused on low-dimensional electronic systems that exhibit interesting physics not present in typical bulk systems. In particular, we have concentrated on studying the interesting properties of graphene, metal thin films, and semiconductor nanowires.

FY 2014 HIGHLIGHTS

We have performed first-principles calculations to illustrate that it is possible to synthesize silicene and germanene on the graphene substrate without destroying graphene's characteristic Dirac-fermion-like linear dispersion around its Dirac points, due to the weak van der Waals interlayer interaction. In addition, multiple phases of single crystalline silicene or germanene with different orientations could coexist at room temperature based on our energetics analysis. The substrate breaks the sublattice symmetry in silicene and germanene and induces a gap at the Dirac point. For silicene on graphene, the gap could be as large as 57 meV. For germanene on graphene, the gap created by the substrate effect is of the same order as that induced by the spin-orbit coupling (SOC) effect. The interplay between the substrate and SOC effects could be used for further band-gap manipulations. Our fundamental study of the electronic structure and energetics of these silicene/graphene and germanene/graphene bilayers may provide important insight for other two-dimensional van der Waals heterostructures.

Interplay Between Superconductivity and Magnetism in Iron-Based Superconductors

Institution: Wisconsin-Madison, University of
Point of Contact: Andrey Chubukov
Email: achubuko@umn.edu
Principal Investigator: Andrey Chubukov
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

The goal of the project is to understand theoretically the interplay between superconductivity, magnetism, and nematic order in Iron-based superconductors (FeSCs), which currently attract high attention in the physics community. The primary goals are to understand the mechanism of superconductivity, the origin of magnetism and of the nematic order which accompanies structural distortion, the co-existence regimes of different orders, and the observed pseudogap-like behavior in the normal state. My research explores the idea that superconductivity in FeSCs is of electronic origin and is caused by the exchange of spin-fluctuations, enhanced due to close proximity to antiferromagnetism. The spin-fluctuation approach has been discussed over a number of years for the cuprates, where it gives rise to a d-wave superconductivity. For the pnictides, which are multi-band materials, the spin-fluctuation approach leads to an attraction in both d-wave and extended s-wave (s^+) channels, and it becomes an issue what type of order the system chooses at a given doping. Besides, due to the presence of multiple Fermi surface sheets, both s-wave and d-wave gaps can have quite non-trivial forms, e.g., an s^+ gap may have nodes. The understanding of magnetically-mediated superconductivity in FeSCs will contribute to a generic understanding of the pairing of fermions near quantum-critical points -- the problems ranging from s-wave pairing by soft optical phonons to color superconductivity of quarks mediated by a gluon exchange. Antiferromagnetism and superconductivity are neighbors in many systems: cuprates, heavy-fermion materials, 5d- oxides, cobaltates, and the study of the interplay between magnetic and superconductivity should have impact on these systems as well.

FY 2014 HIGHLIGHTS

My research in 2013-2014 was focused on properties of Fe-based superconductors, charge order in the cuprates, collective modes in near-critical Fermi liquids, properties of anisotropic triangular antiferromagnets and superconductivity of fermions on hexagonal lattices. All these works were supported only by DOE. The analysis of Fe-based superconductivity has been the primary subject of my DOE project and below I summarize my main results on Fe-based materials. (i) I analyzed how magnetic and nematic transition lines behave under the superconducting dome. (ii) I wrote two review papers on the issue of superconductivity from nominally repulsive electron-electron interaction, (iii) I studied spin resonance in the superconducting state of recently discovered alkali-intercalated iron selenide materials $A_x\text{Fe}_{2-y}\text{Se}_2$ ($A = \text{K, Rb, Cs}$). I considered the novel s^+ superconducting state recently proposed by us, with superconducting gap changing sign between the hybridized electron pockets. We argued that such a state supports a spin resonance. I computed the dynamical structure factor and showed that it is consistent with the results of inelastic neutron scattering. (iv) I studied Raman scattering in the superconducting state of $A_x\text{Fe}_{2-y}\text{Se}_2$. I developed the theory of Raman scattering assuming that the ground state has s -wave symmetry but d -wave is a close second. (v) I wrote a review on different microscopic models for nematicity in the iron pnictides, and on how nematicity is linked to other ordered states of the global phase diagram of these materials – magnetism and superconductivity. (vi) I analyzed the structure of the pairing interaction and superconducting gap in LiFeAs by decomposing the pairing interaction for various k_z wavevector cuts in the Brillouin zone into s - and d -wave components and by studying the leading superconducting instabilities. (vii) I analyzed superconductivity in the coexistence region with spin-density-wave order in weakly doped Fe-pnictides.

Dynamics of the Magnetic Flux in Superconductors

Institution: New York-Lehman College, City University of
Point of Contact: Eugene Chudnovsky
Email: eugene.chudnovsky@lehman.cuny.edu
Principal Investigator: Eugene Chudnovsky
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$240,000 (2014-2016)

PROGRAM SCOPE

The work on the DOE grant at Lehman College is advancing the knowledge of physics of superconductors and their potential applications by addressing fundamental and practical questions of the physics of superconducting materials and circuits. Recently pursued research topics include macroscopic quantum tunneling of the magnetic flux in type-I superconductors, dynamics of topological defects in parental compounds of high-temperature superconductors, effects of topological defects generated by random fields on the long-range order in flux lattices and spin systems, manipulation of nanomagnets by Josephson junctions, and decoherence of flux qubits. The ongoing work and research planned for the nearest future include analytical and large scale numerical studies of the effects of random fields on correlations in superconductors and random magnets, stability of skyrmions in the presence of random fields and lattice deformations, and coupled quantum dynamics of nanomagnets and Josephson junctions. This work will provide deeper insight into glassy properties of flux lattices that are responsible for the critical currents, may help understand the interplay between non-linear spin fluctuations and lattice deformations in high-temperature superconductors, and will suggest applications of Josephson devices for precise measurements of quantum nanomagnetic phenomena.

FY 2014 HIGHLIGHTS

We have studied the connection between topology and long-range behavior of random-field systems. This problem is related to critical currents in type-II superconductors and to the coercivity of disordered magnets. Years of studies of thermodynamic equilibrium of random-field systems by many authors rendered inconclusive results. Meanwhile real systems with disorder rarely reach thermodynamic equilibrium. Our focus has been on reversible versus irreversible behavior. Through rigorous mathematical arguments, supported by numerical simulations on lattices containing up to one billion sites, we have demonstrated that the behavior of the random-field system is governed by topology that depends on the relation between the number of components of the order parameter and dimensionality of space. Presence of topological defects results in irreversible glassy behavior, while in the absence of such defects the system exhibits reversible behavior with correlations decaying exponentially at large distances. In a separate work we have studied Josephson tunneling through a circularly polarized magnetic disc with a vortex, forming a weak link between two superconductors. Our focus has been on the possibility of the detection of the tiny movements of the vortex, due to thermal jumps or quantum tunneling, via measurement of the tunneling current. [1] D. A. Garanin, E. Theory of Layered Organic and Inorganic Materials with Charge-Spin Frustration

Institution: Mississippi State University
Point of Contact: Torsten Clay
Email: r.t.clay@msstate.edu
Principal Investigator: Torsten Clay
Sr. Investigator(s): Sumit Mazumdar; Arizona, University of
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

In a frustrated material the lattice arrangement prevents local energy constraints from being satisfied, leading to a large degeneracy of quantum states and highly unusual electronic properties. Most theoretical work to understand frustration has been carried out on quantum spin models, where charge degrees of freedom have been frozen out. In this project we investigate materials with lattice frustration where instead charge as well as spin degrees of freedom remain important at low temperatures. This theoretical work will be applied to a number of quasi-two dimensional materials, including the organic charge-transfer salt superconductors and layered cobaltates. We will focus in particular on whether frustration is a key element of the unconventional superconductivity found in many of these materials.

FY 2014 HIGHLIGHTS

We developed a correlated-electron minimal model for the normal state of metal-intercalated phenanthrenes. Exact finite cluster calculations showed that while the systems with molecular charges of -1 and -2 are one- and two-band Mott-Hubbard semiconductors, respectively, molecular charge -3 gives two nearly 3/4-filled bands. This carrier density per molecular orbital is nearly the same in the

normal state of the superconducting aromatics and organic charge-transfer solids, and may be the key to understanding unconventional superconductivity in the family of doped polycyclic aromatic hydrocarbons. Importantly, we believe that our work gives a hint to the correct mechanism of superconductivity in the metal-doped fullerides, which remains to be understood two decades after their discovery. We performed the first large-scale correlated-electron calculation of the conducting layer of the organic superconductor family κ -(BEDT-TTF)_{2X}, without assuming an effective 1/2-filled band description. Our results show that within the single-band Hubbard model the system remains a correlated metal even for very strong onsite Coulomb interaction U , with no signs of charge or spin ordering. This may explain why long-range antiferromagnetic order is only found experimentally in few members of the family. We revisited the theory of the spin-Peierls (SP) state in the organic salt (TMTTF)_{2X}. We showed that claims that two distinct SP exist here were a result of poor parameter choices in the two-dimensional model. This work led to a further study of the bond distortion pattern in 1/4-filled SP materials and updated phase diagram for the one-dimensional extended Hubbard model.

Spin and Orbital Physics in Novel Correlated Materials

Institution: New Jersey-Rutgers, State University of
Point of Contact: Piers Coleman
Email: coleman@physics.rutgers.edu
Principal Investigator: Piers Coleman
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

This theoretical project seeks to further our understanding of materials in which the strong magnetic interactions between the electrons give rise to new classes of emergent behavior. There are three areas of focus: (1) Topological Kondo insulators. Kondo insulators are a class of magnetic material where electron screening of local moments drives a crossover from a metal to an insulator at low temperatures. Our proposal in 2010 that certain Kondo insulators are topological, with protected metallic surfaces, has attracted a lot of interest, especially with the confirmation that the Kondo insulator Samarium Hexaboride is topological. This material is of particular interest, because it has a much higher bulk resistivity than other topological insulators, moreover, the strong interactions can induce novel phase transitions at the surface. Our research aims to understand the properties and instabilities of the surface states, and the bulk. (2) Iron Based Superconductors. We are studying the multi-orbital character of the paired state in these materials: current theories assume that the superconducting pairing is orbitally diagonal; we have discovered a much larger class of orbitally entangled states, some with the s-plus-minus symmetry thought to exist in many of these materials. We are trying to link changes in the orbital entanglement with the observed sudden phase transitions from fully gapped to nodal superconductivity. (3) Two dimensional Frustrated Magnetism. Here we seek to understand how frustration in two dimensions can overcome the Hohenberg Mermin Wagner theorem, and drive emergent finite temperature order in a Heisenberg antiferromagnet. We are studying the frustrated honeycomb-triangular lattice, where we believe there may be a finite temperature power-law phase despite the Heisenberg symmetry.

FY 2014 HIGHLIGHTS

(1) Topological Kondo Insulators (TKI's). One of the unsolved paradoxes of SmB_6 , is that the conducting surface states are 'light', with a Fermi velocity that is many times smaller than predicted by the current 'heavy electron' theories. We have discovered that the surfaces of topological Kondo insulators are prone to 'Kondo breakdown', where the screening clouds around the surface magnetic moments break-down. This effect releases charge into the surface states, driving them much lighter, providing a natural explanation of experiments. This work is currently in review with Physical Review Letters. (2) Iron based Superconductors: (IBSC). We have shown that the chirality of d-bands in IBSCs act as orbital Rashba fields, mixing motional and internal orbital angular momenta of the pairs. The atomic orbitals can be regarded as $S=2$ local moments coupled to the orbital $L=2$ motion of the Cooper pairs. If our theory is correct, then the condensate of the IBSCs can exist in two states - a low spin, IBSCs can exist in two states - a low spin s^+ -wave and a high-spin nodal g -wave state. With this theory we are able to account for the unusual properties of KFe_2Se_2 , which undergoes a nodal-fully gapped transition under pressure. This work is currently under review with Nature Physics. (3) Frustrated Magnetism. We have just published a long paper on our studies of a two dimensional Heisenberg antiferromagnet with an interpenetrating hexagonal and honeycomb lattice. Here, fluctuations drive the development of $p=6$ state Clock order between the two lattices. At an intermediate temperature, this Heisenberg magnet displays an emergent finite temperature Kosterlitz Thouless transition in a Heisenberg antiferromagnet. To carry out the rather involved scaling of the spin-wave stiffnesses needed for this project, we applied a method called 'Ricci Flow' borrowed from String Theory and Number Theory. This is the first work to demonstrate the practical application of Friedan scaling to a 2D antiferromagnet.

First-Principles Calculation of Vibrational Mode Lifetimes in Complex Materials

Institution: Clemson University
Point of Contact: Murray Daw
Email: daw@clemson.edu
Principal Investigator: Murray Daw
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

In this project we will develop, test, and apply a new, more efficient method for calculating vibrational mode lifetimes in solids. The method, originally proposed in 2010 by Ted Dickel and Murray Daw, is based on ensemble averages of appropriate functions in phase space that can be carried out by conventional Monte Carlo. The calculation requires a means of calculating interatomic forces. The ultimate goal is to implement the method using forces from an existing first-principles electronic structure code, but the first phase focused on implementation with an empirical potentials code. Recapping the project objectives: (i) Test the proposed approximation on simple models of vibrating lattices, and further understand its range of validity. (ii) Implement the method as a 'wrapper program' (Jazz) for an existing empirical potentials code (LAMMPS). (iii) Use the method to investigate vibrational mode lifetimes in several interesting materials. (iv) Implement the method as a 'wrapper program' for an existing first-principles electronic structure code, and to apply that new method to some interesting examples. This year we completed the first two objectives and began working on the last two.

FY 2014 HIGHLIGHTS

(1) The fourth-moment approximation is very successful in predicting the lifetimes of vibrational modes in most solids. We obtained this conclusion by analyzing extensive ensemble Molecular Dynamics calculations (MD runs averaged over an ensemble of initial conditions) of vibrating solids. We concluded that this approximation works well because the density of states of each individual mode is dominated by a single, broadened peak, which is typical of normal modes in solids. The second moment tracks the overall frequency of the mode, which shifts with temperature (so-called “quasi-harmonic” effect). The fourth moment provides a measure of the temperature-dependent broadening due to anharmonicity beyond that captured by the quasiharmonic shift. We also surmised that atypical systems – such as those with multiple minima (so-called “rattlers”, for example) – will likely require further development. (2) We have produced and published a code for calculating vibrational mode lifetimes based on empirical potentials. The code (“Jazz”) is implemented as a Python wrapper for LAMMPS (a multi-purpose empirical potential code originated and maintained by Sandia National Labs). The anharmonic character of the normal modes is analyzed via the Monte Carlo-based moments approximation. It is distributed as open-source software and can be downloaded from <http://jazzforlammps.sourceforge.net/>. Jazz will work for any material available in LAMMPS. (3) We have begun a study of vibrational modes in several systems of interest. In 3D solids, we are studying the lifetimes of modes in Si- and Ge-based clathrates. In nano-structures, we are studying the modes of nanowires, nanotubes, and graphene sheets. In all systems, we are investigating also the effects of native defects on the mode lifetimes. (4) We have carried out initial tests using the first-principles electronic structure code SOCORRO (originated and maintained by Sandia National Labs).

Time-Dependent Density-Functional Theory of Charge, Energy and Spin Transport and Dynamics in Nanoscale Systems

Institution: California-San Diego, University of
Point of Contact: Massimiliano Di Ventra
Email: diventra@physics.ucsd.edu
Principal Investigator: Massimiliano Di Ventra
Sr. Investigator(s): Giovanni Vignale; Missouri, University of
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$630,000 (2014-2016)

PROGRAM SCOPE

The trend toward extreme miniaturization of electronic devices has fueled a lot of theoretical investigations aimed at understanding the electrical transport properties of quantum-mechanical systems. However, despite considerable progress, this problem still represents a formidable challenge since one has to deal with a quantum many-body system driven out of equilibrium. In this project, we continue our work towards a complete formulation of the transport problem using Time-Dependent Density-Functional Theories (TDDFTs), by which we understand not only the traditional time-dependent DFT, but also our recent derivatives and generalizations, such as the time-dependent current-density functional theory, the quantum continuum mechanics, the stochastic time-dependent current-DFT for open quantum systems, and the very recently developed thermal TDDFT, which includes energy density and the associated inverse temperature field as basic variables. More specifically, the project seeks further theoretical development in the following areas: (i) Calculation of dynamical many-body corrections to the electrical resistance of nanoscale conductors (e.g., many-body corrections to the Landauer formula); (ii) “Luttinger-field” description of thermoelectric phenomena; (iii) Development of

new exchange-correlation energy functionals for charge, spin, and energy dynamics; (iv) Calculations of transport coefficients (viscosity, thermal conductivity, spin conductivity) of electron liquids in the hydrodynamic regime, and understanding of transport properties of nanoscale and atomic systems; (v) *Ab initio* theory of entanglement in atoms, molecules, and nanoscale systems; (vi) Development of the quantum continuum mechanics, towards a “density-functionalized” form of hydrodynamics.

FY 2014 HIGHLIGHTS

(i) Our papers 'Density Functional Theory of Thermoelectric Phenomena', by F. G. Eich, M. Di Ventura, and G. Vignale, Phys. Rev. Lett. 112, 196401 (2014) and “Luttinger field approach to thermoelectric transport in nanoscale conductors”, by F. G. Eich, A. Principi, M. Di Ventura, and G. Vignale, Phys. Rev. B 90, 115116 (2014), present a novel approach to the study of thermoelectric phenomena, based on the introduction of a Luttinger field that couples locally to the energy density. We have shown that our approach reduces to Landauer’s theory in the linear regime, when dynamical corrections can be ignored; (ii) In 'Transverse and longitudinal gradients of the spin magnetization in Spin-Density-Functional Theory', arXiv:1309.4905, F. G. Eich, S. Pittalis, G. Vignale, Physical Review B 88, 245102 (2013) we proposed a new strategy for the construction of an exchange-correlation functional for non-collinear spin DFT; (iii) With Alessandro Principi we performed extensive studies of transport coefficients of electron liquids, and discovered a violation of the Wiedemann-Franz law, connecting the thermal and electrical conductivity of an electronic system in the hydrodynamic regime (see 'Violation of the Wiedemann-Franz law in hydrodynamic electron liquids” A. Principi and G. Vignale, arXiv:1406.2940, submitted to Phys. Rev. Lett.). We have also completed careful studies of plasmon losses in graphene, including electron-electron, electron-impurity, and electron-phonon interactions, finding detailed agreement between theory and experiment [See 'Highly confined low-loss plasmons in graphene-boron nitride heterostructures', by Woessner *et al.*, Nature Materials (2014) DOI: 10.1038/NMAT416]; (iv) Together with Sebastiano Peotta and in collaboration with C.-C. Chien we studied the transport properties of atomic gases subject to gauge fields using exact time-dependent DMRG (Density Matrix Renormalization Group) for conditions under which a quasi-steady state is formed.

EARLY CAREER: Competing Orders in Correlated Materials: Impact of Disorder and Non-Equilibrium Perturbations

Institution: Minnesota, University of
Point of Contact: Rafael Fernandes
Email: rfernand@umn.edu
Principal Investigator: Rafael Fernandes
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$750,000 (2014-2018)

PROGRAM SCOPE

The goal of this project is to explore, understand, and ultimately control the competing electronic ordered states ubiquitously present in correlated materials. These unique systems not only provide empirical access to the collective behavior of interacting electrons, unveiling fundamental properties of quantum matter, but also serve as cornerstones for exciting technological applications. As different parameters of these correlated materials are tuned, distinct competing electronic ordered states emerge, such as magnetism, unconventional superconductivity, charge order, and orbital order. On the one hand, this competition suppresses the onset of desired phases, particularly of high-temperature

superconductivity. On the other hand, the enlarged ground-state degeneracy associated with these multiple many-body instabilities can give rise to unusual inhomogeneous correlated normal states, such as electronic smectic and nematic phases. To advance our understanding and control of these phenomena, a multi-faceted theoretical approach is employed in this project, consisting of: (i) The investigation of relatively unexplored regimes with the potential to unveil novel behaviors – in particular, the study of competing phases taken out of equilibrium to explore the potential to enhance the transition temperatures of unconventional superconductors by optical pulses. (ii) The embracement of realistic features of correlated materials in their microscopic descriptions – in particular, the investigation of the impact that disorder, in its various forms, has on electronic smectic and nematic states present in the phase diagrams of unconventional superconductors. (iii) The promotion of synergy with established and novel experimental probes, with particular emphasis on scanning tunneling microscopy and ultrafast spectroscopy, not only by using data as input of theoretical models, but also by providing concrete guidance for experiments.

FY 2014 HIGHLIGHTS

Funding for this project was initiated in mid-July, 2014. Since then, we have made important progress on the impact of disorder to the unconventional superconducting state promoted by quantum critical fluctuations, and also on the behavior of the nematic degrees of freedom in iron-based superconductors in the presence of impurities. We have also been developing a framework to extract impurity potentials from scanning tunneling microscopy data. Its initial application to dichalcogenide charge-ordered superconductors revealed that the charge density-wave instability in NbSe₂ is promoted not by Fermi surface nesting, but rather by the coupling to soft phonon modes.

Theoretical Description of Pump-Probe Experiments in Ordered Materials

Institution: Georgetown University
Point of Contact: James Freericks
Email: freericks@physics.georgetown.edu
Principal Investigator: James Freericks
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014-2016)

PROGRAM SCOPE

The Department of Energy has a significant investment in large equipment that can generate state-of-the-art ultrashort pulses from free-electron lasers like the Linac Coherent Light Source (LCLS). This has led to a series of new ultrafast pump-probe experiments to try to measure the dynamics of strongly correlated materials. Many of these experiments have been performed on materials in ordered phases, such as charge density wave (CDW) materials or superconductors (SC). We have been performing research in this field for some time now, and in this project, we plan to expand our efforts from primarily working in the normal state, to working in the ordered phases of these materials. We will extend our theoretical calculations to include the effects of the ordered phases, investigating electron-phonon coupled materials that order in a CDW or SC phase. We will examine an interesting type of quantum critical point that is seen a strongly correlated CDW phase, which involves a transition from an insulator to a metallic CDW as a function of temperature, with the metallic phase separating a weakly correlated CDW insulator from a strongly correlated insulator at $T = 0$. Finally, we will work to develop the theoretical description of novel pump-probe experiments like time-resolved electronic Raman

scattering. We will also apply these techniques to models of real materials like graphene and the CDW-ordered material 1T-TaS₂. Our project will be applying recent advances in nonequilibrium many-body physics to experiments of high interest to the Department of Energy (DOE) and represents a significant scientific challenge which is in the area of materials driven far from equilibrium (one of the DOE challenge areas).

FY 2014 HIGHLIGHTS

During the past year, we completed a significant amount of research on the nonequilibrium behavior of the simplest charge-density-wave insulator. We examined time-resolved photoemission, dielectric breakdown, high harmonic generation, and the quantum excitation process. In addition, we completed much work on electron-phonon coupled systems, including situations when the system is in a superconducting state. This includes deriving sum rules for the Green's functions and self-energies even in the presence of external fields, and examining the relaxation pathways and the spectral weight redistribution that one would see in a time-resolved photoemission study. Finally, we corrected and resubmitted a manuscript on time-resolved photoemission in graphene. We also spent time working on universal properties of bad metals by invoking an extremely simple model for the transport density of states and showing that it naturally leads to a linear resistivity at moderate temperature and that it leads to a universal behavior of the thermopower, which is captured qualitatively by the simple Kelvin formula for the thermopower. We have a number of projects underway, which include generalizing the CDW work to models that have many-body interactions and expanding the electron-phonon coupling work to include a renormalization of the phonon bath due to heating by the electrons.

EARLY CAREER: Predictive Theory of Topological States of Matter

Institution: Massachusetts Institute of Technology
Point of Contact: Liang Fu
Email: liangfu@mit.edu
Principal Investigator: Liang Fu
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The goal of this project is to develop a theory of new topological states of matter and predict their material realizations. The PI has mainly focused on topological states protected by crystal symmetries, which he terms 'topological crystalline insulators'. Specifically the PI aims to 1) develop a systematic approach to classify topological phases that exhibit robust surface or edge states, within the framework of band theory of periodic solids, 2) identify their material realizations, predict experimentally testable signatures and propose device applications of topological materials, 3) develop a theory of topological phase transitions in the presence of disorder and/or interaction, and 4) study the rich interplay between topological order and symmetry breaking. Results from this project will significantly expand the horizon of topological matters, offer unique insight into the competition between localization and itinerancy in correlated electron systems, and pave the way for applications in tunable electronics and fault-tolerant quantum computation.

FY 2014 HIGHLIGHTS

(1) In collaboration with Vidya Madhavan's STM group, the PI discovered Dirac mass generation from ferroelectric structural distortion in the topological crystalline insulator (TCI) PbSnSe, which spontaneously and partially breaks the underlying crystal symmetry. This work reveals the first example of a topological system that is highly tunable by symmetry breaking, and unambiguously demonstrates how symmetry protects topological order. Publication: Science 341, 6153 (2013) (2) The PI's group (with Jagadeesh Moodera) proposed the concept of topological field effect transistor based on a two-dimensional topological crystalline insulator, as realized in SnTe thin films. The working mechanism of the proposed device relies on the unique properties of TCI conducting edge states, i.e., applying a vertical electric field opens up a gap and hence shuts off the conduction. Publication: Nature Materials 13, 178 (2014) (3) The PI (with a graduate student Evelyn Tang) found that strain has a dramatic effect on topological crystalline insulator surface states: it creates a pseudo-magnetic field as large as 200T and leads to the formation of Landau levels while maintaining time-reversal symmetry. The PI proposed that these Landau levels could be responsible for interface superconductivity that has been observed (but not understood) in IV-VI semiconductor heterostructures. Publication: Nature Physics 10, 964-969 (2014) (4) The PI's group predicted a new class of topological crystalline insulators in anti-perovskites with chemical formula A_3BO . Experimental groups are currently working to search for the predicted topological surface states. Publication: PRB, 90, 81112 (2014).

Theory of Fluctuations in Superconductors

Institution: Maryland, University of
Point of Contact: Victor Galitski
Email: galitski@umd.edu
Principal Investigator: Victor Galitski
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$103,000 (2014)

PROGRAM SCOPE

The general objective of the DOE project is to explore fluctuation phenomena and related strong-correlation physics in a wide variety of interacting material systems, including superconductors, heavy-fermion materials, topological insulators, and magnetic systems. Specifically, the following research projects are being undertaken and explored: 1. Interplay between topological superconductivity and odd-frequency pairing in superconducting proximity systems and specifically, the role of disorder and fluctuations in these topological heterostructures; 2. Fluctuations and strong-correlation effects in topological Kondo insulators and superconductors; The former have been predicted by the PI and recently discovered experimentally in Samarium hexaboride. One of the important fundamental, open problems is to understand the effect of strong interactions and Kondo fluctuations on the topological surface states, and possible magnetic phase transitions on the surface of these materials. 3. Development of non-perturbative theoretical methods to describe quantum dynamics in fluctuating superconductors, in particular, properties of possible quantum soliton excitations in superconducting/superfluid phases; Soliton dynamics. 4. Understanding Casimir effect (interaction between macroscopic and mesoscopic systems mediated by quantum fluctuations of electromagnetic field) between interacting electron systems; Casimir effect across thermal and quantum phase transitions. Tunable Casimir repulsion between topological states of matter.

FY 2014 HIGHLIGHTS

(1) A theory of proximity effect from a topological superconductor into a disordered metal has been developed [Phys. Rev. B 89, 174521 (2014) and arXiv:1408.4395]. A key new, surprising result is that proximity-induced unconventional superconductivity remains relatively long-ranged and is not suppressed by disorder as strongly as previously believed. This result has important implications for the ongoing experiments on topological superconductor/semiconductor heterostructures. (2) An exact description of a moving soliton in a one-dimensional superconductor has been derived. The exact solution includes an exact soliton spectrum (previously unknown) and effective mass of the soliton. (3) In a series of works [Phys. Rev. B 90, 081113 (2014), Phys. Rev. B 90, 155314 (2014), arXiv:1410.1868], the PI developed a theory of fluctuations in topological Kondo insulators (TKIs) – a new class of strongly-correlated topological insulator, predicted by the PI. A key new result is the occurrence of a magnetic phase transition on the surface of TKIs. (4) A non-perturbative (asymptotically exact) theory of a strongly-correlated one-dimensional TKIs has been developed in preprint, arXiv:1411.5357 (5) In Phys. Rev. B 90, 075420 (2014), the PI proposes a new line of research where the well known Casimir effect (interaction between macroscopic bodies mediated by quantum fluctuations of the electromagnetic field) could be used to probe the internal structure and transitions in low-dimensional materials experiencing the Casimir forces. (6) A theory of tunable repulsive Casimir effect between Weyl semimetals has been developed. (7) In a theory-experiment collaborative paper with the Z. Hasan group at Princeton (under review in Nature Physics), the PI developed a qualitative theory of photoinduced giant surface life-time of an intrinsic topological insulator.

Semiconductor Nanostructures by Scientific Design

Institution: Chicago, University of
Point of Contact: Giulia Galli
Email: gagalli@uchicago.edu
Principal Investigator: Giulia Galli
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$470,000 (2014)

PROGRAM SCOPE

We continued our research on opto-electronic properties of semiconductor nanoparticles on two fronts: (i) method developments and (ii) applications to systems of interest for solar energy conversion. We also extended our investigations to nanostructured solids. On the front of method developments we completed the writing of a code (WEST) for large scale GW calculations [1] and we carried out a systematic analysis [2] of the approximations involved in the solution of the Bethe-Salpeter equation (BSE) based on density functional perturbation theory. On the front of applications, we focused on blinking of isolated Si nanoparticles (NPs) [3] and on multi-exciton generation (MEG) in Ge nanoparticles [4], and on nanostructured Si clathrates [5].

FY 2014 HIGHLIGHTS

1. Absorption and emission spectra from first principles: theoretical improvements: (i) We carried out a parallel implementation of the algorithm previously developed for GW calculations, which takes advantage of separable expressions of both the single particle Green's function and the screened Coulomb interaction and we applied it to systems of unprecedented size (thousands of electrons). (ii)

We systematically studied BSE spectra in Si nanoparticles. 2. Study of nanoparticles and nanostructured solids for solar energy conversion: clathrates, perovskites, and Si and Ge nanoparticles.

Non-Equilibrium Effects in Quantum Coherent Superconducting Nanostructures

Institution: Yale University
Point of Contact: Leonid Glazman
Email: leonid.glazman@yale.edu
Principal Investigator: Leonid Glazman
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

Quantum coherent superconducting circuits are key elements of promising qubit prototypes, the building blocks of a quantum computer. Recent years has witnessed a fast progress in design of nanostructures and in probing their dynamics with time-resolved measurements in the microwave frequency range. These developments call for deeper theoretical understanding of collective modes in model superconducting circuits such as long Josephson junctions arrays, superconducting point contacts, and nanowires. An important subject is the coherence time of such collective modes, fundamentally limited by their interactions with quasiparticles. The present proposal aims at filling the exposed gaps in the theoretical understanding of these issues and at facilitating further development of experimental and theoretical physics of coherent superconducting circuits. Specifically, the aims of this project are: (1) developing a theory of spectra and relaxation of collective modes in long Josephson junctions arrays with quantum-coherent dynamics of the order parameter; (2) elucidating effects of the charge disorder on the dynamics of such arrays; (3) developing a theory of relaxation of the chemical potential imbalance between one-dimensional quasi-condensates coupled by Josephson tunneling; (4) investigating damping of quantum oscillations of the order parameter in superconducting nanobridges and point contacts induced by quasiparticle excitations; (5) addressing large non-equilibrium fluctuations of the superconducting order parameter of a DC-current-biased nanowire discovered in recent experiments. The success of the project will contribute to a deeper understanding of the fundamental properties of quantum coherent superconducting devices. Most of the anticipated results are of immediate interest for a number of experimental groups.

FY 2014 HIGHLIGHTS

In this funding period, we (1) built a theory which ultimately helped to resolve a long-standing puzzle in the physics of Josephson effect, (2) explained the experimentally-observed switching between the superconducting and normal state of a nanowire, (3) developed a dynamical theory of Majorana states in a topological Josephson junction, (4) extended the theory of antiferromagnetic exchange between magnetic impurities in a superconducting host, and (5) proposed a new collective state of interacting bosonic particles having a degenerate spectrum. In the theory of Josephson effect, we related the energy relaxation time of a qubit to the dissipative part of the Josephson current. That enabled, for the first time in 50 years since the seminal Josephson's publication, a precision measurement of the dissipative part of the Josephson current. Our dynamical theory of Majorana states set limits for the prospects to detect these states by means of measuring Shapiro steps in current-voltage characteristics of a topological Josephson junction. The theory of antiferromagnetic exchange which we developed, accounts for the formation of localized states (so-called Shiba states) associated with the magnetic

impurities in superconductors. This extension of theory is important for designing ways of engineering p-wave superconductors from readily available elements. The results of our research were published in nine papers, including articles in Nature, Nature Physics, Applied Physics Letters, and four publications in Physical Review Letters.

EARLY CAREER: Simulation of Correlated Lattice and Impurity Systems Out of Equilibrium

Institution: Michigan, University of
Point of Contact: Emanuel Gull
Email: egull@umich.edu
Principal Investigator: Emanuel Gull
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Correlated quantum systems out of equilibrium exhibit a wealth of intriguing and unexpected quantum phenomena. Our theoretical understanding of these phenomena lags far behind our experimental capabilities, as standard analytic approaches routinely fail and a solution of the quantum mechanical equations of motion precise enough to describe correlation physics is not available. In this project I propose to develop unbiased and numerically exact methods for numerically simulating correlated quantum impurity and lattice models out of equilibrium, based on continuous-time quantum Monte Carlo algorithms. We will use these methods to systematically study the physics of correlated quantum systems in non-equilibrium situations.

FY 2014 HIGHLIGHTS

2014 allowed us to analyze the behavior of impurity systems in steady state, e.g. with a voltage applied, and thereby allowed us to examine the voltage splitting of the Kondo peak with numerically exact methods.

High Performance First-Principles Molecular Dynamics for Predictive Theory and Modeling

Institution: California-Davis, University of
Point of Contact: Francois Gygi
Email: fgygi@ucdavis.edu
Principal Investigator: Francois Gygi
Sr. Investigator(s): Giulia Galli; Chicago, University of
Eric Schwegler; Lawrence Livermore National Laboratory
Students: 4 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$633,963 (2014)

PROGRAM SCOPE

This project aims to develop high-performance software tools for First-Principles Molecular Dynamics (FPMD) simulations, and apply them in investigations of materials relevant to energy conversion processes. FPMD is an atomistic simulation method that combines a quantum-mechanical description of electronic structure with the statistical description provided by molecular dynamics (MD) simulations. This reliance on fundamental principles allows FPMD simulations to provide a consistent description of

structural, dynamical and electronic properties of a material. This is particularly useful in systems for which reliable empirical models are lacking. FPMD simulations are increasingly used as a predictive tool for applications such as batteries, solar energy conversion, light-emitting devices, high-K dielectric materials and phase-change materials for optical storage devices. The accuracy and predictive power of FPMD comes at the price of a high computational cost. Simulations of systems including a few hundred atoms require high-performance computers and parallel programs. This project addresses the issues of extending the size of systems that can be simulated, improving the accuracy of the electronic structure calculations underlying FPMD simulations, and increasing the efficiency of sampling methods beyond the conventional molecular dynamics approach. Furthermore, we are developing new algorithms for the computation of spectroscopic data, such as Raman and infrared spectra. The computation of these quantities during a simulation allows for a direct comparison with experimentally measured optical and vibrational spectra. These new algorithms are implemented in high-performance simulation codes that run on the ANL BlueGene/Q Leadership-class computer. They are currently applied to simulations of liquids, aqueous solutions, and solid/water interfaces relevant to electro-chemical energy conversion devices.

FY 2014 HIGHLIGHTS

We redesigned numerically intensive parts of the Qbox code to improve scalability on the BlueGene/Q platform, enabling FPMD simulations of a 4096-atom silicon carbide (SiC) sample (16384 electrons) and static electronic structure calculations of a 12288-atom SiC sample (49152 electrons) on 524288 cores of ANL Mira. We developed scalable algorithms for electronic structure computations using accurate hybrid density functionals, combining a random search for an optimal distribution of orbitals, and a replication of orbitals among processors. This enabled PBE0 calculations of the electronic ground state of a 4096-atom SiC sample (16384 electrons) on ANL Mira (BlueGene/Q) using 32k cores, with 6400s / SCF iteration. We implemented calculations of electric polarization and polarizability in Qbox, enabling simulations of infrared and Raman spectra, respectively. We carried out the first *ab initio* simulations of the Raman spectra of liquid water by combining FPMD and density functional perturbation theory, showing the importance of electronic effects in the interpretation of Raman spectra. We simulated the IR spectrum of water at the alumina (0001)/water interface. We carried out the first *ab initio* calculation of the absolute position of the band edges in liquid water using the GW approximation, an essential step toward the prediction of water redox potentials w.r.t. band edges of semiconductors and insulators. We carried out PBE0 simulations of a dilute NaCl aqueous solution, showing that changes of the water structure are mostly localized in the ion's first solvation shell. We implemented rare-event sampling methods using a client-server model in Qbox, coupling a DFT calculation with a driver program that implements an arbitrary sampling algorithm. Simulations of liquid water using replica-exchange molecular dynamics between 200 K and 600 K allowed for direct comparisons of the sampling efficiency with traditional FPMD simulations.

Quantum Quench Dynamics-Crossover Phenomena in Non-Equilibrium Correlated Quantum Systems

PROGRAM SCOPE

We are developing tools to analyze crossover phenomena in the transient dynamics of closed quantum systems, using boundary conformal field theory, integrability, and numerical diagonalization. Studying for instance the real-time evolution of the Loschmidt echo and the work distribution function in quantum impurity systems, we are able to determine the characteristic crossover time, energy and spatial scales (as well as the full scaling functions) related to the Kondo coupling and to the electron interactions in the Hamiltonian. This, in turn, provides powerful methods to investigate the physics of these systems, both theoretically and experimentally. Currently, we are working our way towards the transient dynamics of open quantum systems by studying disordered quantum spin systems from the quenched to the annealed limit, finally considering the case of a fully fluctuating environment.

FY 2014 HIGHLIGHTS

We developed a framework to tackle local quantum quenches in integrable impurity systems, combining a mapping onto a boundary problem with the form factor approach to boundary-condition-changing operators. We showed how to compute exactly the Loschmidt echo and the distribution of the work done during the quantum quench. Our results display an interesting crossover physics characterized by the energy scale of the impurity corresponding to the Kondo temperature. We discussed in detail the non-interacting case as a paradigm and benchmark for more complicated integrable impurity models, and checked our results using numerical methods. The calculated time evolution of the Loschmidt echo was found to be in beautiful agreement with independent numerical studies of an equivalent lattice model. Applying the same formalism to the Kondo case is a bit more involved, since the form factors are more complicated in this case. However, the problem is not fundamentally different from the case treated in the preprint, the physics of the quenches being essentially interacting in that case as well. We also studied crossovers in quantum impurity problems from the point of view of entanglement entropy. This is a potentially very rich direction of research, as the entanglement might provide an alternative way to study subtle correlation phenomena such as the screening cloud, and might also exhibit, in out of equilibrium set-ups, deep relations with the full counting statistics. In this context however, the entanglement is particularly difficult to study since the methods of conformal invariance cannot be applied. We established that the entanglement is a non-perturbative quantity at small coupling, but that it can be approached perturbatively at strong coupling in the Kondo and resonant level model cases by using the underlying integrability. Finally, we developed a variant of the foregoing form factors approach to calculate the entanglement non-perturbatively.

PROGRAM SCOPE

We are entering a new golden era of condensed matter physics with practical applications to devices. The combination of qualitatively new electronic materials (like graphene), atomic scale experiments

going on around the world, the level of interest in theoretical understanding and support of experiments the highest it's ever been, backed by the most powerful computers we ever had, have made this golden age possible. Our expertise and this project pertain to the two-dimensional electron flow in semiconductors, an essential component of this new research horizon. Although we have already made significant progress in this area, much remains to be learned about how to control the flow of electrons, what exactly it is microscopically, and how to exploit some of its unusual properties of new materials in creative ways to make devices, especially very fast and efficient devices.

FY 2014 HIGHLIGHTS

In 2014 we have completed work on quantum optimal control theory to demonstrate high-fidelity coherent control of electronic charge in semiconductor double quantum dots. We continued work on magnetoconductance that indicates fractal scaling. In the calculations of the fractality we used detrended fluctuation analysis—a widely used method in time-series analysis—and show its usefulness in the interpretation of the conductance curves. We continued work on branched electron flow and made several new discoveries to be published. In addition, we started a new line of work on spectroscopy of graphene and related carbon nanosystems that promises a far better idea of the factors controlling the spectroscopy than found in the existing literature.

EARLY CAREER: New States of Matter and Quantum Simulation with Ultracold Alkaline Earth Fermions

Institution: Colorado, University of
Point of Contact: Michael Hermele
Email: Michael.Hermele@Colorado.edu
Principal Investigator: Michael Hermele

Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

A major goal of condensed matter physics is the identification and characterization of new states of matter. Strongly correlated quantum systems, in which interactions among the constituents play a crucial role and lead to numerous incompletely understood phenomena, provide a fruitful setting to pursue this goal. This project aims in part to explore new parameter regimes of strongly correlated quantum systems, in part to help identify promising candidate systems for new states of matter. Current and recent efforts focus on two classes of systems: (1) Ultracold fermionic alkaline earth atoms (AEA) in optical lattices: The primary interest in these systems stems from the fact that ultra-cold AEA can have large nuclear spins (up to $I=9/2$) with $J=0$. As a result, to an excellent approximation, a very large $SU(N)$ spin symmetry ($N = 2I+1$) is present. Earlier work of the PI and collaborators pointed out similarities between these systems and more familiar $SU(2)$ frustrated magnets, highlighting the potential richness of condensed matter phenomena in ultra-cold AEA. (2) Correlated electron systems with strong spin-orbit coupling: These systems include iridates and other 5d transition metal oxides, as well as f-electron materials. Such systems are characterized by interplay between strong spin-orbit coupling and substantial electron correlation. This leads to novel magnetic and electronic degrees of freedom that provide a new set of microscopic building blocks, potentially leading to topological and other new states of matter. In addition, this project also aims to advance the understanding of the role of symmetry in quantum phases of matter, with a particular focus on topological phases of matter. Goals include

building bridges between powerful but abstract classifications and physical properties, and understanding constraints imposed by general principles on properties of such phases.

FY 2014 HIGHLIGHTS

1. In $A_2B_2O_7$ pyrochlores, we observed that strong spin-orbit coupling can lead to a novel type of Kramers doublet for which the Kramers pseudospin is time-reversal odd (as it must be), but does not transform like a magnetic dipole under space group. Instead, the pseudospin has mixed dipolar-octupolar character. This is distinct from the $j_{\text{eff}}=1/2$ doublets that occur in iridates, which have dipolar pseudospin. We showed that dipolar-octupolar (DO) doublets can occur for $5d^1$, $5d^3$ and various $4f$ ions with D_{3d} site symmetry, for instance both the A and B sites in the pyrochlore structure. In fact, there is evidence DO doublets occur for the f-moments in A=Nd, Dy pyrochlores. We showed that the most general symmetry-allowed spin exchange Hamiltonian for DO doublets on the pyrochlore lattice is the surprisingly simple spin-1/2 XYZ model. This model supports two distinct quantum spin ice phases, one of which is a novel “octupolar” quantum spin ice that we identified for the first time. This work was published as: Y.-P. Huang, G. Chen and M. Hermele, Phys. Rev. Lett. 112, 167203 (2014). Inspired by our work, Melko and co-workers found evidence via quantum Monte Carlo simulation for a Z_2 spin liquid phase dubbed “quantum kagome ice,” in a model of DO doublets on the kagome lattice (1407.0037). 2. We collaborated with the Dessau group (angle resolved photoemission spectroscopy experiment) at Boulder, focusing on understanding the effect of Rh doping in $Sr_2Ir_{1-x}Rh_xO_4$. In particular, we proposed a simple mechanism by which Rh doping may lead to the observed hole doping of the Ir 5d states. This work is currently available as arXiv:1406.4978 and is being submitted for publication. 3. We devised and tested a method for detecting crystal symmetry fractionalization from ground state wavefunctions, in certain topological phases. This work was in collaboration with Andrew Essin, Ling Wang and Olexei Motrunich, and is available at arXiv:1409.7013 and is under consideration for publication.

Funding: \$689,999 (2014)

PROGRAM SCOPE

Vision: We aim at establishing general and predictive mathematical theories for solids and computational methods that implement them. We will then apply these methods to outstanding solid-state problems, with a view to solving them computationally. Theories: We will develop electronic structure theories for solids that are predictive in the sense that the fidelity of simulation can be increased systematically; that can handle excited electronic states and thus response properties; that

can be applied to strongly correlated electronic structures by exposing hidden mathematical structures and symmetries therein. To achieve this, we will extend systematic diagrammatic many-body methods to solids in ground and excited states at zero and nonzero temperatures with pristine and doped states. We will implement them in parallel software, utilizing highly scalable Monte Carlo algorithms. We will also fully develop and apply quantum Monte Carlo (QMC) methods for solids including those with strong correlation. We will furthermore explore emerging, novel, systematic mathematical theories and computational methods for strongly correlated solids including density matrix renormalization group, dynamical mean-field theory, and Slater-determinant-based QMC including auxiliary-field QMC, full configuration-interaction QMC, and more. Software: We will create a suite of software implementing the aforementioned predictive electronic structure theories for solids, which are, by virtue of exploiting novel algorithms, scalable with respect to both problem size and computer size. Applications: We will apply the predictive methods as implemented in massively parallel software to some of the most outstanding condensed matter problems, including unexplained experimental results. Our target problems include cuprate high- T_c superconductivity, structures of molecular crystals, excited states in solids, Peierls transitions in Luttinger liquids, and 2D Mott–Hubbard insulators.

FY 2014 HIGHLIGHTS

We have published or submitted 32 papers and book chapter in journals such as Science, Nat. Commun., and J. Chem. Phys. We made a large stride toward our understanding of the high- T_c superconductivity in cuprates by performing realistic, accurate, and massively parallel QMC calculations of three cuprate materials. They revealed the strong coupling of magnetic and lattice degrees of freedom present in these materials. We invented three novel, scalable stochastic methods that can compute excited states of molecules or solids by combining many-electron theories with Monte Carlo algorithms. The most fully developed among these is the auxiliary-field QMC method with an appropriate constraint on its auxiliary field to remain excited-state-like, which can thus calculate the quasiparticle energy bands of solids. The second is the full configuration interaction QMC method with a modified propagator, which can yield not only excited-state energies of a molecule but also its density of states. The third combines *ab initio* many-body perturbation theories with Monte Carlo integrations to calculate directly the correlation energies and quasiparticle energy bands of solids without the fermion sign problem. We lead the development of quantum metrics for strong correlation. Entanglement entropy classifies topological insulators and superconductors and is one of the most important concepts in quantum critical systems. We extended this concept to a broader class of tensor network wave functions such as the Multiscale Entanglement Renormalization Ansatz (MERA). We developed new methods for strong correlation. We combined Density Matrix Renormalization Group (DMRG) and QMC to arrive at a scheme for strong correlation with accuracy unachievable with either method alone. We developed density matrix embedding theory for strong correlation. We pioneered the use of symmetry-projected Hartree-Fock wave functions as an auxiliary field QMC (AFQMC) method, improving both accuracy and efficiency. We performed *ab initio* calculations of a benzene crystal and a phase transition in solid CO_2 .

Theory of Novel Superconductors

Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$315,000 (2014-2016)

PROGRAM SCOPE

The research in this program is devoted to a series of problems related to electron pairing, magnetism, and disorder in unconventional superconductors. Studies are directed towards understanding the microscopic mechanism of Fe-based and other novel superconductors, and developing quantitative and even predictive methods. The optimal materials for high-temperature superconductivity almost certainly represent a set of measure zero in the space of all possible materials. Finding them by conventional experience-based methods has proven frustrating. Working with collaborators in the *ab initio* community, we aim to develop computational methods to guide the search for new superconductors, focusing on unconventional pairing mediated by electronic excitations treated within the fluctuation exchange approximation. The goal will not be a quantitative predictor of the critical temperature T_c for a given material, but an understanding of how crystal structure, Fermi surface electron orbital character, and local interactions influence it. Research performed in collaboration with Prof. Roser Valenti at U. Frankfurt and her group.

FY 2014 HIGHLIGHTS

(1) Spin fluctuation theory in Fe-based superconductors. With R. Valenti DFT group, we studied pairing by spin fluctuations in Fe chalcogenide systems, in particular trying to understand the pressure dependence of T_c . Empirically it is known that applying approximately 10 GPa raises the T_c of FeSe from 8K to about 30K, but other Fe-based materials have very different pressure dependences. We found that FeSe is quite an unusual material, in that several magnetic states compete and lead to magnetically frustrated ground state; pressure dependence of T_c is due to the rapid suppression of pairbreaking fluctuations with pressure (ms. in preparation). We also studied intercalated FeSe systems, and showed how to understand the effect of layer separation and doping on T_c (arXiv:1410.7565). Finally, we investigated the effect of glide plane symmetry in Fe-based superconductors and the possibility of eta-pairing (arXiv:1411.0070) (2) Phenomenological theories of disorder in Fe-based superconductors. In the past year we have developed a strong collaboration with R. Prozorov at Ames and T. Shibauchi at Kyoto who are both making measurements of electron irradiation at the Irradiated Solids Lab in Paris. We compared with T_c suppression and penetration depth measurements on a number of samples. (Nat. Comm. 5, 5657 (2014); Phys. Rev. X 4, 041032 (2014)) We also performed 5-band Bogoliubov deGennes calculations of impurity bound states with Brian Andersen at Niels Bohr Institute. (Phys. Rev. B 88, 220509 (2013); *ibid*, 90, 134520 (2014); arXiv:1407.1846)

Theory of Topological Quantum Numbers in Low Dimensions

Institution: Pennsylvania State University
Point of Contact: Jainendra Jain

Principal Investigator: Jainendra Jain
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$125,000 (2014)

PROGRAM SCOPE

Many remarkable phenomena in two dimensions, such as the fractional quantum Hall effect (FQHE), topological insulators, anomalous quantum spin Hall effect, Majorana modes and Chern insulators, have topological underpinnings. A general topological classification serves as a useful guide but does not tell

us under what conditions the states would occur, and what interesting properties of these states go beyond topology. My goal has been to investigate the experimental realizability of various topological states of matter. This has required detailed microscopic calculations, as well as close collaboration with experimental colleagues. The topics of interest include the physics at the edge of a FQHE state, rapidly rotating ultra-cold atoms, signature of fractional braid statistics, FQHE of composite fermions and of two-component bosons. We have made progress on some of these topics. In collaboration with experimental colleagues at Columbia, we have identified a small skyrmion in the excitation spectrum in the vicinity of the $1/3$ state. In collaboration with experimental colleagues at Princeton, we have shown that spin phase transitions are a very sensitive probe of the effect of Landau level mixing. We have also performed theoretical calculations that show that the edge of the $5/2$ FQHE is 'reconstructed' for the experimental parameters. Our current research focuses on certain concrete ideas that we believe should make a direct observation of fractional statistics possible in rotating cold atom systems. In addition, we are exploring the possibility of creating a Fermi liquid metal in a system of interacting bosons in two dimensions. We are also in the process of creating a comprehensive catalog of all FQHE states that we can envision at the moment for multi-component systems, which should be very useful for the analysis of FQHE experiments in graphene as well as for identifying new phenomena.

FY 2014 HIGHLIGHTS

The articles supported by the DOE grant are listed below. Some of the summaries are as follows: In paper 3 we have shown that certain states, such as those occurring at $4/11$ and $5/13$, have an origin different from all other fractional states. In paper 6 we have shown that the partially polarized fractional quantum Hall state at $3/8$ is, theoretically, an exact representation of a chiral p-wave pairing. In 6 we have proposed a way to measure fractional braid statistics in cold atom systems, where it appears as fractional angular momentum. EARLY CAREER: Emergence of High T_c Superconductivity out of Charge and Spin Ordered Phases

Institution: Cornell University
 Point of Contact: Eun-Ah Kim
 Email: eun-ah.kim@cornell.edu
 Principal Investigator: Eun-Ah Kim
 Sr. Investigator(s):
 Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
 Funding: \$150,000 (2014)

PROGRAM SCOPE

We will study mechanisms and roles of charge/spin orders in two classes of high T_c superconductors: (1) Cuprates and (2) Fe-based superconductors. For cuprates the PI played a central role in identifying one of the new charge ordered phases in the cuprates: intra-unit-cell (IUC) nematic and its coupling to stripe dislocations. We will build on this experience to pursue associated quantum phase transitions in collaboration with Davis group, while seeking microscopic understanding of the roles IUC nematic and smectic play in superconductivity. For Fe-based superconductors, we will develop new ways to analyze scanning tunneling spectroscopy (STS) data to probe electron-collective mode coupling and test their role in superconductivity. Through parallel efforts in the two chemically distinct HTSC's exhibiting tantalizingly similar phase diagrams, we will seek more broadly applicable organizing principles. We will take a symmetry-guided "middle-up/down approach": applying symmetry and quantum field theory based perspective to experimental data and using the results as input to microscopic models. The coexistence or proximity between charge and spin order and superconductivity occur in a region where interaction energy is comparable to kinetic energy. While the resulting complexity in the electronic phase diagram is an important problem in the modern materials research, the uncertainty principal inhibits a single sweep numerical solution of relevant fermionic hamiltonians. The PI and collaborators have proven through the discovery of IUC nematic that a middle-up/down approach can be very effective. We will extend the scope of the approach to include various numerical techniques through collaborations with experts. The combination of the theoretical expertise of the PI in this field, and synergetic interactions with Davis group (STS) at Cornell puts her in a position to make unique contributions that can impact both theory and experiments.

Correlation Effects and Magnetism in Actinides: Elements and Compounds

Institution: New Jersey-Rutgers, State University of
Point of Contact: Gabriel Kotliar
Email: kotliar@physics.rutgers.edu
Principal Investigator: Gabriel Kotliar
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of our research is to achieve a fundamental understanding of the solid state phases of materials containing elements from the actinide series. To reach this goal we will construct computational electronic structure tools based on extensions of the Dynamical Mean Field Theory (DMFT) such as LDA+DMFT to carry out first principles calculations of these correlated materials. In addition we develop simplified physical pictures and phenomenological models of the various phases of

these elements and their electronic structure which in turn can be used to predict new experiments. Building on the advances of the previous funding period, we will focus on the magnetic properties of the actinides. We will elucidate the physical principles that govern the formation of local moments of the 5f electrons, their quenching in non-magnetic materials and their possible magnetic long range order phases. We will use LDA+DMFT to compute the spectrum of the spin fluctuations of delta Pu. We will extend our previous structural studies to complex structures such as the alpha phase, and develop faster algorithms to evaluate its total energy as a function of volume.

FY 2014 HIGHLIGHTS

Predicted the inelastic neutron scattering cross section of delta Pu, and validated the theoretical approach against experimental results from LANL.

Toward High-Accuracy Point Defects Calculations in Materials

Institution: Case Western Reserve University
Point of Contact: Walter Lambrecht
Email: wxl2@case.edu
Principal Investigator: Walter Lambrecht
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

The goal of the project is to improve our understanding of point defects in materials, in particular systems with strong correlations, and electron-phonon coupling, such as oxides. The project initially was geared toward the development and testing of new methods to incorporate self-energy effects (as obtained in the quasiparticle self-consistent (QS)GW) method for the host system in larger cell defect calculations by using a real space representation of the self-energy expanded in muffin-tin orbitals and/or a related LDA+U approach. In the process of studying particular systems, new directions evolved leading to a new focus, namely to explore how phonons contribute to the dielectric screening and how this enters into different aspects of electronic structure, for example GW self-energy, exciton binding energy, and self-trapped polaron formation. Several aspects of this overall focus of the project were pursued in different materials systems, including ZnO, V_2O_5 , halide perovskites, oxide perovskites, transition metal dichalcogenides and rare-earth nitrides. In terms of point defects, an important test case considered was N_2 on the Zn-site in ZnO. It was proposed by us as a possible candidate for explaining a N-related shallow level in ZnO and shown to be related to a known electron paramagnetic resonance (EPR) center. Further work is on-going on this topic to study alternative N-involving complexes, such as V_{Zn}^{-NO} and to further confirm the proposed model by explicit calculations of the EPR g-factors and hyperfine factors. The effects of strain on the band structure and in particular spin-orbit splittings were investigated in MoS_2 and graphene. Another layered material, V_2O_5 , was explored, as an ultrathin (monolayer) material and found to present extreme challenges in terms of understanding lattice polarization effects on the band structure. Halide perovskites, a new promising family of solar cell materials were explored in terms of phonons and electronic band structure and their interactions.

FY 2014 HIGHLIGHTS

1) We collaborated with Mark van Schilgarde at King's College, London, UK to explore the possibilities of a real space representation of the QSGW self-energy in an Imto basis set for defect calculations. The code manipulating the self-energy and adapting it from one system to another was mainly developed by him and is now ready to be tested in various defect situations. On the other hand, we have continued our previous approach of adapting U parameters of LDA+U to QSGW band structures to then study defects in LDA+U. This was applied to the problem of the oxygen vacancy in LaAlO_3 and to the study of self-trapped polarons. These studies are still in initial stages. 2) We continued our study of V_2O_5 . While in the first year the focus was on understanding the phonon differences in bulk and monolayer, we now carried out QSGW band structure calculations and found QSGW to overestimate the gap much more than usual. The solution to this problem appears to be the inclusion of lattice vibration effects on the long-range polarization which in turn affects the screening of the Coulomb interaction W entering the GW approach. This results from large longitudinal optical – transverse optical (LO-TO) splittings. We devised a first approximate scheme to include this and are planning to further explore it in future years. At the same time it focused our attention to this problem which appears to affect more systems than previously anticipated. 3) We continued our study of halide perovskites with an in-depth study of phonons and their relation to phase transitions. We also discovered that strong LO-plasmon coupling may be expected in these materials due to the low phonon frequencies and high plasmon frequency even for low carrier concentration due to the low electronic screening and extremely low hole mass.

Structure and Dynamics of Material Surfaces, interphase-interfaces and Finite Aggregates

Institution: Georgia Institute of Technology
Point of Contact: Uzi Landman
Email: uzi.landman@physics.gatech.edu
Principal Investigator: Uzi Landman
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$210,000 (2014)

PROGRAM SCOPE

This research program focuses on development, implementation and employment of quantum and classical simulation methodologies of predictive power, enabling their use as tools of discovery in investigations of the microscopic processes underlying generation and properties of novel materials in various forms and degrees of aggregation, under equilibrium and non-equilibrium conditions or subject to extreme environments. The program targets the elucidation of patterns in the size-dependence of materials properties where “small is different”, bridging the molecular, cluster and condensed-phase regimes. Topics in our research program include: 1. Nanoscale systems exhibiting unique structures, organizations, stabilities, reactivities, dynamics, and response patterns which endow them with unique physical and chemical properties. These systems include: (i) Gas-phase and surface-supported nanoclusters exhibiting structural isomerization transitions that gate their mobility and dynamic structural fluxionality, thus enabling their nanocatalytic activity. This includes studies of nano-catalyzed water splitting and generation of synthetic fuels. (ii) Nanocrystallites with superatom electron-shell structure stabilities, self-assembled into ordered superlattices, and exhibiting collective response mechanisms and unique optical and transport characteristics. 2. Bottom-up growth mechanisms of atomically precise graphene nanostructures. Investigations (using electronic structure, transport, and relativistic quantum field theory models) of topological effects in graphene nanostructures, including

graphene-based topological insulators and transport in atomically-precise segmented graphene nanoribbons. 3. The properties of confined electron and atom trapped systems exhibiting highly correlated, and entangled and spontaneous symmetry breaking; systems include semiconducting interfaces and graphene quantum nanostructures with and without external fields.

FY 2014 HIGHLIGHTS

(1) Hydrogen-bonded nano-silver superlattice: Structure and mechanical chiral response. Noble metal nanoparticles have had a deep impact across a diverse range of fields, including catalysis, sensing photochemistry, optoelectronics, energy conversion, and medicine . We reported [Nature Materials 13, Pg. 807 (2014)] the single-crystal X-ray structure of a superlattice made in the high-yield synthesis of $\text{Na}_4\text{Ag}_{44}(\text{p-MBA})_{30}$ protected –silver nanoparticles [our article in Nature 501, Pg. 399 (2013)], and found with quantum simulations that its structure and cohesion derive from hydrogen bonds between bundled p-MBA (para-mercaptobenzoic acid) ligands. The superlattice's mechanical response to hydrostatic compression was found to be characterized by a molecular-solid-like bulk modulus $B_0=16.7$ GPa, exhibiting anomalous pressure softening ($B_0' < 0$) and a compression-induced transition to a soft-solid phase. Such a transition involves ligand flexure, which causes gear-like correlated chiral rotation of the nanoparticles, pivoting about the hydrogen bonds that serve as hinges. The emergent behaviour of the superlattice assembly exemplifies the melding of the seemingly contrasting paradigms of 'small is different' and 'more is different'. Graphene - transport and topological effects in graphene nanoribbons (GNRs). Fundamental issues pertaining to the very nature of carriers in GNRs of variable width and edge terminations - namely, the crossover from ultra-relativistic to non-relativistic quantum behavior -which are of basic science interest as well as relevant for future applications of graphene, were addressed with numerical simulations and relativistic quantum-field position-dependent-mass model, unveiling fundamental clues and topological effects via analysis of Fabry-Perot-like oscillations in the electric conductance of GNR junctions. The work allows an effective treatment of a broad range of transport regimes in GNRs, [see Nature-Scientific Reports, Jan. 20 (2015)].

Strongly Correlated Electronic Systems: Local Moments and Conduction Electrons

Institution: Massachusetts Institute of Technology
Point of Contact: Patrick Lee
Email: palee@mit.edu
Principal Investigator: Patrick Lee
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$160,000 (2014)

PROGRAM SCOPE

The project focuses on the search for emergent phenomena in solids due to the strong correlations between electrons. The idea is that while the physics is governed by a relatively simple Hamiltonian, at low energy and low temperature, novel particles and fields may arise. An example we focus on recently is the emergence of Majorana fermions in solid state systems such as the ends of superconducting wires. We plan to explore novel phenomena associated with these Majorana fermions and look for signatures which may help in their detection.

FY 2014 HIGHLIGHTS

We discuss the problem of quasi-particle poisoning in Majorana fermions. The presence of quasi-particles breaks the parity conservation which is essential to protect the identity of the Majorana fermions. For any future application such as quantum memory or computation, it is crucial to know what the relaxation time is due to quasi-particle poisoning. We propose an experiment to measure this poisoning time. The result is published in Physical Review B89, 140505 (2014). In a second work we pointed out that Majorana fermions can lead to novel phenomenon of 'equal spin Andreev reflection'. Unlike conventional Andreev reflection, the reflected hole carries the same spin as the electron hitting the barrier. For certain polarization, the reflection is 100%. This can leave to a way to generate a highly polarized spin current. The result is published in Physical Review Letters 112, 037001 (2014).

Anharmonic and Thermal Effects Associated with Jammed Solids

Institution: Pennsylvania, University of
Point of Contact: Andrea Liu
Email: ajliu@physics.upenn.edu
Principal Investigator: Andrea Liu
Sr. Investigator(s): Sidney Nagel; Chicago, University of
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$245,000 (2014)

PROGRAM SCOPE

At the jamming transition, there are diverging length scales that lead to qualitatively new physics. As a result, a rigid packing at the zero-temperature jamming transition represents an extreme limit of a solid in several ways. In a well-defined sense, such a marginally jammed solid is the epitome of disorder; it is disordered and has the lowest possible rigidity. Thus, it lies at the opposite pole from a zero-temperature crystal where order is perfect. Moreover, at the jamming transition, the response to shear is infinitely weaker than the solid's response to compression. This is similar to the response of a liquid and distinguishes the jammed solid from a perfect crystal, where the ratio of the shear to bulk modulus, G/B , is of order unity. Finally, at the jamming transition, the regime of linear response shrinks to zero so that the solid is completely anharmonic; any infinitesimal stress forces the solid into non-linear behavior. One of our major objectives is to understand the anharmonic behavior of jammed solids. These include understanding the nature of the anharmonic vibration modes, looking in particular for anharmonic echoes. We will also study the particle rearrangements that occur when such a system is sheared or compressed beyond its limit of stability. A second focus of this work is to investigate to what extent an ordinary solid be described as lying between the two extremes of perfect order and complete disorder; can it be coherently described by perturbations around each limit? A third area builds on our recent work on the sensitivity of jammed solids to boundary conditions. Here we will study surfaces of amorphous packings, which can behave very differently from the bulk. This leads to a final objective, which is to understand the complicated role that temperature plays near the jamming transition.

FY 2014 HIGHLIGHTS

(1) Existence of linear response regime in jammed solids. The harmonic approximation is the foundation of much of solid state physics. Calculations that invoke this simplifying assumption are said to be in the linear regime. While the harmonic approximation is not exact, the existence of a linear regime is essential to our understanding of ordered solids. In two recent papers, we examined the effect of

nonlinearities in jammed sphere packings. We proved that that packings at densities above the jamming transition have a linear regime in the thermodynamic limit despite an extensive number of altered contacts. Thus, we showed that the harmonic approximation is on footing as firm for disordered solids as for ordered solids. (2) Between order and disorder: mechanical extremes of a solid. On first being introduced to solid-state physics, we typically learn about ideal perfect crystals. We are taught to describe real solids, which must always have imperfections, in terms of perturbations about crystalline order. However, such an approach only takes us so far: a glass, another ubiquitous form of rigid matter, cannot be described in any meaningful sense as a crystal with defects. Is there an opposite extreme to a crystal, an idealized solid with ``complete disorder,' that can be used as an alternate starting point for understanding real materials? We have shown that the solid made of particles with finite-range interactions at the jamming transition constitutes such an extreme limit. We found that jamming physics is not restricted to amorphous systems but instead is relevant and even dominates the behavior of solids with surprisingly high order. Our findings place the perfect crystal and the jammed solid as extreme poles from which one can understand mechanical behavior. Thus, ordinary matter should be thought of as existing somewhere on the continuum between these two idealized limits.

Charge Carrier Holes Correlations and Non-Abelian Physics in Nanostructures, Quantum Hall Effect and Hybrid Superconductor/Semiconductor Structures

Institution: Purdue University
Point of Contact: Yuli Lyanda-Geller
Email: ylyandag@purdue.edu
Principal Investigator: Yuli Lyanda-Geller
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$115,000 (2014)

PROGRAM SCOPE

The goal of the project is to advance theory of spectra, interactions and correlations of charge carrier holes in nanostructures, including the effects of magnetic field and strain. Earlier unknown single-particle spin-orbit couplings in quantum dots and rings and new effective many-body interactions and correlations will be elucidated and explored. These features are absent in electronic systems but are specific to holes and can have profound impact on non-Abelian physics. We study paired and parafermion Fractional Quantum Hall effect states in 2D hole liquid. We will show that non-equidistant low-lying quantization levels in magnetic field in 2D hole Quantum Hall systems offer remarkable opportunity to control the Landau Level mixing by tuning carrier density and magnetic field simultaneously. It is then feasible to tune, the effective three-body correlations crucial in non-Abelian states. By numerically simulating two dimensional holes (2DH) in 001 grown GaAs via exact diagonalization, we expect to find the optimal setting for the non-Abelian fractional quantum Hall states. Some of the effects we plan to explore can also arise, but have never been studied, in two-dimensional electronic systems. We will investigate these cases as a test bed for our work on holes. We study novel correlated Quantum Hall states in the vicinity of crossings in 2D holes energy spectrum. Investigation of hole charge density wave states in high Landau levels, and their competition with other quantum Hall states at the crossing points. We also investigate novel charge density wave phenomena, especially caused by strain in both electron and hole 2D systems. We conduct theoretical study of Majorana Fermion excitations in hole nanowires proximity coupled to wave superconductors. We will demonstrate that spectral features of the charge carrier holes in quantum wires, newly emerging in our project, have profound effect on feasibility of observing Majorana physics.

FY 2014 HIGHLIGHTS

Our accomplishments for 2014. (I) Theory of Magnetic field spectral crossings in Luttinger holes in quantum wells: We showed an analytical solution for 2D holes in a quantum well in a magnetic field. The most important feature is coupling of the motion along the growth axis and the in-plane cyclotron motion as a result of Luttinger spin-orbit interactions. Our main finding is crossing of levels of holes in a magnetic field. We explained experiments on cyclotron mass and g-factor of 2D holes. (II) Calculation of hole spectrum and Haldane pseudopotentials for holes in a spherical geometry: We found spectra of Luttinger holes on a spherical shell, developing the procedure analogous to that for electrons. We obtained single particle states, with the spectrum identical to that of holes on the plane, and hole-hole interactions by calculating Haldane pseudopotentials. (III) Calculation of the effects of Landau Level (LL) mixing at ground state crossing in hole spectra: We calculated N-body interaction potentials, renormalizing hole-hole interactions in the presence of mixing of hole states in a magnetic field. We showed that variation of magnetic field near level crossings serves as a knob that tunes such mixing and enhances the 3-body interactions. Our preliminary results indicate that filling factor $\frac{1}{2}$ Fractional quantum Hall effect (FQHE) of holes exhibits excitations with non-Abelian statistics. (IV) Study of phase diagram and edge states of the filling factor 5/2 FQHE state with LL mixing and finite well thickness in a disc configuration: We find that due to the neutralizing background and LL mixing, there is a phase transition from the anti-Pfaffian to the Pfaffian states. LL mixing overcomes the effects of edge reconstruction and leads to an increased charge $e/4$ quasihole size. Due to finite thickness, these properties are enhanced dramatically. Only the Pfaffian and anti-Pfaffian states continue to possess energy gaps, while gaps for compressible stripe states close.

Geometric Phases and Topological Effects in Graphene and Magnetic Systems

Institution: Texas-Austin, University of
Point of Contact: Allan H MacDonald
Email: macdpc@physics.utexas.edu
Principal Investigator: Allan H MacDonald
Sr. Investigator(s): Qian Niu; Texas-Austin, University of
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

We performed theoretical studies on electronic and transport properties of a) graphene systems, b) magnetic systems, c) topological insulators and superconductors, and d) MoS₂ and other two-dimensional materials.

FY 2014 HIGHLIGHTS

We predicted that a large anomalous Hall effect occurs in an important class of antiferromagnetic metals, Mn₃Ir and related materials. This prediction has motivated experimental efforts by a number of groups around the world aimed at performing studies of single crystal materials. We completed important theoretical studies of the fractional quantum Hall effect in graphene and of the quantized anomalous Hall effect in graphene on an antiferromagnetic substrate. The fractional quantum Hall effect in graphene represents a new frontier because of an approximate four-fold flavor degeneracy. We completed important new work on spin pumping and spin-transfer torques in antiferromagnetic metals.

This is an area of research that is growing rapidly in the moment. The pioneering work on this topic, now nearly ten years old, was supported by an earlier funding period of this DOE grant.

Electronic and Piezoelectric Phenomena in Nanostructures

Institution: Pennsylvania, University of
Point of Contact: Eugene Mele
Email: mele@physics.upenn.edu
Principal Investigator: Eugene Mele
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 3 Undergraduate(s)
Funding: \$146,000 (2014)

PROGRAM SCOPE

The electronic properties of graphene-derived nanomaterials, topological insulators and topological semimetals will be studied. Our proposed work develops and applies new theoretical models for understanding the low energy electronic properties of these materials and can guide their integration into electronic, optoelectronic and electromechanical applications. Specifically, we will study the electronic physics of multilayer epitaxial graphenes and new approaches to the study of topological insulators and semimetals. This work focuses on the development and application of theoretical methods that identify the microscopic role of symmetry, broken symmetries, and externally applied fields in controlling the quantum electronic behavior of these systems.

FY 2014 HIGHLIGHTS

Topological Dirac Semimetals in Three Dimensions Saad Zaheer (Penn Graduate Student) and E.J. Mele: We discovered that the two dimensional pseudo-relativistic physics of graphene near its charge neutrality point can be realized in three dimensional materials. In prior theoretical work this has been anticipated at phase transitions from inversion symmetric topological to normal insulators but this scenario requires fine tuning the electronic system to a critical point. Instead, our work identifies particular space-groups that allow 3D Dirac points as robust symmetry protected degeneracies in the bulk. These singularities are distinct from three dimensional chiral Weyl points: the Dirac singularities can be understood as a merger of Weyl nodes in a lattice where their annihilation is prevented by a crystallographic symmetry. We developed the nontrivial symmetry criteria necessary to identify these groups and, as an example, present *ab initio* calculations of beta-cristobalite BiO₂ which exhibits three Dirac points at the Fermi level. We predict that beta-cristobalite BiO₂ is a metastable material, so it is a candidate 3D pseudo-relativistic analog to graphene. Further, we predict a Dirac point like Fermi surface in three dimensional materials in a distorted spinel structure. The predictions are based on density functional theory as well as phenomenological $k \cdot p$ symmetry analysis. The four examples identified are: BiZnSiO₄, BiCaSiO₄, BiMgSiO₄ and BiAlInO₄. These systems are electronically three dimensional analogs of graphene and will host rich low energy topological phenomena. Reference: S.M. Young, S. Zaheer, J.C.Y. Teo, C.L. Kane, E.J. Theory of Surface and Interface Physics of Correlated Electron Materials

Institution: Columbia University
Point of Contact: Andrew Millis
Email: millis@phys.columbia.edu
Principal Investigator: Andrew Millis
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The aim of this project is to develop and apply the theoretical tools necessary to understand the properties of surfaces and interfaces involving materials exhibiting strong electronic correlations (such as high transition temperature superconductors, colossal magnetoresistance manganites, and Mott metal-insulator systems), with the aims of (a) using the systems as a lens for understanding fundamental issues in correlated electron physics, (b) uncovering new physics existing at surfaces and interfaces, and (c) establishing modalities for controlling phenomena which may be useful in energy and device applications.

FY 2014 HIGHLIGHTS

We have provided new insights into the density functional plus dynamical mean field method widely used to study correlated materials, showing that standard theory wrongly predicts that many Mott insulators are metals and gives an incorrect estimate of the charge transfer across oxide interfaces, identifying the key issue of the energy splitting between oxygen and transition metal orbitals and introducing a new double counting method that corrects the problems. We also extended the density functional plus dynamical mean field theory methodology to enable the first total energy calculations including lattice relaxations with this method. This methodological advance will be important for future work because it enables the determination of structures of correlated electron materials. In collaboration with an experimental colleague, A. Pasupathy, and a former postdoc, R. Fernandes, we obtained results which challenge one of the basic tenets of metal physics. Our theoretical calculations, combined with Pasupathy's scanning tunneling microscopy measurements of the surface of NaFeAs (parent compound of the iron-pnictide family of high T_c superconductors) showed that the apparently conventional fermi liquid phase of the material is in fact characterized by very large amplitude, very slowly fluctuating wave of spin density order, made visible by the scattering off of impurities, far beyond the linear response picture believed to describe fermi liquid metals.

Optical, Transport Phenomena, and Interaction Effects

Institution: Utah, University of
Point of Contact: Eugene Mishchenko

Principal Investigator: Eugene Mishchenko
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$110,000 (2014)

PROGRAM SCOPE

We study physics of chiral electron states, whose properties depend on the direction of electron propagation. Such states exist in a variety of practical realizations: two-dimensional electron gas in semiconductor quantum wells with spin-orbit interaction, Dirac fermions in graphene (2D) or carbon nanotubes (quasi-1D), protected surface states in topological insulators, etc. The emphasis is on investigating transport phenomena and effects of electron-electron interactions from a general perspective, on elucidating features common to various chiral systems, and on applying to newer materials the techniques previously proved successful for other chiral systems. As an example, the method of transport equations used by us to study spin Hall effect was subsequently applied to the problem of optical conductivity in graphene, within the scope of this project. Among specific problems currently studied are properties of collective plasmon modes in graphene, effects of resonant impurities on properties of graphene and topological insulators, the role of many-body effects on the optical properties of carbon nanotubes. We employ broad range of methods including quantum transport theory based on kinetic equations, diagrammatic technique, hydrodynamics of electron liquid, etc. Both analytical as well as numerical approaches are utilized. As far as the fundamental physics is concerned, our main effort is to study transport phenomena and effects of electron-electron interactions from a general perspective of elucidating features common to various chiral systems.

FY 2014 HIGHLIGHTS

We have developed a quantum-mechanical approach to calculating equilibrium particle currents along the edges of systems with nontrivial band spectrum topology. Our approach does not require any a priori knowledge of the band topology and, as a matter of fact, treats topological and nontopological contributions to the edge currents on the same footing. To illustrate the application of our method we demonstrated the existence of “topologically nontrivial” particle currents along the edges of three different physical systems: two-dimensional electron gas with spin-orbit coupling and Zeeman magnetic field, surface state of a topological insulator, and kagomé antiferromagnet with Dzyaloshinskii-Moriya interaction.

Simple Metals at High Pressures and Impact of Spin-Orbit in 5d Atom Compounds by Electronic Structure Quantum Monte Carlo Methods

Institution: North Carolina State University
Point of Contact: Lubos Mitas
Email: lmitas@ncsu.edu
Principal Investigator: Lubos Mitas
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014-2016)

PROGRAM SCOPE

Our research is focused on development and application of advanced many-body methods to calculations of spin, electronic and atomic structures and optical properties of energy-related materials. We employ correlated wave function approaches such as electronic structure quantum Monte Carlo (QMC) which is capable of overcoming the limitations of traditional methods in explicit treatment of electron many-body phenomena. This promising methodology enables us to study problems which are at the forefront of condensed matter physics such as materials with strong correlations and complex

systems with competitions of many-body effects. Our QMC investigations are focused on several application and method development areas. In particular, we plan to study alkali and alkaline metals at high pressures such as Li, Na, Be and others, with the goal of evaluating energy differences between competing or nearly degenerate structures and establish thus high accuracy QMC data for these systems. We plan to develop the QMC methodology for more accurate description of both metallic and insulating solid phases. For 5d and heavier elements the spin-orbit interaction (SOI) becomes very important and we plan to develop QMC methods with explicit treatment of spins as quantum variables and study such SOI effects in this class of materials. These developments will be based on our recent calculations of spin-orbit interactions in atoms using variational Monte Carlo method with the goal to generalize the QMC methodology to the more accurate QMC projector approaches.

FY 2014 HIGHLIGHTS

The project was initiated in September 2014 and the postdoctoral research associate was hired from October 1st. We have started preparations for quantum Monte Carlo (QMC) runs of Li systems based on our previously carried out preliminary calculations. In collaboration with A. Ambrosetti and F. Pederiva (U. Padova, U. Trento, Italy) we have been involved in development of QMC methods for spin-orbit interactions and one of the testing systems has been a fermi gas with repulsive interactions and Rashba spin-orbit coupling. This has led to new calculations that enabled to study, for example, the onset of Stoner instability and also validation of the developed methodology for studies of competing spin-orbit and correlation effects in periodic systems.

Nonequilibrium Phenomena in Topological Insulators

Institution:	New York University
Point of Contact:	Aditi Mitra
Email:	aditi.mitra@nyu.edu
Principal Investigator:	Aditi Mitra
Sr. Investigator(s):	
Students:	0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$145,000 (2014)

PROGRAM SCOPE

The aim of the project is to study two-dimensional and three-dimensional topological insulators under out of equilibrium conditions such as an applied bias voltage and external irradiation by light. The goal is to explore what kinds of topological phases of matter can be stabilized under the combined effect of drive and dissipation. Specific systems that will be studied are Floquet topological insulators where a laser can modify topological properties. The project will also explore the effect of interactions and dissipation on driven topological insulators, and on hybrid topological insulator-ferromagnetic systems.

FY 2014 HIGHLIGHTS

Graphene irradiated by a circularly polarized laser has been predicted to be a Floquet topological insulator (TI) showing a laser-induced quantum Hall effect. A circularly polarized laser also drives the system out of equilibrium resulting in non-thermal electron distribution functions that strongly affect measurable quantities. The PI's group has made significant progress in understanding Floquet TIs by fully accounting for the inherently non-equilibrium nature of these systems, and by also accounting for dissipative mechanisms. Theoretical predictions for experimentally measurable quantities such as

photo-emission spectra as well as the Hall conductance have been obtained. While for a closed system with no external dissipation, the Hall conductance was found to be far from the quantized limit due to the system retaining memory of its initial state, coupling to a sufficiently low temperature reservoir of phonons was found to produce effective cooling, and thus an approach to the quantum limit, provided the frequency of the laser was large as compared to the band-width. For laser frequencies comparable to the band-width, strong deviations from the quantum limit of conductance was found even for a very low temperature reservoir, with the precise value of the Hall conductance determined by a competition between reservoir induced cooling and the excitation of photo-carriers by the laser. The results for the open system were obtained by solving a Floquet kinetic equation that accounts for phonon-induced inelastic scattering between different quasi-energy levels.

Modeling the Self-Assembly of Ordered Nanoporous Materials

Institution: Massachusetts, University of
Point of Contact: Peter Monson
Email: monson@ecs.umass.edu
Principal Investigator: Peter Monson
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

This project is about modeling the assembly processes in the synthesis of nanoporous materials. Such materials are of enormous importance in modern technology with application in the chemical process industries, biomedicine and biotechnology as well as microelectronics. An ongoing theme in porous materials science and engineering is the tailoring of pore structure for specific applications. Silicate and aluminosilicate chemistry provides an enormously valuable route to stable nanoporous materials. The number of possible materials structures is almost without limit. The origin of this is the low coordinate bonding in these materials and the uniformity of binding energies between different structures. We focus on two classes of materials: microporous crystalline materials, such as zeolites, and ordered mesoporous materials. In the first case the pores are part of the crystalline structure, while in the second the structures are amorphous on the atomistic length scale but have order on the length scale of 2 - 20 nm. Our models are based on the assembly of corner sharing silica tetrahedra in the presence of structure directing agents. Our modeling approach is the first to capture silica polymerization, nanopore crystallization, and mesopore formation through computer-simulated self assembly. We are applying both lattice and off-lattice models to shed new light on zeolite nucleation. The first component of this is the study of silica polymerization across a broad pH range. We then consider the nucleation of all-silica zeolite analogs modeled using transition path sampling applied to our lattice model of silica. The final component involves the study of pathways connecting amorphous and ordered phases. For ordered mesoporous materials we are investigating issues like the influence of surfactant chain length on the cooperative templating of mesoporous structures, as well as the interplay between silica polymerization and mesoscale surfactant assembly.

FY 2014 HIGHLIGHTS

(1) Off-Lattice Modeling: We have developed a reactive parallel tempering Monte Carlo method for searching for ground state structures of our off-lattice model of silica polymerization. This method generalizes parallel tempering to the case where the tempering variable is the equilibrium constant for

the silica condensation reaction. This Monte Carlo simulation approach can form a variety of phases of silica including both dense silica polymorphs and some zeolite frameworks. We are extending our work on mesoporous silica synthesis to our off-lattice model of silica polymerization. This has involved a new coarse-grained model for water-surfactant-silica systems and a new Monte Carlo / molecular dynamics method for simulating both mesophase formation and silica polymerization. (2) Lattice Model: We have extended our lattice model of silica polymerization over a broad pH range, by modeling the addition of organic structure directing agents alongside hydroxide to tune pH. Our simulations have revealed the transition from gel formation at low pH and high silica concentration, to the nanoparticle regime at high pH and low silica concentration. This work has appeared in the following article: M. N. Khan, S. M. Auerbach, and P. A. Monson, "Lattice Model for Silica Polymerization: Monte Carlo Simulations of the Transition between Gel and Nanoparticle Phases," J. Phys. Chem. B 118, 10989-10999 (2014). We have introduced templates into our parallel tempering simulations for finding ground states of the lattice model of silica. This has led to the formation of new structures that were not formed in the absence of the template, and has generated new insights into the impact of template size and concentration on the structures produced. Review Article: We published an invited review article based upon our DOE-funded work, "Modeling the Assembly of Nanoporous Silica Materials", S. M. Auerbach, W. Fan, and P. A. Monson, International Reviews in Physical Chemistry, 34, 35-70 (2015).

Non-Equilibrium Physics at the Nanoscale

Institution: Illinois-Chicago, University of
Point of Contact: Dirk Morr
Email: dkmorr@uic.edu
Principal Investigator: Dirk Morr
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$330,000 (2014-2016)

PROGRAM SCOPE

Experimental advances in the fabrication of nanoscale systems have provided us with the unprecedented opportunity to investigate non-equilibrium transport phenomena from the atomic to the mesoscale in a wide variety of materials. The ability to visualize the flow of charge or energy at smaller and smaller length scales allows us to establish a fundamental connection between the transport properties of nanoscopic systems at the atomic and global scale, enabling the development of smart and functional nanoscopic components for energy research and quantum computation. The objective of this research program is to develop a comprehensive theoretical framework to investigate complex non-equilibrium transport phenomena in nanoscopic systems. This program will (a) identify the key elements that govern non-equilibrium charge and energy transport in nanoscopic systems, such as interactions, geometry, or topology, (b) determine how these elements shape the relation between local and global transport properties, and (c) identify the basic principles required for the quantum design of transport properties. To achieve these objectives, this program will employ field-theoretical non-equilibrium methods to investigate how the emergence of complex correlations, driven by the interplay between interactions, electronic symmetries, disorder and the coupling to external environments, determines the non-equilibrium transport properties in nanoscopic realizations of correlated Kondo systems, topological insulators, graphene, and photovoltaic materials. These projects will establish a constructionist framework to describe, control, and quantum design charge and energy transport at the nanoscale by identifying the signatures of strong correlations in non-equilibrium transport, by demonstrating how the flow of charge and spin can be manipulated at the atomic scale through lensing, strain and the creation

of topologically non-trivial states, and by establishing criteria for optimal energy transport in photovoltaic materials.

FY 2014 HIGHLIGHTS

Rapid advances in quantum computation and spin electronics, heralded by the discovery of topological insulators, have been hampered by the inability to control the flow of spin and charge at the nanoscale. We demonstrated that such control can be established in nanoscopic two-dimensional topological insulators by breaking their time reversal symmetry via magnetic defects. This allows for the emergence of two novel phenomena: the creation of nearly 100% spin-polarized charge currents, and the design of highly tunable spin diodes. These phenomena are robust against edge disorder and dephasing effects, and thus provide a new venue for controlling the flow of spin and charge. We developed a non-equilibrium Keldysh Greens function formalism to study excitonic energy transport in hybrid organic-inorganic perovskites and biological complexes. We succeeded in identifying the relation between global and local transport properties in light-harvesting biological complexes, such as the total exciton flux, the spatial exciton flow pattern, the local recombination rate, and the local exciton density. This approach is ideally suited to elucidate the microscopic model underlying efficient energy transport and to reveal the conditions necessary to optimize it. We proposed a novel theoretical approach to identify the microscopic mechanism of heavy fermion Cooper pairing. By elucidating the relation between non-equilibrium transport and electronic structure, we extracted the momentum form of the magnetic interactions between f-electron moments in CeCoIn₅ from experimental quasi-particle interference (QPI) spectroscopy. This allowed us to make a series of quantitative predictions for the symmetry and magnitude of the superconducting gap, the critical temperature, and phase-sensitive QPI spectra. Their good quantitative agreement with experiments provides strong evidence for f-electron mediated Cooper pairing as the origin of heavy-fermion superconductivity.

Spin-Orbit Tailoring of Materials Properties

Institution: California-Davis, University of
Point of Contact: Warren Pickett
Email: pickett@physics.ucdavis.edu
Principal Investigator: Warren Pickett
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$120,000 (2014)

PROGRAM SCOPE

Spin-orbit coupling (SOC) rose in visibility almost a decade ago with the discovery of topological insulators (TIs) based on SOC and inverted bands. SOC connects the direction of the electron's orbital moment with that of its spin moment, while having an effect on both and coupling to magnetic order and to the lattice. For TIs the impact is qualitative – a matter of fact rather than one of magnitude, and small couplings may still be important. For most other areas of application of SOC (and for TIs as well) the magnitude is important. In this project we extend our earlier computational discoveries of surprisingly large orbital moments in 3d oxides up to 0.7 Bohr magnetons, an order of magnitude larger than had been obtained for 3d systems. 4d and 5d materials, with much larger SOC, are being studied. For both 3d and 5d oxides the interplay between SOC and strong correlation provides a rich platform for several types of behavior, and symmetry breaking is found to be a crucial factor in determining the ground and low energy excited states.

FY 2014 HIGHLIGHTS

The interplay and competition between several comparable energy scales has been studied in several systems. The energy scales are spin-orbit coupling strength, repulsive Coulomb interaction, Hund's exchange energy, crystal field splitting, and bandwidth. For open shell cations in oxides, breaking of symmetry is the dominant feature, and enlarged simulation cells must be adopted to allow the many underlying symmetries to be violated by the interactions. $\text{LaNiO}_3/\text{LaAlO}_3$ multilayers provide a vivid example, displaying a combination of charge, spin, and orbital order with also a lowering of structural symmetry. In the heptavalent Os^{7+} compound KOsO_4 , symmetry breaking by structure and by spin-orbit coupling enables an orbital moment to emerge in the e_g subshell, something that is impossible in cubic symmetry. Our theoretical study of a newly synthesized quadruple perovskite (a former student is a member of the synthesis team) $\text{CaCO}_3\text{V}_4\text{O}_{12}$ is showing it to be one of the most intricate systems yet studied by (correlated) density functional theory, with charge states (and associated moments, orbital occupations, and structural distortions) of both Co and V feeding back on each other. Lastly, the mixed valent niobate $\text{Nb}_{12}\text{O}_{29}$ has been found to be a novel and highly anisotropic Heisenberg-Kondo lattice system.

Complex (anti)ferroic Oxides: Statics and Dynamics at Finite Temperatures

Institution: South Florida, University of
Point of Contact: Inna Ponomareva
Email: iponomar@usf.edu
Principal Investigator: Inna Ponomareva
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$135,000 (2014)

PROGRAM SCOPE

Complex oxides that exhibit ferroic, antiferroic or multiferroic properties are of extreme fundamental and technological importance. Fundamentally such materials are very attractive because they exhibit delicate energy competitions which result in the appearance of some spontaneous property (magnetization, electric polarization or strain) or particular type of ordering. Technologically they are in the heart of numerous applications. A few examples include memory applications, pyroelectric sensors, pressure sensors, capacitors, optical communications, ultrasonic motors, phase-array radars, ultrasound imaging and actuators, thermistors, filters, light detectors, high-power microwave devices, and many others. However, despite their special role in both fundamental and applied sciences, many such materials and their properties remain rather poorly understood. Some examples include statics and dynamics of antiferroelectrics and relaxors, exotic energy conversion mechanisms in (anti)ferroics, fundamental intrinsic dynamics of such materials, and (anti)ferroic phenomena at the nanoscale. Such lack of understanding critically hinders both scientific and technological progress, especially as it applies to the nanoscale. The ultimate goal of this project is to achieve a fundamental understanding of statics and dynamics of complex oxides that exhibit ferroic, antiferroic, multiferroic or relaxor properties at both macro- and nano-scales through state-of-the-art computer simulations. The potential outcomes of this research include (1) state-of-the-art computational tools for modeling static and dynamical properties of bulk and nanoscale complex (anti)ferroic oxides; (2) deep atomistic understanding of energy converting mechanisms in such materials; (3) fundamental understanding of dynamical properties of (anti)ferroics and relaxors at microwave and infrared frequencies.

FY 2014 HIGHLIGHTS

1. We have achieved a systematic understanding of the role of mechanical boundary conditions in the soft mode dynamics (J. Phys.: Condens. Matter 26, 435901 (2014)). 2. We have established the possibility to drastically alter electric response of ferroelectric ultra-thin films by partial charge compensation. (Appl. Phys. Lett. 104, 012909 (2014)). 3. We have developed a force-field to study finite-temperature properties of antiferroelectric PbZrO_3

Theoretical and Computational Studies of Characteristics of Metallic Nanostructures

PROGRAM SCOPE

Our work focuses on understanding structure-function relationship in nanomaterials so as to enable the long term goal of rational design of functional materials, which are of immense scientific and technological interest. We are particularly interested in understanding factors that control the magnetic and optical properties of these materials and their response to ultrafast external fields. Part of our effort is in developing and applying appropriate theoretical and computational techniques which provide more accurate descriptions of excited and bound states, and electron correlation effects than afforded by the popularly used density functional theory (DFT). To ensure dynamical stability of nanostructures we also determine their vibrational dynamics and thermodynamics. Additionally, we develop non-adiabatic techniques to expose the non-equilibrium behavior of nanosystems, as in the presence of external fields. Through systematic study of characteristics for a set of selected materials and corroboration of their results with experimental data, we formulate rules and guidelines for predictive material design. The research stages in the different projects include determination of one or more of the following: 1) the geometric and electronic structure of lowest energy structures using reliable schemes (e.g. DFT); 2) vibrational dynamics and thermodynamics through density functional perturbation theory (DFPT); 3) magnetic properties via our nano-DFT+ DMFT (dynamical mean field theory) approach; 4) optical response, using time dependent density functional theory (TDDFT) and its density matrix version as proposed by us for systems with bound states, multiple excitation and strong correlation effects; 5) development of the non-adiabatic time dependent spin density function theory NA-TD-SDFT; 6) structural evolution of nano-sized systems using self-learning kinetic Monte Carlo (SLKMC) simulations.

FY 2014 HIGHLIGHTS

(1) Non-adiabatic Time-Dependent Spin-Density Functional Theory for strongly correlated systems: With our proposed methodology for calculating a frequency dependent exchange-correlation functional we can describe spectral properties of strongly-correlated systems such as YTiO_3 within multi-orbital time-dependent spin-density functional theory. Calculation of the nonequilibrium response of YTiO_3 under an applied short laser pulse shows novel behavior of its charge dynamics. Our DFT + Nonhomogeneous DMFT approach for finite systems when applied to determine the magnetic properties of Fe nanoparticles containing up to 147 atoms, displays much better agreement with the experimentally

observed non-monotonous dependence of magnetization as function of cluster size than that obtained from the DFT and DFT+U approaches. (2) Magnetocrystalline anisotropy (MCA) of FePt nanoparticles: We find an enhancement of MCA for the FePt nanoparticles containing up to 150 atoms as compared to that of Fe nanoparticles of the same size and geometry and bulk FePt with L_{10} structure. We trace this enhancement to the increased spin and orbital moment of Pt atoms which raises the spin-orbit coupling constant. Our DFT study of geometric, electronic, and magnetic properties of $\text{Fe}_x\text{Au}_{113-x}$ ($x=23, 56, 90$) nanoparticles shows preference for the core-shell structure with the Fe core maintaining magnetic moment of $\sim 2.8 \mu_B$, which is 27% enhancement from the bulk value, and correlated with the local coordination of Fe atoms and with the charge depletion from Fe to Au atoms. (3) Tuning plasmon excitations in transition-metal doped arrays of noble-metal nanochains: For pure noble and transition metal (TM) chains we find that as the number of chains in the array increases the plasmon peak shifts to higher energies and appears in the visible range for an array of three gold chains, each consisting of more than 10 atoms.

Theoretical Investigations of Single Particle Spectroscopies of Novel Materials

PROGRAM SCOPE

The goal of this project is to gain insight into the properties of novel quantum materials using theoretical and computational modeling of electron correlations. We have focused on several problems in this general area. First, we have investigated magnetism in correlated oxides and oxide interfaces, using both microscopic modeling of exchange and anisotropy in the presence of spin-orbit coupling and continuum field theory descriptions of effective interactions. This has led to new insights into stabilizing topological spin textures known as skyrmions in low dimensional chiral magnets. Second, we have continued our work on high T_c superconducting cuprates in the underdoped region. Our goal is to understand the interplay between the normal state pseudogap seen in spectroscopies and additional order parameters, like charge density waves (CDW) which compete with superconductivity, and lead to the Fermi surface reconstruction observed in quantum oscillations. As part of this effort, we have developed the formalism to describe quantum oscillations in a vortex liquid state, which has short range pairing correlations in addition to a density wave that breaks translational symmetry. Finally, we continue to collaborate with the experimental group at Argonne National Labs on analysis of angle resolved photoemission spectroscopy and x-ray data on superconducting and CDW materials.

FY 2014 HIGHLIGHTS

(1) Most theoretical studies of skyrmions have focused on chiral magnets with broken bulk inversion symmetry, where the skyrmion crystal phase is stabilized in a rather small regime of parameter space by easy-axis anisotropy. In contrast, we considered 2D and quasi-2D systems with broken surface inversion [PRX 4, 031045 (2014)] and showed that skyrmion crystals are more stable over a much broader range of parameters than in 3D. We pointed out the importance of easy-plane anisotropy, and show that it arises naturally from the same spin-orbit coupling that leads to the chiral Dzyaloshinskii-Moriya (DM)

interaction. These results are directly relevant for magnetic thin films and for magnetism at oxide interfaces. (2) We demonstrate in a simple model the surprising result that turning on an on-site Coulomb interaction in a doped band insulator leads to the formation of a half-metallic state. Our results [PRL 112, 106406 (2014)] suggest a new route to half metallic behavior, and will hopefully motivate searches for new materials for spintronics. (3) We have developed a theoretical framework for describing quantum oscillations in a phase fluctuating superconductor where the pairing correlations are short ranged in both space and time. Building on our 2013 Nature Communication paper on this topic, we have been systematically comparing the results of a semi-classical analysis with that of a more rigorous analysis in the Landau level basis. (4) We have collaborated with the Argonne group on the analysis of photoemission, x-ray and scanning tunneling microscopy data on the CDW material 2H-NbSe₂ intercalated with Mn and Co. We find that both at high temperatures and at large intercalation, the CDW order becomes short-ranged due to fluctuations of its phase, while a well-defined amplitude persists and gives rise to an energy gap in the electronic excitation spectrum.

First-principles Investigations of Fundamental Physics and New Materials for Optoelectronic Applications

Institution: Pennsylvania, University of
Point of Contact: Andrew Rappe
Email: rappe@sas.upenn.edu
Principal Investigator: Andrew Rappe
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$185,000 (2014)

PROGRAM SCOPE

By using first-principles electronic structure methods, we investigate the fundamental physics of optoelectronics and design materials with the specific optoelectronic properties. These studies require understanding of electronic structure, including modeling light absorption, photovoltaics, and photoconductivity. The solar cell, one of the most important applications of optoelectronics, has attracted a great deal of attention due to the demand for new energy sources. However, the power conversion efficiency of solar cells based on p-n junction is subject to the Shockley-Queisser limit. The bulk photovoltaic effect (BPVE) in materials without inversion symmetry has been proposed as an efficient way to transform solar energy. In particular, ferroelectric materials with spontaneous polarization can separate light-induced carriers. Therefore, finding ferroelectric materials with band gaps in the visible light range, strong polarization, and high BPVE is a promising direction for solar cell research and toward other optoelectronic applications. We computationally design materials with low band gap and high polarization. Several strategies have been proposed: solid solutions with partially substituted A or B-site cations in perovskites, defects, and structural transition induced band gap reduction. Once we have materials with a proper band gap, we explore whether they can show strong BPVE. In the meantime, we investigate the effects of strain, stress, electronic correlation, and phonons on the BPVE of the material, particularly, ferroelectrics. We perform materials design to find materials with high BPVE. Based on our understanding of optoelectronics and our material design strategies, we can build connections between the material composition and structural phase, and the material light response. Therefore, our project can guide the development of new materials for solar cell applications and other areas related to light-matter interaction in solids.

FY 2014 HIGHLIGHTS

By using first-principles methods, we have computationally designed a series of Zn^{2+} partially substituted KNbO_3 perovskite solid solutions, showing lowered band gaps within the visible light range. More generally, we propose a strategy to substantially reduce the band gap by as much as 1.2 eV, while maintaining relatively high polarization through local rhombohedral-to-tetragonal structural transition in perovskites. Hybrid halide perovskites can show as much as 20% power conversion efficiency. These materials are showing great potential as next generation solar cell materials. We have demonstrated that BPVE plays an important role in providing such high efficiency. This can potentially explain the observed large open-circuit voltage and I/V hysteresis in hybrid halide perovskites. Besides perovskites, other types of materials were also extensively investigated for optoelectronic applications. LiAsSe_2 , LiAs_2 and NaAsSe_2 can show large BPVE, and their optical dielectric constant displays substantial enhancement induced by stress. With low band gaps and high optical responses, these materials have potential for use as bulk photovoltaics.

Next Generation Photon and Electron Spectroscopy Theory

Institution: Washington, University of
Point of Contact: John Rehr
Email: jjr@phys.washington.edu
Principal Investigator: John Rehr
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

Our research program aims to develop quantitative theories and associated codes for next-generation calculations of photon and electron spectroscopies. A main goal is to incorporate correlation effects beyond the quasi-particle approximation over a spectral range from the visible to x-ray energies. Our approach is based on first principles methods, e.g., real-space multiple-scattering and Bethe-Salpeter equation (BSE) techniques, which are implemented in the FEFF and OCEAN codes developed in our research program. These many-body effects include inelastic losses, core-hole interactions, vibrations, and now strong correlations, effects for which accurate theories are among the most challenging problems in condensed matter theory. Practical theoretical developments are essential to obtain predictive calculations of optical and x-ray spectra and other excited state properties for a wide class of materials. Consequently our research is important for advancing fundamental theoretical understanding of materials properties. Indeed, our codes are in use world-wide for interpreting x-ray spectra, e.g., at DOE synchrotron x-ray facilities, as documented by thousands of citations. Besides x-ray absorption, x-ray emission, and x-ray photoemission spectra, our computational methods are applicable to new spectroscopies including RIXS (resonant-inelastic x-ray scattering), and spectra from time-dependent x-ray sources.

FY 2014 HIGHLIGHTS

A major highlight of our recent research has been the development of an approach for treating many-body effects in x-ray and electron-spectroscopies based on cumulant-expansion methods. Rather than wave-functions, this powerful theoretical formalism is based on an exponential form of the electron Green's function in the time-domain, and naturally builds in effects beyond the quasi-particle

approximation, including vertex corrections. The method has proved to be advantageous compared to conventional GW approaches, yet simplifies the calculations. This effort was a major topic of our research project and is leading to a number of breakthroughs. A recent success is the treatment of multiple plasmon satellites in the XPS spectra of materials ranging from graphite to graphene. Another is an improved calculation of spectral functions and electron correlation energies. Remarkably we recently found that the cumulant method can be applicable to strongly correlated systems. For example, we showed that a real-time calculation of the cumulant explains the charge transfer satellites in x-ray photoemission spectra. These satellites characterize strong local correlations which have been formidably difficult to treat with first principles, e.g., configuration-interaction, methods. Notable improvements have also been made to our spectroscopy codes: our GW/Bethe-Salpeter Equation code OCEAN has been extended to treat large systems such as water and ice, and our real-space Green's function code FEFF has been extended to include Hubbard-model corrections in f-electron systems. Finally in collaboration with the Northeastern University group, we have developed a novel way to calculate many-body edge singularity effects in RIXS.

PROGRAM SCOPE

The program's scope is the theoretical investigations of the many-body effects and the ensuing collective modes that are manifested by actinide materials. One focus of the program is the enigmatic phase transition exhibited by URu_2Si_2 at low temperatures, which has evaded classification for over 25 years. The possibility that the transition is characterized by an order parameter which is of an entangled spin and orbital is studied. Such an entangled order parameter is not measurable through standard experimental probes, which may explain why this phase transition remains enigmatic. Properties, such as the phase diagram under pressure and magnetic field, are studied theoretically. The collective modes related to the ordering are also being investigated. A second focus is the unusual magnetic anisotropy found in the collective magnetic excitation spectra of the cubic uranium mono-chalcogenides. The research focuses on the effects of the Hund's rule exchange and the spin-orbit coupling. The research utilizes a description based on the under-screened Anderson lattice Model. A third focus is the collective modes that have been observed in some paramagnetic heavy-fermion semiconductors and semimetals. This includes SmB_6 which has been recently re-classified as a Topological Kondo Insulator. The relation of the magnetic modes to critical fluctuations is being studied together with the effect of doping that may induce a Lifshitz transition. The scope of the project also includes studies of Intrinsically Localized Modes, or persistent lattice vibrations with finite spatial extents. Unusual anharmonic lattice vibrations, which are not described by the usual harmonic theory of phonons, have been reported in alpha-uranium at high temperatures. The possibility of Intrinsically Localized vibrational Modes (ILMs) occurring in plutonium compounds are being investigated in this program.

FY 2014 HIGHLIGHTS

The Fermi surface of URu_2Si_2 has been studied experimentally and theoretically. It has been found that the Fermi-surface reconstructs at the transition, and results in a doubling of the size of the unit cell. The experimental results are consistent with a change of the electronic symmetry from body-centered tetragonal to simple tetragonal, without there being any change in the atomic positions. Therefore, the transition has been identified as involving a nesting of the Fermi-surface through the $(1,0,0)$ reciprocal lattice vectors. The folding of the electronic Brillouin zone has been identified as producing a gap on most of URu_2Si_2 's Fermi surface. ILMs have been extensively studied in idealized one-dimensional classical systems. We have investigated the occurrence of ILMs one-dimensional quantum systems, and have shown that this can be generalized to three-dimensional systems. In one-dimension, we found that ILMs are produced by anharmonic interactions and occur even for the smallest interaction strength due to divergences in the one-dimensional two-phonon density of states. This work has been shown to be generalizable to higher dimensions. However, the ILMs only occur for specific center of mass momenta. The special volumes of momenta occur on high symmetry lines that are close to the Brillouin zone boundary. The reason for ILMs to occur only in these special regions of the Brillouin zone, is that the van-Hove singularities in the two-phonon density of states coalesce and become large and perhaps even divergent. The large value of the density of states at the edges of the two-phonon continuum enables the anharmonicity to produce ILMs at energies outside the continuum. This work also includes a group theoretic analysis which shows that the spectrum of ILMs have internal quantum numbers and intrinsic spins of either $S=0$ or $S=2$. The $S=2$ bosonic excitation would come close to providing a solid state version of the graviton.

Fundamental Studies of Complex Oxides and Their Interfaces

Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

This project is devoted to a theoretical study of the physics of the complex oxide materials and their interfaces. These materials come with complex crystal structures, with metal-oxygen octahedra, bringing in the electron-lattice coupling via the Jahn-Teller effect, competing magnetic interactions such as double exchange and super exchange, and spin-orbital coupling. In addition, strain and polar interfacial potential could drastically alter the bulk behavior, resulting in an interface, with behavior drastically different from either of the parent materials. An example of this is the formation of a two dimensional electron gas at the $\text{LaAlO}_3/\text{SrTiO}_3$ polar interface and the rich variety of phases observed there. The objective of this proposal is: (1) To develop a microscopic understanding of the observed behavior in the complex oxides and their interfaces and (2) To develop key concepts of interface physics incorporating the insight gained from the density-functional calculations. The intellectual challenge is to understand the strong interplay between a variety of effects such as the strong correlation, Jahn-Teller effect, orbital ordering, coupling between the spin, charge, and orbital degrees of freedom, competing magnetic interactions, etc., which results in a rich variety of phenomena in these materials. We have carefully selected a few specific problems for study based on potential new physics and current

experimental efforts. The proposed research topics include closely related problems in the correlated oxide physics, viz., (i) Rashba spin-orbit effect at the oxide surfaces and interfaces, (ii) Possible origin of the Kosterlitz-Thouless transition at the $\text{LaAlO}_3/\text{SrTiO}_3$ interfaces, (iii) Spin-Orbital ordering in the frustrated spin-ice oxides, and (iv) Development and Incorporation of the Gutzwiller density-functional approach into the muffin-tin orbitals method for correlated systems. Close interaction with the experimenters is envisaged.

FY 2014 HIGHLIGHTS

1) Rashba Effect in the Oxide Surfaces and Interfaces -- One highlight of our research was a study of the Rashba effect in the oxides. The effect describes the momentum-dependent spin splitting of the electron states and is the combined result of the spin-orbit interaction and the inversion-symmetry breaking. The effect is at the heart of a class of proposed spintronics devices. In this work, we showed that the Rashba effect in the perovskite structures can be tuned by manipulating the two-dimensional electron gas (2DEG) by an applied electric field, using it to draw the 2DEG in or out of the surface. These ideas were studied by a comprehensive density-functional study of the recently discovered KTaO_3 surface. Analytical results obtained with a tight-binding model unraveled the interplay between the various factors affecting the Rashba effect. 2) Electronic structure of $\text{Ba}_3\text{CuSb}_2\text{O}_9$: A candidate quantum spin liquid compound -- Using density functional methods, we studied the electronic structure of the title quantum spin liquid compound. While Cu atoms are expected to be Jahn-Teller centers, no distortions are observed in the system suggesting a dynamical Jahn-Teller effect and the issue was under intense debate. Solving a simple model by exact diagonalization, we showed that the electronic correlation effects in general enhance the tendency towards a Jahn-Teller distortion by reducing the kinetic energy due to correlation effects. Our calculations did indeed show a significant Jahn-Teller distortion, when we included the correlation effects within the Coulomb-corrected GGA + U method. We argued for the presence of a random static Jahn-Teller distortion rather than a dynamical effect because of the potential fluctuations inherently present in the system caused by a significant disorder. This work helped clarify the nature of the electronic structure and especially of the Jahn-Teller effect in this material.

Strongly Correlated Electrons

Institution: Florida State University

Principal Investigator: Pedro Schlottmann
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$180,000 (2014-2016)

PROGRAM SCOPE

Strongly correlated electron systems continue to be a central problem in condensed matter physics. Many phenomena are still awaiting an explanation and new effects of potential technological relevance are being discovered. The purpose of the study is to gain further insight into the mechanisms and properties of correlated electron systems. This proposal addresses aspects of heavy fermions, such as quantum criticality due to antiferromagnetic correlations, the temperature and field dependence of the NMR relaxation in the topological Kondo insulator SmB_6 , quantum criticality in ferromagnetic Kondo systems such as YbNi_4P_2 , and the hidden order phase in URu_2Si_2 which has eluded a satisfactory

explanation for almost 25 years. Common threads are the interplay of localized and itinerant electron states at various energy scales and the physical complexity resulting from the coexistence and competition between different kinds of order involving charge, orbital, spin and lattice degrees of freedom. Selective tuning of the properties can be achieved by changing chemical compositions or by varying the external conditions through pressure, temperature and magnetic fields. Trapped ultracold atoms provide a unique opportunity to study a Fermi gas with effective spin larger than $1/2$ under extremely pure conditions. The properties studied in atomic gases are closely related to those studied in solid materials, such as phase separation, bound states and superfluidity. Spin-orbit effects can be optically induced into atoms and varied in a controlled manner. In particular, for one-dimensional traps mathematically exact solutions and controlled approximations are available. Field theoretical methods to be employed in all projects are renormalization groups, slave bosons, Schwinger bosons, bosonization, the quantum inverse scattering method and Bethe's Ansatz, wherever applicable.

FY 2014 HIGHLIGHTS

(1) A two electron pocket model including Umklapp processes (the nesting vector is commensurate with the lattice) to allow the transfer of pairs of electrons between the pockets was studied. This model is able to generate a superconducting dome surrounding the quantum critical point due to antiferromagnetic fluctuations, without destroying the crossover from the non-Fermi liquid to the Fermi liquid regime. (2) The NMR relaxation in the strong topological Kondo insulator SmB_6 has been investigated. For a clean surface the Landau quantization of the surface states gives rise to highly degenerate discrete levels and the relaxation rate is not Korringa-like. In the dirty limit the Landau levels are broadened and $1/T_1$ is Korringa-like. (3) The high-field, high-frequency electron spin resonance (ESR) spectra of $\text{Nd}_3\text{Ga}_5\text{SiO}_{14}$ has been interpreted in terms of spin-cluster excitations. (4) The threshold singularities of a one-dimensional gas of fermions with spin S interacting via an attractive δ -function potential have been studied using Bethe's Ansatz and field-theoretical methods.

Theoretical Studies in Very Strongly Correlated Matter

Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$230,000 (2014)

PROGRAM SCOPE

The goal of this program is to formulate an analytical understanding of the dynamics of very strongly interacting Fermi systems, widely recognized as a 'hard-problem' in Condensed Matter Physics. The program has a strong link to experimental results on ARPES (angle resolved photoemission) line shapes, as well as transport quantities such as the resistivity, Hall constant and thermopower of correlated electron systems. The PI has recently put forward a formalism, termed the extremely correlated Fermi liquid (ECFL) theory, that manages to circumvent several difficult aspects of the strong correlation problem. It leads to controlled and quantitative calculational schemes. At the present state of development, self-consistently reliable results have been found in the somewhat over-doped hole density regime. In the ECFL formalism, the original problem is replaced by a perturbation type problem, where the small parameter λ lies between 0 and 1. Here λ is related to the density of double occupancy.

This latter problem can be treated systematically to successive orders in λ , so that one can build up progressively better approximations. One can use the skeleton graphs expansion for the Greens functions, and in future applications, it is planned to use Monte Carlo methods to sum this series to high orders. This theoretical approach is valid for many models of contemporary interest, including the large U Hubbard model and the t-J model, as well as the single impurity Anderson model. The program also involves calculation of the frequency dependent Greens functions at high T, by computer aided series expansions, and to match this with the analytical theory. For this purpose, development of new algorithms for computing the series for the dynamical Greens function and density-spin density correlation functions to high order in inverse temperature are being developed.

FY 2014 HIGHLIGHTS

We completed two benchmarking projects recently, comparing the new theory with exact results for the single impurity Anderson model and the infinite dimensional strong coupling Hubbard model. In both cases we found that the calculated Z (wave function renormalization) of the lowest order expansion becomes inaccurate for low hole density $\delta \leq 0.25$. However, upon scaling the frequency with the computed Z factor, the ECFL theory and the (similarly scaled) exact results for both of these models agree remarkably well at essentially all densities near the Fermi level. A significant result is that the particle hole asymmetry predicted by the ECFL theory is confirmed quantitatively in the exact results in both models. This asymmetry has been argued by the PI to be central to understanding the ARPES line shapes, so that we have now independent theories that agree in this regard. Our earlier work shows that this also agrees with the experimental data on Cuprate superconducting materials in the appropriate regime. In follow up projects, we have recast the new formalism in much simpler terms than the original presentation, avoiding the Schwinger equations formalism altogether. This is based on the new result that Gutzwiller projected electrons can be represented in terms of usual Fermions, through a mapping that parallels the Dyson-Maleev mapping, where one expresses spins in terms of (regular) Bosons. A path integral formulation of this problem was found. Another result published is a purely diagrammatic method for the (above mentioned) λ expansion to arbitrary orders, analogous to the Feynman rules. This expansion is essential for applying Monte Carlo resummation techniques. Another result published by our group is a computer generated high temperature series for the dynamical one particle Greens function to 8th order in the hopping parameter, earlier results stop at the 4th order.

Novel Fractional Quantum Hall and Quantum Spin Hall Effects in Interacting Systems

PROGRAM SCOPE

The research in this program involves theoretical (numerical) study of the correlated topological physics in strongly interacting systems. We study and determine the quantum phase diagram for such systems and the characteristic topological and transport nature of the new emerging quantum phases with topological order and fractionalized quasi-particles. In our computational approach, we develop novel

numerical algorithm for detecting and characterizing new topological phase, entanglement spectrum, and the topological nature and statistics of the quasi-particles in these systems. We have focused on a few related topics in strongly correlated systems including: (a) The fractional quantum spin Hall effect (FQSHE) in topological bands without a magnetic field and quantum phase transition; (b) The space time emergent super-symmetry in the edge state of topological superconductor; (c) Extracting Modular matrix through minimum entangled states to identify different topological phases; (d) Theoretical discovery of the chiral spin liquid and quantum phase diagram for frustrated magnetic systems based on computational method developed in the past a few years.

FY 2014 HIGHLIGHTS

The research in this program involves theoretical (numerical) study of the correlated topological physics in strongly interacting systems. We have focused on a few related topics in strongly correlated systems including: (a) The fractional quantum spin Hall effect (FQSHE) in topological bands without a magnetic field and quantum phase transition; (b) The space time emergent super-symmetry in the edge state of topological superconductor; (c) Extracting Modular matrix through minimum entangled states to identify different topological phases; (d) Theoretical discovery of the chiral spin liquid and quantum phase diagram for frustrated magnetic systems based on computational method developed in the past a few years. Density Matrix Renormalization Group (DMRG) simulations of the nontrivial quantum phase transition and the space time supersymmetry (SUSY): We explore the novel feature of the quantum phase transition for topological superconductors in the presence of spontaneous breaking of the time-reversal symmetry (TRS). In contrast to ordinary symmetries, super-symmetry interchanges bosons and fermions. The topological states themselves may be interpreted as arising from spontaneously broken super-symmetry, indicating a deep relation between topological phases and SUSY. We demonstrate the fractional central charge and scaling law of spin correlations to establish the super-symmetry numerically. We also develop computational method to identify and characterize quantum states with topological order: Following theoretical proposal, we develop numerical methods of obtaining minimum entangled states (MES) and extracting the modular matrix to characterize the topological order of quantum systems. Very recently, we generalized such a method to larger scale simulation based on DMRG calculations. By studying two coupled fractional Chern (FC) insulators, we find a new route to realize non-abelian quantum Hall effect (QHE) state in strongly coupled bilayer systems.

Many-Body Theory of Energy Transport and Conversion at the Nanoscale

PROGRAM SCOPE

This project addresses the fundamental challenge of understanding quantum systems far from equilibrium, while simultaneously exploring the potential of nanostructured materials for applications in energy-conversion technologies. The main focus of the project is quantum thermoelectrics. The enhancement of thermoelectricity due to electron wave interference in nanostructures is investigated in both the linear and nonlinear regimes. The focus is on increasing the power factor via electron-wave

engineering. This approach can be combined with higher-order nanostructuring designed to minimize the thermal conductance to create revolutionary new types of thermoelectrics with exceptionally high figure of merit ZT . To elucidate the local quantum mechanisms responsible for enhanced thermoelectricity, we investigate local probes of thermoelectricity in quantum systems. The possible relation between thermal eddy currents, nonmonotonic variations of the local temperature, and the enhancement of thermoelectricity are being explored. The nonlinear Peltier effect is studied, with the goal of increasing the efficiency of quantum heat pumps in the nonlinear regime through engineered junction asymmetry. Fundamental research on the nonequilibrium many-body theory of nanostructures is conducted in parallel, to enable the applied research on nanoscale energy conversion. Recently, the PI and collaborators showed that the local temperature of a weakly-driven nonequilibrium quantum system measured by a scanning thermal probe is consistent with the zeroth and second laws of thermodynamics, and agrees with that inferred from an independent electrical noise measurement. This project will investigate under what conditions such a fluctuation-dissipation theorem also applies to the far-from-equilibrium case, and to what extent the local temperature so defined is consistent with the laws of thermodynamics. The effect of coarse graining (or measurement resolution) will also be investigated.

FY 2014 HIGHLIGHTS

A theory of local temperature measurement of an interacting quantum electron system far from equilibrium via a floating thermoelectric probe is developed. It is shown that the local temperature so defined is consistent with the zeroth, first, second, and third laws of thermodynamics, provided the probe-system coupling is weak and broad band. For general probe-system couplings, the local temperature obeys the Clausius form of the second law and the third law exactly, but there are corrections to the zeroth and first laws that are higher-order in the Sommerfeld expansion. The corrections to the zeroth and first laws are related, and can be interpreted in terms of the error of a nonideal temperature measurement. Moreover, the temperature inferred from an independent electrical noise measurement is shown to be identical to that measured by a floating probe within the leading-order Sommerfeld approximation. Large thermoelectric corrections are predicted for ideal voltage measurements at finite temperature in nonequilibrium quantum systems, up to 24% of the peak voltage in a graphene nanoribbon.

Non-Equilibrium Relaxation and Aging Scaling of Magnetic Flux Lines in Disordered Type-II Superconductors

PROGRAM SCOPE

Technical applications of type-II superconductors in external magnetic fields require an effective flux pinning mechanism to reduce Ohmic losses due to flux creep and flow. The physics of interacting vortex lines subject to strong thermal fluctuations and point-like or extended disorder has therefore been a major research focus in condensed matter physics. This research aims for a thorough theoretical

characterization of the stochastic fluctuations and out-of-equilibrium relaxation processes of interacting vortices subject to various pinning centers. To this end, a versatile three-dimensional Monte Carlo simulation code and a Langevin molecular dynamics algorithm, both based on an elastic string representation of the magnetic flux lines, are employed to extract steady-state observables and two-time correlation functions. The resulting data represent a detailed study of the dynamical relaxation features towards equilibrium as well as non-equilibrium steady states starting from experimentally realizable initial conditions, encompassing sudden thermal, magnetic field, and driving current quenches. Thus universal and non-universal characteristics in the physical aging and glassy relaxation regimes are explored, and thereby unique dynamical signatures that distinguish samples with point pins and extended correlated defects are identified. Future goals include to quantitatively characterize the associated growing length scale in the system, to propose specific experimental setups amenable to probing the different dynamical regimes, and to stimulate the development of novel tools for material characterization and optimization.

FY 2014 HIGHLIGHTS

Extensive Langevin molecular dynamics simulations have been performed to explore in detail the non-equilibrium aging properties of vortex systems subject to either point-like or columnar defects, when in a previously equilibrated state suddenly the magnetic field is increased or reduced, and correspondingly flux lines are either added or removed from the system. Switching off the vortex interactions, removing the disorder, and separately following the originally present and added vortices resulted in a comprehensive understanding of the ensuing complex relaxation kinetics (manuscript in preparation). A series of numerical experiments was initiated to investigate the relaxation features of driven interacting flux lines from an initial non-equilibrium steady state towards either another driven stationary state, or thermal equilibrium. The Langevin dynamics code was also used to extract flux line segment pinning time distributions at point defects, providing clear evidence for collective pinning behavior (just published in *The Physical Review E*, Dec. 2014). In addition, an effectively two-dimensional Coulomb glass model was utilized to further investigate the structural relaxation processes and associated aging scaling in the Bose glass phase of vortices pinned to columnar defects by means of Monte Carlo simulations (published in *The Physical Review E*, Sep. 2014). Another current project concerns the numerical extraction and analysis of the characteristic length scale associated with coarsening during these relaxation processes. Finally, simple driven model systems known to exhibit logarithmic growth laws have been studied (manuscript in preparation). These projects have involved seven graduate students, who have become familiar with modern computational methods and sophisticated data analysis, and have acquired advanced mathematical tools developed in non-equilibrium statistical mechanics.

Unconventional Metals in Strongly Correlated Systems

Institution: Massachusetts Institute of Technology
Point of Contact: Senthil Todadri
Email: senthil@mit.edu
Principal Investigator: Senthil Todadri
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$115,000 (2014)

PROGRAM SCOPE

The research seeks to develop a theoretical understanding of non-Fermi liquid metallic behavior and its relationship to superconductivity in correlated electron systems such as heavy electron metals, cuprate superconductors and other materials. The most notorious empirical example of such non-Fermi liquid behavior is in the normal state of the optimally doped cuprates but over the past decade has been demonstrated in a number of non-cuprate materials. A striking example is heavy electron materials on the verge of a quantum phase transition to magnetism. Superconductivity is often optimized when the departure from Fermi liquid behavior in the 'normal' state is strongest. The proposed project will explore the nature of the electronic excitations of a non-fermi liquid and its relationship with superconductivity. The PI and his group are currently developing controlled methods to study the emergence of superconductivity out of non-fermi liquid normal states using field theoretic expansion methods combined with renormalization group ideas. In the future he will also explore phenomenological models to understand the feedback of superconducting fluctuations on the normal state excitations and their role in producing non-fermi liquid properties. Another project focuses on studying the novel surface and bulk properties of strongly correlated topological insulators. Other projects are the effects of disorder on various correlated ordered states such as spin density wave metals or pair density wave superconductors.

FY 2014 HIGHLIGHTS

(1) Superconductivity and non-fermi liquid metals: Quantum criticality is often implicated for both the breakdown of Fermi liquid theory and the superconductivity seen in many correlated metals. In a paper (under review in PRB) we described progress in studying these issues theoretically in two dimensional metals pushed close to the onset of nematic order which breaks crystal rotation but not translation symmetries. A theoretical framework for such a quantum critical point was developed earlier in my group (D. Mross, J. McGreevy, H. Liu, and T. Senthil, Phys. Rev. B 82, 045121 (2010)) but that work did not address possible instabilities toward superconductivity. Recently, we reported controlled calculations within this framework and showed that superconductivity is strongly enhanced near such quantum critical points. This is one of the few, and hence valuable, examples where the idea that quantum criticality can enhance superconductivity can be theoretically analyzed reliably and given firm foundation. The methods developed also enabled solving a different class of problems - namely the quantum phase transition between the composite Fermi liquid state in the half-filled Landau level and the Moore-Read non-abelian quantum Hall state. Closely related is the phase transition between two different kinds of popular quantum spin liquids (the spinon Fermi surface state and a different 'paired' version). (2) Strongly correlated three dimensional electronic topological insulators: A fundamental open problem in condensed matter physics is how the dichotomy between conventional and topological band insulators is modified in the presence of strong electron interactions. In a paper (published in Science) I, together with my student C. Wang and former MIT student A. Potter showed that there are 6 new electronic topological insulators that have no non-interacting counterpart.

Orbital-Free Quantum Simulation Methods for Application to Warm Dense Matter

Institution: Florida, University of
Point of Contact: Samuel Trickey
Email: trickey@qtp.ufl.edu
Principal Investigator: Samuel Trickey
Sr. Investigator(s): James Dufty; Florida, University of
Frank Harris; Utah, University of / Florida, University of

Students: Keith Runge; Arizona, University of / Florida, University of
3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$255,000 (2014)

PROGRAM SCOPE

Development and exploratory use of orbital-free forms of free-energy density functional theory (DFT) is the focus. Motivation is the pressing need for affordable, reliable simulations of warm dense matter (WDM). WDM is important experimentally for planetary interiors, hyper-velocity impacts, heavy-ion beam experiments, and dynamically accessed high-pressure regimes (e.g., pathway to inertial confinement fusion). Predictive computational WDM characterization is important because of limited experimental diagnostic access. A major challenge is that WDM is a mixture of atoms, ions, and free electrons. Powerful zero-temperature quantum mechanics techniques for electronic structure are stressed severely to treat WDM while standard plasma methodology omits crucial quantum effects. Current best practice is *ab initio* molecular dynamics (AIMD) with the electron forces on the ions from DFT. Ordinarily this is in the Kohn-Sham (KS) form, which causes a computational bottleneck. KS calculations scale up in cost as the cube of the number of occupied KS states, a very large number at WDM temperatures (T up to 300,000 K or more). The orbital-free formulation, depending only on the electron density, eliminates this bottleneck. But the historic orbital-free approaches (Thomas-Fermi and refinements) cannot describe the condensed matter physics (including bonding) crucial to WDM. This project thus focuses on developing reliable, non-empirical free-energy density functionals for (i) non-interacting kinetic energy and entropy, and (2) exchange correlation free energy, with emphasis on accuracy and generality of applicability. We also develop and publish numerical techniques and software, including downloadable open-source orbital-free AIMD software, projector augmented wave data sets and pseudo-potentials for WDM. To our knowledge we are the only academic group in the world devoted primarily to finite-T DFT.

FY 2014 HIGHLIGHTS

1. We developed the first wholly un-empirical exchange-correlation (XC) free-energy density functional in the local density approximation. It depends only on first principles Monte Carlo (MC) data and is constructed to be smooth with well-behaved derivatives over the entire density-temperature regime of warm dense matter (WDM). Derivation was by systematic thermodynamic analysis of the MC data. This is the long-missing finite-T extension of the Perdew-Zunger and Vosko-Wilk-Nussair T=0 functionals (1981!). Paper: Phys. Rev. Lett. 112, 076403 (2014).
2. Our orbital-free non-interacting free-energy functionals [Phys. Rev. B 88, 161108(R) (2013)] and the new XC free-energy functional were implemented in the PROFESS orbital-free code. In turn it was interfaced to the Quantum-Espresso electronic structure package to provide orbital-free DFT driven *ab-initio* molecular dynamics (AIMD) simulations of WDM. Released under GNU GPL, the software is downloadable from www.qtp.ufl.edu/ofdft. Paper: Computer Phys. Commun. 185, 3240 (2014).
3. We began studies now well underway of (a) liquid-vapor phase transitions in Al with our new OFDFT functionals in AIMD; (b) Deuterium phase diagram with OFDFT functionals driving path-integral molecular dynamics; (c) Relationship of grand-canonical ensemble (in which free energy DFT is derived) and canonical ensemble (in which actual calculations must be done), (d) application of classical maps.
4. We organized 4 sessions of Sanibel Symposium 2014 on *ab initio* simulations at extreme conditions, had 3 visitors (Bonitz, Lutsko, Segev), saw 'Frontiers and Challenges in Warm Dense Matter' (Springer) appear, and gave invited talks at M4 (Canada) by Chakraborty, Sanibel 2014 by Karasiev, HarrisFest (Mexico) by Dufty, Runge, and

Trickey; and Interat. Materials Conf. (Mexico) and WATOC (Chile) by Trickey along with several others. 5. See www.qtp.ufl.edu/ofdft for the complete record.

Quantum Simulations of Orbitally Controlled Physics and Nanoscale Inhomogeneity in Correlated Oxides

Institution: Ohio State University
Point of Contact: Nandini Trivedi
Email: trivedi.15@osu.edu
Principal Investigator: Nandini Trivedi
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$360,000 (2014-2016)

PROGRAM SCOPE

I will focus on both metal-insulator and superconductor-insulator transitions driven by disorder in conventional s-wave superconductors. My aim is to investigate the effect of emergent nanoscale inhomogeneity on local electronic structure and dynamical susceptibilities that could be measured by various scan probes.

FY 2014 HIGHLIGHTS

We calculated the dynamical conductivity across the superconductor-insulator transition (SIT) driven by tuning the ratio of the charging energy to the Josephson energy. We showed that there is a threshold in absorption at low frequencies, well below the pair breaking scale, associated with the amplitude or Higgs mode. And most importantly, we found that the Higgs mode vanished at the quantum critical point with a universal conductivity. We further included the effects of disorder and found that it leads to an expanded quantum critical region with a different critical conductivity, indicating a change in the universality class.

Nonequilibrium Thermodynamics in Magnetic Nanostructures

Institution: California-Los Angeles, University of
Point of Contact: Yaroslav Tserkovnyak

Principal Investigator: Yaroslav Tserkovnyak
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$375,000 (2014-2016)

PROGRAM SCOPE

The nascent field of spin caloritronics addresses emergent out-of-equilibrium phenomena in thermally-biased magnetic systems. This proposal focuses on the geometric gauge fields and related geometric and topological aspects in the interactions between collective and itinerant degrees of freedom (associated with diverse magnetic orders), the former encoding “memory” (i.e., slow variables) and imprinting evolving geometrical spin textures, while the latter transmitting “signals” through these curved backgrounds. Energy and spin (angular momentum) are at the core of the investigation, bringing about phenomenological framework based on conservation laws, hydrodynamic continuity, magnetic order, symmetries, and dynamic reciprocities. The main objective of the proposal is to identify and study

self-organized nonlinear phenomena and dynamical phase transitions in thermally driven magnetic systems. Particular attention is paid to low-dissipation, mainly, insulating systems, where quantum statistics, coherence, and correlations play an important role. The PI believes the ideas developed as a result of this project may find wide applications within nonequilibrium phenomenology of magnetism, in the era ushered in by a range of experimental tools and novel phenomena (such as spin pumping, spin Hall effect, and spin Seebeck effect) to thermally agitate and probe complex magnetic heterostructures. The relativistic electronic correlations, which are at the heart of the relevant microscopies, will be playing a central role.

FY 2014 HIGHLIGHTS

The main accomplishment for the project within fiscal year 2014 is represented by the preprint titled “Interfacial Spin and Heat Transfer between Metals and Magnetic Insulators.” In this work, we study the role of thermal magnons in the spin and heat transport across a normal-metal/insulating-ferromagnet interface, which is beyond an elastic electronic spin transfer. Using an interfacial exchange Hamiltonian, which couples spins of itinerant and localized orbitals, we calculate spin and energy currents for an arbitrary interfacial temperature difference and misalignment of spin accumulation in the normal metal relative to the ferromagnetic order. The magnonic contribution to spin current leads to a temperature-dependent torque on the magnetic order parameter; reciprocally, the coherent precession of the magnetization pumps spin current into the normal metal, the magnitude of which is affected by the presence of thermal magnons.

Charge and Spin Dynamics in Bulk and Heterostructured Dilute Magnetic Semiconductors

Institution: Missouri, University of
Point of Contact: Carsten Ullrich
Email: ullrichc@missouri.edu
Principal Investigator: Carsten Ullrich
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$105,000 (2014)

PROGRAM SCOPE

This project studies the dynamics of collective excitations of the itinerant carriers in dilute magnetic semiconductors (DMS). Plasmon-type excitations are not only of interest in their own right, but are ideal for testing microscopic models for the carrier dynamics in semiconductors. The following problems will be studied: (1) Plasmons and spin waves in bulk DMS. Plasmons in p-type semiconductors are usually strongly Landau damped, but there are indications that it may be possible to find plasmon modes outside the particle-hole continua. Such modes will be sensitive to details of disorder broadening, such as correlated versus random disorder, or a self-consistent treatment of disorder scattering. We will also extend our formalism to study Stoner excitations and spin waves in ferromagnetic DMS. (2) Spin Coulomb drag beyond the local approximation. The spin Coulomb drag (SCD) is an intrinsic effect which represents an ultimate limitation for spintronics. The linewidth of intersubband spin plasmons in quantum wells represents a new and purely optical way to measure the SCD effect, using inelastic light scattering. We propose a new and more accurate way of calculating the SCD in quantum confined systems, beyond the usual local approximation. A detailed analysis of light scattering experiments, including Rashba and Dresselhaus spin-orbit coupling, will be performed. (3) Collective intersubband excitations in semiconductor heterostructures. We will extend our approach for charge and spin

dynamics in DMS to lower-dimensional and quantum confined systems, with the goal of studying collective intersubband excitations in n- and p-type systems. In particular, changes of the line shape as the system undergoes a ferromagnetic transition will reveal how the carrier dynamics in DMS is influenced by disorder, band-structure, spin-orbit coupling, and many-body effects.

FY 2014 HIGHLIGHTS

During the period of October 2013 to September 2014 we have focused on two projects, and have made major progress in both of them. The first project was carried out by my postdoc Mehul Dixit (who left my group on October 1 for a position in industry), and involved the theoretical analysis and numerical simulation of spin-flip waves in CdMnTe quantum wells. In the presence of magnetic fields, this material is a superparamagnet, which leads to a strong spin splitting of the subbands. The spin-flip wave is modulated due to Rashba and Dresselhaus spin-orbit coupling, which is amplified by electronic many-body effects. We have published a joint experimental-theoretical study earlier [Phys. Rev. B 87, 1221303 (2013)] together with the group of Florent Perez in Paris. We during the past year we have carried out an in-depth theoretical analysis, with many analytical and numerical results. This work will soon be ready for publication. The collaboration between PI Ullrich and the group in Paris has intensified over the past year; next summer, the PI will spend a month in Paris, supported by a local grant. The second project was carried out by my graduate student Shahrzad Karimi, and has just been accepted for publication in Phys. Rev. B. It is a study of the three- to two-dimensional crossover in time-dependent density-functional theory (TDDFT). The most popular density functionals (LDA and GGA) are known to breakdown in the ground state when the system becomes more and more confined in 2D, and we have now shown, for the first time, when and how the corresponding breakdown occurs in the dynamical regime. We find that semilocal xc functionals collapse for quantum well widths close to the 2D Wigner-Seitz radius (which means that they will still work for many typical quantum wells). On the other hand, orbital functionals will cross over correctly from 3D to 2D.

Computational Studies of Hydrogen Interactions with Storage Materials

Institution: California-Santa Barbara, University of
Point of Contact: Chris Van de Walle
Email: vandewalle@mrl.ucsb.edu
Principal Investigator: Chris Van de Walle
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

We are conducting computational studies with the goal of developing new insights for hydrogen interactions with materials. We use state-of-the-art density functional calculations and address energetics and electronic structure. We pursue new computational approaches, such as the incorporation of van der Waals interactions within density functional theory. Our recent work has focused on borohydrides, LiH, layered compounds such as MoS₂ and MoO₃, and perovskite-structure oxides. For hydrogen storage materials our results provide direct insight into the processes of hydrogen uptake and release, and help in developing guidelines for designing storage media with improved storage capacity and kinetics. We propose atomistic mechanisms for the material's decomposition that involve mass transport mediated by native defects. In addition to the hydrogen storage aspect, we view our results from the perspective of other applications, including electrochromism and photochromism,

as well as proton conduction. Hydrogen can be incorporated in high concentrations in materials that crystallize in the perovskite crystal structure, such as rare-earth or transition-metal doped BaZrO₃ and SrZrO₃. These materials not only display higher hydrogen solubility than other metal oxides, but also proton conductivity at elevated temperatures. Proton conductors based on perovskites are used in solid oxide fuel cells. We are focusing on building an understanding of the interactions between hydrogen, acceptor dopants, and native point defects. This will help in designing novel electrolyte materials. Our overall goal is twofold: (1) to develop guidelines for designing materials with improved properties; and (2) to generate new fundamental knowledge, for instance, about mechanisms that govern ionic transport in insulators.

FY 2014 HIGHLIGHTS

(1) Role of native defects in the decomposition of Li₄BN₃H₁₀ Li₄BN₃H₁₀ releases greater than 10 wt% hydrogen when heated. Still, its practical application is limited due to the cogeneration of ammonia. Based on first-principles results we have proposed an atomistic mechanism for the decomposition that involves mass transport mediated by native defects. The release of NH₃ is associated with the formation and migration of negatively charged hydrogen vacancies inside the material, and it can be manipulated by the incorporation of transition-metal impurities. (2) Van der Waals interactions in density functional calculations A number of methods have been proposed to include van der Waals interactions within density functional theory (DFT). We have compared the performance of several of these functionals specifically for describing the structural and electronic properties of MoS₂ and MoO₃, materials at the focus of our project. Our conclusion is that the combination of the semiempirical Grimme D2 method with the hybrid functional HSE06 leads to a very good description of structural and electronic properties. (3) Properties of layered compounds: MoS₂ and MoO₃ We have used our methodology for calculating properties that are essential for applications but still unknown or controversial. We have traced the evolution of the band structure as a function of the number of layers in MoS₂, starting from a monolayer, which has a direct gap, to the bulk material, which has an indirect gap. These findings are analyzed in terms of the orbital composition of the valence- and conduction-band edges at the various high-symmetry points in the Brillouin zone. We challenge the common belief that the change in band gap of MoS₂ as a function of the number of layers is due to quantum confinement. We have also performed calculations of the elastic constants in bulk MoS₂, and investigated the effects of hydrostatic pressure, shedding light on experiments.

Dynamical and Non-Equilibrium Effects in Higher-Order and Pump and Probe X-Ray Scattering

Institution: Northern Illinois University
Point of Contact: Michel van Veenendaal
Email: veenendaal@niu.edu
Principal Investigator: Michel van Veenendaal
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$130,000 (2014)

PROGRAM SCOPE

The aim of this project is to develop theoretical tools that allow a better understanding of X-ray experiments performed at the nation's light sources. X-ray spectroscopy is entering a new era with an increased emphasis on the study of dynamics and nonequilibrium effects that is essential for understanding phenomena relevant to solving the challenges in energy and information technology. The

first focus is centered on the study of the local X-ray scattering amplitude of a system excited away from equilibrium by, for example, a femtosecond optical or terahertz pulse. Typical examples of such effects are charge-transfer and spin crossover phenomena. When studying finite-size systems, the nonequilibrium dynamics can be treated quantum mechanically by including the coupling to local vibronic modes, dissipation and the effects of loss of coherence. The second focus is on larger systems and the ultrafast melting of long-range charge, orbital, spin, and structural order. The research is directed towards creating an understanding of the disappearance of the order as measured by the decrease in X-ray diffraction and resonant elastic X-ray scattering intensities. The effects of coupling between the electronic states and the lattice, orbital degeneracy, and electron count are studied. This provides insight into the conditions for a transition from a local to a collective response and the possible emergence of new phenomena due to correlation effects. Results on model systems are then extended and modified to allow the calculation of X-ray spectroscopies, such as time-dependent X-ray absorption and dichroism and resonant elastic scattering. The project also involves extensive collaborations with experimental groups. Here, the focus has been on the study of strongly correlated materials, such as transition-metal compounds, using X-ray spectroscopic tools that were the focus of the theoretical research in previous funding cycles.

FY 2014 HIGHLIGHTS

Just prior to the start of the year, significant progress was made in the study of the ultrafast phase transitions. Insulator-to-metal transitions have been observed in VO_2 , V_2O_3 , manganites, etc. A model was developed for the ultrafast insulator-to-metal transition in VO_2 following photoexcitation. The model explains several key features, such as a structural bottleneck, coherent structural motion combined with phase shifts in the oscillation, the absence of ultrafast metal-to-insulator transitions, and the need for a critical fluency. The work on photo-induced phase transitions has been continued with the study of charge-order melting. In particular, the focus has been on model systems of 100,000 and more sites to study the nonequilibrium thermodynamics of photoexcited systems. In the past decade, Resonant Inelastic X-ray Scattering (RIXS) has made remarkable progress as a spectroscopic technique. In collaboration with Ken Ahn from New Jersey Institute of Technology and experimentalists from Brookhaven and Argonne National Laboratories, a study was made of resonant inelastic x-ray scattering on single-layered charge, orbital and spin ordered manganites. Good agreement has been found between the theory and experiment, which demonstrates the potential of K-edge RIXS as a probe for the screening dynamics in materials. X-ray scattering is also an important tool in high-pressure studies due to the large penetration depth of the X-rays. An example of such a study is the behavior of vanadium sesquioxide, V_2O_3 , at high pressures. From X-ray Raman scattering, we found that screening effects, which are strong in the corundum phase, become weakened at high pressures. The theoretical calculations indicate that this can be related to a decrease in coherent quasiparticle strength, suggesting that the high-pressure phase is likely a critical correlated metal, on the verge of Mott-insulating behavior. This work was an Editor's Selection in Physical Review Letters.

Self-Healing Nanomaterials: Multimillion-Atom Reactive Molecular Dynamics Simulations

Institution: Southern California, University of
Point of Contact: Priya Vashishta
Email: priyav@usc.edu
Principal Investigator: Priya Vashishta
Sr. Investigator(s): Rajiv Kalia; Southern California, University of
Aiichiro Nakano; Southern California, University of
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$180,000 (2014)

PROGRAM SCOPE

This project focuses on self-healing nanomaterials capable of sensing and repairing damage in harsh chemical environments and in high temperature/high pressure operating conditions. We perform petascale simulations to study self-healing processes in anticorrosion coatings for metals and in ceramic nanocomposites.

FY 2014 HIGHLIGHTS

We enabled an unprecedented scale of quantum molecular dynamics (QMD) simulations through algorithmic innovations. A lean divide-and-conquer density functional theory algorithm significantly reduces the prefactor of the $O(N)$ computational cost. The resulting parallel efficiency was 0.984 on 786,432 IBM Blue Gene/Q cores for a 50.3 million-atom system. The time-to-solution was 60-times less than the previous state-of-the-art, owing to high floating-point performance (50.5% of the peak). QMD simulations involving 16,661 atoms reveal a novel nanostructural design for on-demand hydrogen production from water using Al particles. We found that orders-of-magnitude faster reactions with higher yields can be achieved by alloying Al particles with Li. A key nanostructural design is identified as the abundance of neighboring Lewis acid-base pairs, where water-dissociation and hydrogen-production require very small activation energies. These reactions are facilitated by charge pathways across Al atoms that collectively act as a 'superanion', and a surprising autocatalytic behavior of bridging Li-O-Al products. Furthermore, dissolution of Li atoms into water produces a corrosive basic solution that inhibits the formation of a reaction-stopping oxide layer on the particle surface, thereby increasing the yield. These mechanisms not only explain recent experimental findings, but also predict the scalability of this technology at industrial scales. We also examined water confined in nanoporous silica using molecular dynamics simulations. The simulations reveal intermixed low-density water and high-density water and with distinct local structures in nanopores of silica. The simulations also show dynamic heterogeneities in nanoconfined water. The temporal decay of cage correlation functions is well described by stretched exponential relaxation. The exponent has a unique value, which agrees with an exact result for diffusion in systems with static, random traps.

Disorder and Interaction in Correlated Electron Systems

Institution: Boston College, Trustees of
Point of Contact: Ziqiang Wang
Email: wangzi@bc.edu
Principal Investigator: Ziqiang Wang
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$480,000 (2014)

PROGRAM SCOPE

This project studies the emergent quantum electronic states, low energy excitations, and unconventional superconductivity in correlated electron materials. The first part investigates the microscopic origin of superconductivity in Fe-pnictide superconductors. A novel mechanism of superconductivity driven by charge and orbital fluctuations will be explored. A microscopic theory will be developed for the spin state transition induced by the large Hund's rule coupling to address the

substantial variations of the ordered moments, the highly incoherent metallic state with the anomalous temperature dependence of the spin-susceptibility, the orbital and the electron/spin nematic order. The second part studies two central unresolved problems in high- T_c cuprate superconductors: What controls T_c and what is the origin of the normal state pseudogap? Guided by new experimental findings, the program will study how the out-of-plane atomic and electronic structure affects the electronic states in the CuO_2 plane and the superconducting (SC) transition. The project investigates the scenario where the pseudogap state originates from a symmetry breaking phase transition of incommensurate, d-wave bond density wave order. The effects of electronic disorder resulting in the valence bond glass state will be investigated. The third part aims at advancing the theoretical understanding of the Mott transition. The challenge of the strong correlation problem is a consistent description of both the coherent quasiparticles and the incoherent excitations. The project proposes that the crucial ingredient uniting these disparate ideas of Brinkman-Rice-Gutzwiller and Hubbard is the binding between doublons and holons. A microscopic theory will be developed to describe doublon-holon binding in the Hubbard model and applied to study the Mott transition, magnetism, and spin-liquid phases on different lattices. The notion of an electron-fractionalized antiferromagnetic (AF*) phase without coherent quasiparticles will be investigated.

FY 2014 HIGHLIGHTS

Mott Transition: Stoner and Fractionalized Antiferromagnet in the Hubbard model The Hubbard model is the “Standard Model” of correlated materials and the Mott transition is the most important Hallmark and the paradigm of the strong correlation problem. Understanding the Mott transition and its interplay with magnetism is a central unresolved problem of the “Standard Model”. We have developed new ideas, new techniques, and realized new physics beyond those obtainable in the dynamical mean field theory. We found that the binding between doubly occupied (doublon) and empty (holon) sites governs the incoherent Mott-Hubbard excitations and plays a key role in the Mott transition. We construct a new saddle-point solution with doublon-holon binding in the Kotliar-Ruckenstein slave-boson functional integral formulation of the Hubbard model. On the half-filled honeycomb lattice and square lattice, the ground state is found to exhibit a continuous transition from a paramagnetic semimetal/metal to an antiferromagnetic (AF) ordered Slater insulator with coherent quasiparticles, followed by a Mott transition into an electron-fractionalized AF* phase where a charge gap opens and electrons fractionalize into separate spin and charge elementary excitations without coherent quasiparticles. Such a phase structure appears to be generic for bipartite lattices without magnetic frustration. We showed that doublon-holon binding unites the three important ideas of strong correlation: coherent quasiparticles, incoherent Hubbard bands, and deconfined Mott insulator.

Strong Correlation DMRG and DFT

Institution: California-Irvine, University of
Point of Contact: Steven White
Email: srwhite@uci.edu
Principal Investigator: Steven White
Sr. Investigator(s): Kieron Burke; California-Irvine, University of
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$237,322 (2014)

PROGRAM SCOPE

We are successfully comparing one of the most popular electronic structure methods, density functional theory (DFT), with the extremely precise density matrix renormalization group (DMRG). DFT has two quite different facets: an 'in principle' aspect, in which DFT is exact but impractical to compute, and a 'common approximations' aspect, where an approximate functional is assumed, which may have uncertain accuracy. The 'common approximations' approach has proved extremely useful for a vast array of systems where correlations are not too strong. Improving these approximations for strong correlation is an important goal for this field. For one dimensional systems, DMRG provides essentially exact results. With these results, we can explore both the 'in principle' and 'common approximations' aspects of DFT. For three dimensions, DMRG becomes impractical, except in a modest basis for moderate sized molecules. We have developed and continue to develop 1D model systems constructed so the lessons we learn about DFT for the 1D model apply to the realistic 3D world. For example, a key issue for DFT is finding accurate gaps. We find that for strongly correlated 1D 'pseudosolid' model systems, the gaps in DFT do not open properly in 1D, just as in 3D. We have been able to calibrate correlations energies in our 1D systems to that they are very similar in size, per atom, to 3D. Finding the exact solution with DMRG allows us to back calculate exact DFT quantities and this has led us to some surprising conclusions. Most recently we proved that DFT can always be guaranteed to converge if one uses the exact functional (Physical Review Letters 111, 093003, 2013). But a variety of work can still be performed with these comparisons. We will explore in the upcoming months common problems and potential fixes for regular DFT calculations.

FY 2014 HIGHLIGHTS

The principle achievement of the 2014 FY is the publication of a comprehensive account of convergence in density functional theory, 'Kohn-Sham calculations with the exact functional', in Physical Review B (90, 045109). This publication has been well received garnering an Editor's Choice award and high praise from the community at both the 2014 March Meeting, where T.E. Baker presented on the findings as well as the Institute of Pure and Applied Mathematics's summer school on density functional theory (also presented by T.E. Baker). In general, we have received reaction that the paper has been hailed as a solid account of issues many groups face. Several more exciting projects are underway. We are preparing to submit two articles as next steps in our work to explore DFT with exact conditions provided by DMRG. First, we have developed a simplified interaction in one dimension based on an exponential that we will submit to Physical Review A. It is natural to implement such an interaction into DMRG and decreases computational times in other calculations as well. It is hoped that future works working in one dimension will use this interaction as it converges to a high accuracy quickly in both DMRG and DFT systems owing to the short decay length. Remarkably, the energetics and properties of pseudo-atoms in this system are nearly exactly what is expected from the more commonly used, but more difficult to converge, soft-Coulomb interaction. We will use it to explore the band gap problem and are preparing a full account for publication on that topic right now. The second paper we are preparing is a proof of principle that machine learning can learn the fundamental universal functional guaranteeing that DFT has a well defined form. This is a ground-breaking study targeted for Physical Review Letters. The consequences for electronic structure calculations are the first realization of the longstanding dream of determining a fully orbital free DFT.

Thermodynamics and Kinetics of Phase Transformations in Energy Materials

Institution: Northwestern University
Point of Contact: Christopher Wolverton
Email: c-wolverton@northwestern.edu
Principal Investigator: Christopher Wolverton
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$780,003 (2014-2016)

PROGRAM SCOPE

In many areas of sustainable energy (batteries and supercapacitors, solar fuel oxides, hydrogen storage, etc.), functional materials are engineered to undergo phase transformations. Both thermodynamic and kinetic factors need to be taken into account when designing new materials. Thermodynamics sets the necessary-but-not-sufficient conditions for the suitability of a particular material in a given application. High-throughput computation of the total (free) energies can serve as a useful thermodynamic screen for potential materials, but the potential configuration space is too vast to be amenable to an exhaustive search. The kinetics of transformations are often very difficult to assess at a mechanistic level, since so many processes could be rate limiting. The complexity of these phenomena makes computational design difficult, not least due to the lack of suitable theoretical methods and computational tools. To address the needs of the next stage of the Materials Genome Initiative, we propose to develop systematic, quantitatively accurate first-principles methods to address two important problems: (i) predict and optimize the thermodynamics of phase transformations over a large composition and structure space, and (ii) model the kinetics of nucleation and mass transport in solid-state chemical reactions. Task (i) will be addressed by combining state-of-the-art statistical algorithms for uncovering hidden relations in large computed data sets with high-throughput computation of reaction enthalpies and novel DFT-based crystal field and compressive sensing lattice models for predicting electronic and configurational entropies. Task (ii) will be addressed by developing predictive high-throughput framework for defect energetics and diffusivity calculations, combined with symmetry-adapted structure prediction methods.

FY 2014 HIGHLIGHTS

Accomplishments (and publications, where applicable) have fallen into the following research areas: [1] H. A. Hansen and C. Wolverton, 'Kinetics and Thermodynamics of H₂O Dissociation on Reduced CeO₂(111)', J. Phys. Chem. C 118, 27402 (2014). [2] M. Aykol and C. Wolverton, 'Local environment dependent GGA+U method for accurate thermochemistry of transition metal compounds', Phys. Rev. B 90, 115105 (2014). Proximity Phenomena in Graphitic Nanostructures: Theoretical Studies

Institution: South Florida, University of
Point of Contact: Lilia Woods
Email: lmwoods@usf.edu

Principal Investigator: Lilia Woods
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$50,000 (2014)

PROGRAM SCOPE

The objective of this project is to investigate Casimir/van der Waals interactions and thermal exchange processes involving graphitic nanostructures. The unique electronic structure, optical response and dimensionality give rise to a series of interesting effects relying on the long-ranged dispersive interaction involving graphene nanostructures. Our studies contributed significantly to the understanding of the underlying interplay between quantum mechanical and thermal effects that help us find new opportunities to tailor Casimir/vdW interactions in terms of the strength, distance and temperature dependence, and even sign. The related phenomenon of electromagnetic heat exchange was also studied in depth showing heat management pathways by controlling the properties of graphene systems. Our work shows the limitations and advantages of using graphene systems especially at the near-field regime of operation.

FY 2014 HIGHLIGHTS

Several important results were achieved in this period. More specifically, a microscopic approach of near-field heat transfer in graphitic nanostructures was presented showing features not accessible via an effective medium theory. Graphene transverse electric models can also be enhanced in a near-field exchange process utilizing metamaterial composites. Depending on the particular metamaterial, it is suggested that the role of chemical potential and scattering rates of graphene can be probed in near-field radiation. Van der Waals and Casimir interactions between graphitic systems were also studied with the purpose of developing effective theoretical techniques for an adequate description. More specifically, a Lifshitz-like approach was developed for graphene nanoribbons as a prototype of quasi-1D systems interacting via a van der Waals force. Furthermore, the zero-point summation method was extended to be applicable to planar and spherical systems characterized by a constant conductivity motivated by the fact that under certain conditions graphene can be described by a constant conductivity. A series-expansion method was also presented for graphitic systems for which the dilute regime is applicable. This approach is especially attractive as it enables one to deal with edge effects and nontrivial geometries in a transparent way.

EARLY CAREER: Quantum Mechanical Simulations of Complex Nanostructures for Photovoltaic Applications

Institution: Colorado School of Mines
Point of Contact: Zhigang Wu
Email: zhiwu@mines.edu
Principal Investigator: Zhigang Wu
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

In this proposal, the PI will first address the excited-state problem within the DFT framework to obtain quasiparticle energies from both Kohn-Sham (KS) eigenvalues and orbitals; and the electron-hole binding energy will be computed based on screened Coulomb interaction of corresponding DFT orbitals. The accuracy of these approaches will be examined against many-body methods of GW/BSE and quantum Monte Carlo (QMC). The PI will also work on improving the accuracy and efficiency of the GW/BSE and QMC methods in electronic excitation computations by using better KS orbitals obtained from orbital-dependent DFT as inputs. These new developments will then be applied to investigate a chosen set of complex nanostructures that have great potential for opening new routes in designing materials with improved transport, electronic, and optical properties for Photovoltaic (PV) and other optoelectronic usages: (1) Hybrid interfaces between materials with distinct electronic and optical properties, such as organic molecules (conjugated polymers, e.g. P3HT) and inorganic semiconducting materials (Si and ZnO). Complicated interface structures, including interface bonding configurations, compositional and geometrical blending patterns, interfacial defects, and various sizes and shapes of inorganic nanomaterials, will be considered for the purpose of understanding the working mechanisms of present organic/nano PV systems and designing optimum interface structures for fast charge separation and injection. (2) Complex-structured semiconducting nanomaterials that could induce charge separation without pn- or hetero-junctions. The new methodology will allow the PI to investigate the performance of realistic semiconducting nanomaterials of internal (impurities, defects, etc.) and external (uneven surface, mechanical twisting and bending, surface chemistry, etc.) complexities on optical absorption and charge transport against charge trapping and recombination.

FY 2014 HIGHLIGHTS

(1) Transitions between Semimetal and Semiconductor in Graphene. We reveal that a semimetal-to-semiconductor transition can be induced geometrically without breaking the sublattice symmetry. For the same patterning periodicity, however, breaking the sublattice symmetry increases the gap, while phase cancellation can lead to a semiconductor-to-semimetal transition in non-Bravais lattices, and the Dirac points move in accordance with the anisotropy induced by the defect. Our GW/BSE calculations reveal large band gap renormalization and giant excitonic effects. In addition, we find that topological phase transition occurs with large bulk gap and small spin-orbit interaction. (2) Band gap engineering of silicon nanowires via twisting. We investigated the effect of twisting on electronic properties of silicon nanowires (Si NWs). As twisting angle increases, E_g increases slightly except for the [111] NW, then it decreases dramatically for the [001] and [011] NWs, while E_g in the [001] NW decreases nearly linearly with twisting angle. Thus our calculations suggest that electronic structures of Si NWs can be tuned by twisting. (3) Tailoring the optical gap of silicon quantum dots for photovoltaic cells. Our first principles analysis indicates that connecting conjugated organic ligands to silicon quantum dots using vinyl connectivity can satisfy both requirements. For a prototype assembly of 2.6 nm dots, we predict that triphenylamine termination will result in a 0.47 eV redshift along with an enhanced near-edge absorption character. Robustness analyses of the influence of oxidation on absorption and of extra alkyl ligands reveal that the control of both factors is important in practical applications. (4) Quasi-particle energies from density functional theory. We have developed the quasiparticle-DFT (QP-DFT) method based on the first-order perturbation theory, whose computational overhead is essentially the same as that of DFT DFT and accurately calculated the fundamental band gap (E_g) by QP-DFT.

Laser-Induced Ultrafast Magnetization in Ferromagnets

Institution: Indiana State University
Point of Contact: Guoping Zhang
Email: guoping.zhang@indstate.edu
Principal Investigator: Guoping Zhang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 2 Undergraduate(s)
Funding: \$0 (Research was supported with prior fiscal year funding.)

PROGRAM SCOPE

Our project focuses on a new frontier in future magnetic recording and fast magnetic storage device using the laser-induced ultrafast demagnetization in ferromagnets. Our goal is to develop a clear understanding of how the laser can demagnetize magnetic samples so quickly. This potentially has a big impact on the future devices.

FY 2014 HIGHLIGHTS

We have made remarkable progresses in the fiscal year 2014. (1) We discovered that pressure can directly affect the demagnetization process in ferromagnetic 3d metals. The stronger the pressure is, the smaller the demagnetization is. The reason for this is that there are several optically accessible bands shifted, which become off-resonant. This can be directly tested experimentally. This result was published in Phys. Rev. B Volume 88, 144425 (2013). (2) For the first time, we crystal-momentum dispersed the ultrafast spin change in fcc Co. This result demonstrates that in contrast to the existing wisdom, the demagnetization is not uniform in any pockets of the Brillouin zone. Instead, some pockets are more strongly excited than others. We develop an animation for the entire demagnetization in the three-dimensional space. This result was published in the prestigious Scientific Reports Volume 4, Article number: 5010 (2014). (3) We finally uncovered the role of the exchange interaction in the laser-induced demagnetization process. Since the beginning of femtomagnetism, it has been hotly debated how an ultrafast laser pulse can demagnetize a sample and switch its spins within a few hundred femtoseconds, but no consensus has been reached. In this paper, we propose that an ultrafast reduction in the exchange interaction by a femtosecond laser pulse is mainly responsible for demagnetization and spin switching. This result was published in Journal of Cond. Matt. Volume 26, 376001 (2014).

Theory of Defects in Electronic Materials

Institution: Rensselaer Polytechnic Inst.
Point of Contact: Shengbai Zhang
Email: zhangs9@rpi.edu
Principal Investigator: Shengbai Zhang
Sr. Investigator(s): Peihong Zhang; New York-Buffalo, State University of
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$300,000 (2014)

PROGRAM SCOPE

The goal of this project is to carry out theoretical development for accurate predictions of defects properties in electronic materials, and to perform, in parallel, cutting-edge research in defect physics, such as non-equilibrium doping, deep-level engineering, excited-state properties, and defect-defect

interaction and correlation using first-principles theoretical tools with balanced accuracy and computation efficiency. We employ a comprehensive set of density functional theory (DFT) methods such as the local density approximation (LDA) and generalized gradient approximation (GGA)-based molecular dynamics (MD), the time-dependent DFT (TDDFT), and the hybrid functional methods, and the many-body GW quasiparticle perturbation theory. We examine, for charged defects, the response of the screening charge to the defect and the effects of the artificially introduced compensating jellium background, with the aim of eliminating unphysical interactions. Non-equilibrium doping is an active research topic of high current interest. We will push the frontier of *ab initio* defect study from mainly isolated point defects to strongly interacting defects, e.g., clustering, and from mainly ground-state properties to excited-state properties. We will also explore possible paths to lower dopant ionization energy in ultrawide gap materials. Designing electronic materials with controllable properties is important for the development of economically viable, resource-sustainable, and environmentally friendly energy materials. Such materials are the key to technology breakthroughs in increased energy harvesting, transformation, storage, and utilization efficiencies, which in turn secure U.S. leadership in clean energy technologies, increase U.S. national security, improve U.S. economic prosperity, and increase U.S. global competitiveness.

FY 2014 HIGHLIGHTS

Negatively charged nitrogen-vacancy (NV^-) center in diamond has emerged as a promising system for quantum information. Its promise has inspired unprecedented research interests in optical manipulations of defect states, and has fostered the search for alternative low-cost defect systems. We predict an NV^- -like color center in c-BN, consisting of a substitutional oxygen and an adjacent boron vacancy. It displays most of the interesting properties of the NV^- center, is optically accessible with a zero-phonon line of about 1.6 eV, and shares much of the characteristics of the GC-2 center often observed in c-BN [Phys. Rev. Lett. 113, 136401 (2014)]. Kagome lattices have attracted great attention for understanding the physics of frustration. Spin frustration is expected to yield fascinating exotic physics. Other physical quantities such as electronic orbitals should also show frustration in a Kagome lattice. We proposed a three-dimensional elemental carbon Kagome lattice, whose stability is comparable to C_{60} . Orbital frustration in this system is responsible for the emergence of a direct band gap of 3.43 eV. Both the electron and hole effective masses are comparable to those of Si, while the imaginary part of the dielectric function is similar to that of direct-gap GaN and ZnO [Phys. Rev. Lett. 113, 085501 (2014)]. Doping wide-band-gap (WBG) materials is among the most difficult challenges, with p-type GaN perhaps the only exception. As a promising low-cost alternative, ZnO has attracted significant attention. However, stable p-type ZnO is still a major obstacle, due to the formation of small polarons. A new type of polaron explains why GaN can be p-doped with Mg, whereas ZnO cannot be p-doped with Li. The unique feature of the polaron in GaN lies in its highly anisotropic localization. In contrast, the same polaron in ZnO cannot sustain such an anisotropic localization: a spontaneous symmetry breaking leads to a deep hole state [Phys. Rev. B 90, 165301 (2014)].

Electronic Structure and Fundamental Physics of Semiconductor Nanostructures

Institution: Colorado, University of
Point of Contact: Alex Zunger
Email: alex.zunger@colorado.edu
Principal Investigator: Alex Zunger
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$210,000 (2014)

PROGRAM SCOPE

Project scope: Testing our fundamental understanding of the basic interactions that govern the electronic properties of semiconductor nanostructures requires access to spectroscopically rich and highly resolved data. Alas, this is afforded mostly by rather large nanostructures such as self-assembled epitaxial systems (InAs/GaAs; HgTe/CdTe; GaAs/AlAs), containing typically 100,000 or 1,000,000 atoms per computational unit cell. This size regime is well outside the range of DFT methodologies. At the same time, continuum-like methods (based on envelope functions) that can handle large nanostructures lack the atomistic resolution needed to describe the underlying electronic structure phenomenology. Using our previously developed screened-pseudopotential plus configuration interaction approach we can directly address million-atom nanostructures of the sort described above. Our scope is to use this methodology for understanding fundamental electronic processes in nano and eventually meso-scopic systems

FY 2014 HIGHLIGHTS

Highlights: The way large scale calculations lead to theoretical discovery of new nanostructure mechanisms (i) Discovery of a first-order, giant Rashba spin splitting in semiconductor nano wires; (ii) the discovery of a novel channel of light-hole to heavy-hole coupling in strained quantum dots, mediated by intermediate states (analogous to super exchange in magnetism), (iii) prediction of emergent density of states features in nanowires that are not associated with the conventional, orbitally classified states such a 1S, 1P, 1D. (iv) Microscopic explanation of the spectroscopic features observed in million-atom quantum dots embedded in nanowires. (v) Careful calculation of the electronic states in HgTe/CdTe quantum wells at the critical well thickness where topological band inversion occur shows that the relevant HH1 and E1 states anti-cross rather than cross, leading to gapped Dirac cones.

Unconventional Spin and Orbital Ordering in Semiconductor Nanostructures

Institution: New York-Buffalo, State University of
Point of Contact: Igor Zutic
Email: zigor@buffalo.edu
Principal Investigator: Igor Zutic
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$140,000 (2014)

PROGRAM SCOPE

Semiconductor nanostructures, such as quantum dots (QDs), provide an interesting interplay of interaction effects in confined geometries and novel opportunities to control the spin and orbital ordering at the nanoscale. However, owing to the computational complexity of including even a small number of magnetic impurities (~ 10), there is a need to apply various approximations schemes to accurately describe magnetic QDs. Unfortunately, a widely used mean-field theory leads to spurious phase transitions and an incorrect description of a carrier density in small magnetic systems. These difficulties impede the progress in understanding of the fundamental properties and the potential applications of semiconductor nanostructures. To systematically address this situation, our main objectives are: (i) developing a comprehensive framework suitable to study the interplay of many-body effects and quantum confinement in small magnetic systems, focusing on the inclusion of spin

fluctuations and developing computational methods beyond the mean-field approximation. (ii) exploring novel possibilities for the control of spin and orbital ordering in semiconductor nanostructures, as well as to provide proposals for their experimental implementation.

FY 2014 HIGHLIGHTS

The ground state of a nonmagnetic quantum mechanical system is widely expected to be nodeless. While this notion also provides a valuable guidance in understanding the ordering of energy levels in semiconductor nanostructures, there are reports that nodal ground states for holes are possible. However, the existence of such nodal states has been debated and even viewed merely as a theoretical artifact. We reveal [Phys. Rev. B 89, 045315 (2014)] that nodal ground states in quantum dots are not limited to a specific approach. Remarkably, the emergence of nodal hole states at the top of the valence band can be attributed to the formation of orbital vortex textures through competition between the hole kinetic energy and the coupling to the conduction band states. A novel magnetic semiconductor (Ba,K)(Zn,Mn)₂As₂, isostructural to 122 Fe-based superconductors, has a decoupled spin and charge doping, unlike the vast majority of magnetic semiconductors. This provides a unique opportunity to elucidate the microscopic origin of the magnetic interaction and ordering in dilute magnetic semiconductors (DMS). We show that [Phys. Rev. B 90, 140403(R) (2014)]: (i) the conventional density functional theory accurately describes this material, and (ii) the magnetic interaction emerges from the competition of the short-range superexchange and the longer-range spin-spin interaction mediated by the itinerant As holes. We predict a clear path to enhance Curie temperature, T_C , in novel DMS with an already record-high T_C . Realizing acoustic analogues of active optical devices has been a long-standing challenge. Phonon lasers could provide versatile sources of coherent acoustic waves used 3D imaging of nanostructures or creating periodic strain of a material to rapidly modulate its optical and electronic properties. We propose a nanoscale realization of a phonon laser utilizing phonon-assisted spin flips in quantum dots to amplify sound [Phys. Rev. Lett. 111, 186601 (2013)].

DOE National Laboratories

Integrated Modeling of Novel Materials

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor
Email: ttaylor@lanl.gov
Principal Investigator: Alexander Balatsky
Sr. Investigator(s): Jian-xin Zhu; Los Alamos National Laboratory
Matthias Graf; Los Alamos National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$541,195 (2014)

PROGRAM SCOPE

Complex electronic materials exhibit strong electronic correlations along with strong electronic coupling to multiple degrees of freedom, like lattice and spin. New data reveal substantial spatial inhomogeneity in superconductors, heavy fermion materials and at interfaces. This project follows two new directions: investigation of the role of interfacial interactions and competing states that emerge in films and properties of materials with Dirac spectrum of excitations. Theoretical understanding of the role of inhomogeneity, coupling to spin and lattice degrees of freedom and competition is a crucial missing step in our understanding of complex materials. The overarching goal of the project is to provide an

understanding of the fundamental physical processes that are important in determining the nanoscale inhomogeneity and coupling to other degrees of freedom in correlated electronic materials. Physical processes include: drivers and mechanisms of inhomogeneity, coupling to local lattice and spin degrees of freedom, transport and dynamics. Our goals are to discover new laws that govern the behavior of states of matter and to create the essential new understanding demanded by these discoveries. The hypothesis of our research approach is that correlations and competing interactions are manifested in both real and momentum space inhomogeneity, as seen in STM (scanning tunneling microscopy), NMR (nuclear magnetic resonance), and ARPES (angle resolved photo emission spectroscopy) data. Therefore, we are developing theoretical models and computational tools that focus on competing states due to momentum space anisotropies and spatial inhomogeneity. Our approach will allow for combined techniques that make contact with a momentum space characterization of inhomogeneous materials.

FY 2014 HIGHLIGHTS

1) We continue developing many-body methods combined with density functional theory to investigate the consequences for electron mass renormalization, electronic hot spots in the spectral function, and stability of superconductivity against competing states. 2) We are developing a parallel lattice BdG (Bogoliubov-de Gennes) code for studying the response functions in superconductors with spatial inhomogeneities and momentum space anisotropies in the bulk and at interfaces. An existing BdG code has been developed for multiband materials like the pnictide superconductors. We further develop algorithms for model calculations relevant to the pnictide and heavy-fermion superconductors and topological materials. 3) We developed understanding between the interplay of electronic correlations and electron-phonon coupling in correlated electron systems by solving the Anderson lattice model within the Gutzwiller approximation. 4) Inelastic Electron Tunneling Spectroscopy and negative U superconductivity in Dirac Materials. We have developed a formalism to investigate inelastic electron tunneling spectroscopy in topological insulators and in graphene. Inelastic scattering leads to the formation of negative U centers that can serve as nucleation centers for superconductivity on the surface of topological insulators and graphene.

EARLY CAREER: First Principles Predictions of Phase Stability in Complex Oxides

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Valentino Cooper
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$400,000 (2014)

PROGRAM SCOPE

The goal of this project is to use first principles methods to predict materials with enhanced properties that can be synthesized and remain active under device relevant conditions. This project aims to develop and implement robust, high-throughput computational approaches for exploring phase stability. The ultimate goal is to facilitate the prediction-to-synthesis process through a synergistic effort involving (i) electronic structure calculations for properties predictions, (ii) phenomenological/empirical models for examining phase stability and (iii) experimental validation. The abundance of possible cation chemical identities and arrangements makes complex oxides (such as perovskites) an ideal playground for first principles studies. This variability gives rise to an array of physical, chemical, electrical and

magnetic properties as well as possible competing structures. First year efforts have emphasized properties predictions; primarily in ferroelectric/piezoelectric oxides and oxide interfaces and surfaces.

FY 2014 HIGHLIGHTS

(1) Modelling disorder in perovskite solid solutions [Voas *et al.*, *Phy. Rev. B* 90, 024105 (2014)]: Disorder in relatively ordered $K_{0.5}Na_{0.5}NbO_3$ supercells (a promising lead free piezoelectric) was modeled employing the special quasirandom structure method. Using this method we showed that the transition between the high temperature Pm and low temperature R3c phases is driven by Na-O interactions. As such, this method could be useful for discovering new high-response piezoelectrics. (2) Transparent conducting oxides: A delta-doped approach [Cooper *et al.*, *Sci. Rep.* 4, 6021 (2014)]: In a joint theory and experimental study, a new class of transparent three-dimensional conducting oxides was discovered based on the control of spacer layer thickness in 2D conducting oxide heterostructures. This transparent conducting oxide has transparency and electron mobilities similar to that of the more expensive indium-tin-oxide (ITO) and thus may be a useful alternative transparent electrode. (3) Polar catastrophe at the $SrTiO_3$ (111) surface [Sivadas *et al.*, *Phy. Rev. B* 89, 075303 (2014)]: Using density functional theory, we investigated the surface electronic structure of $SrTiO_3$ (111) slabs. We find that it is possible to create a 2d electron gas at these surfaces. The observed thickness dependent carrier densities, emphasize the importance of understanding the competition between electronic reconstruction and polar distortions when analyzing the 2D electron gas (2DEG) behavior of (111) and (110) interfaces. (4) Antisite defects in a pristine cathode material [H. Dixit *et al.* *ACS Nano*, DOI:10.1021/nn505740v (2014)]: Using atomic-scale theory and experiment we identify Ni antisite defects as the predominant defects in pristine (uncycled) lithium-manganese-rich oxide cathode material. Furthermore, these defects have facet-dependent formation energies. These results suggest that by controlling electrode surface orientation defect behavior can be altered, thus having implications for improving battery performance.

Theoretical Studies of Collective Phenomena

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris
Email: morrisj@ornl.gov
Principal Investigator: Elbio Dagotto
Sr. Investigator(s): Randy Fishman; Oak Ridge National Laboratory
Satoshi Okamoto; Oak Ridge National Laboratory
Adriana Moreo; Oak Ridge National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,301,000 (2014)

PROGRAM SCOPE

This project studies the emergence of complex collective electronic states in several families of materials, and their possible competition, or cooperation, in special regimes of temperatures, carrier densities, and external fields. The specific materials that are being investigated by our team include pnictides and cuprates high critical temperature superconductors, ferrites, cobaltites, molecule-based magnets, multiferroics, and a variety of artificially-created superlattices and interfaces involving oxide perovskites. These compounds are characterized by having several simultaneously active spin, charge, and orbital degrees of freedom, forming complex states where the many competing tendencies are delicately balanced. Our overarching goal is to reach a sufficient degree of understanding and control of model Hamiltonians for broad classes of materials with competing tendencies such that quantitative

predictions can be achieved. Our most recent work have addressed three specific objectives: (1) study of new collective states that may appear in artificial heterostructures, with associated exotic transport properties; (2) study of competing interactions in frustrated magnets and associated multiferroic tendencies; (3) study of the Fe-based superconductors in the intermediate on-site Coulomb repulsion regime via spin-fermion models and search for novel states with spin and orbital order. All these challenging topics are at the frontier of research in Condensed Matter and Materials Science. Ours is a synergistic team that takes advantage of the ORNL research environment via several collaborations with other BES-supported experimental and theoretical teams, as well as with researchers at the local neutron and computational user facilities.

FY 2014 HIGHLIGHTS

We have used microscopic models to predict the orientation dependence of the critical magnetic field for BiFeO₃. The model we developed is now being employed to describe the directional dichroism of BiFeO₃, or the change in optical absorption when the direction of propagation of light or, equivalently, the direction of the magnetic field, is reversed. *Ab initio* calculations of BiFeO₃ have shown that the polarization induced by the magnetic order below T-N actually points opposite to the ferroelectric moment above T-N, in agreement with recent measurements. Dynamical mean field theory (DMFT) calculations were performed for Co oxides and artificial heterostructures of Au- and Ir-based oxides. These calculations revealed that Co oxides undergo a transition from a mixture of high-spin and low-spin states to a purely low-spin state by reducing the dimensionality from 3D to 2D. This accounts for experimental results of optical and x-ray spectroscopy. Based on tight-binding modeling and density functional theory calculations, this FWP predicted that artificial heterostructures of Au- and Ir-based oxides grown along the [111] crystallographic axis would become novel topological insulators (TIs). DMFT calculations taking into account strong correlation effects confirmed the TI state in the Au-based oxide heterostructure.

SciDAC: Optimizing Superconductor Transport Properties through Large-Scale Simulation

Alexei Koshelev; Argonne National Laboratory
George Crabtree; Argonne National Laboratory
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$514,000 (2014)

PROGRAM SCOPE

The SciDAC partnership 'Optimizing Superconductor Transport Properties through Large-Scale Simulation' (short: OSCon) was established in September 2012. The main objective of this project is to develop and apply novel methods for optimizing superconductors for energy applications using large-scale computational algorithms and tools. The resulting numerical tools will pave the way for a systematic method to design superconductors with high critical currents. So far the quest for optimal superconductors with respect to largest critical current was only conducted via the Edisonian process of laborious experimental trial and error. OSCon is a joint effort of the Materials Science Division (MSD) and the Mathematics and Computer Science Division (MCS) of Argonne National Laboratory. The overall

project is carried out in collaboration with SciDAC Institutes using large-scale computation and leveraging DOE's leadership-class computing facilities.

FY 2014 HIGHLIGHTS

List of FY 2014 Highlights : (1) Iterative GPU solver for the large λ -limit completed, supplemented with highly flexible and sophisticated pinning landscape generator: Details, performance tests, and examples are written up and submitted to the Journal of Computation Physics; Detailed study of the weighted Jacobi method to optimize the performance concluded. (2) First critical current optimization results: In collaboration with the SciDAC institutes FASTMath and SUPER PIs we conducted several case studies of pinning configuration with small number of optimization parameters showing very encouraging results; two papers on optimal random arrays and regular square arrays are being prepared at present. (3) Scalable unstructured mesh code stabilized and in the process of being deployed on leadership class computers (Mira) (4) Advanced vortex detection and tracking: In collaboration with the SciDAC Institute SDAV (PIs Tom Peterka and Carolyn Phillips) we developed advanced vortex detection and tracking algorithms, which help to analyze and understand the underlying dynamical processes in superconductors (two papers submitted). Postdoc Hanqi Guo was hired in FY 2014 to do data analysis and visualization. (5) Successful explanation of dynamics in superfluids: In collaboration with the group of Kathy Levin we studied defect dynamics in superfluids; ASCR highlight submitted (6) Several experimental verifications (papers submitted or in preparation): Understanding the effect of competing defects (columnar and nanorods). Simulations explain experimental results quantitatively; Reentrance of superconductivity in parallel fields explained; Direct simulation of exact nano-particle pinning landscape observed in experiments – simulation shows almost perfect agreement; Vortex crossing and tilted field dynamics in experiment explained through simulations; Simulations of BZO nanoparticles plus strain field defect simulated. (7) Received time allocation on the Mira/Tukey supercomputer.

Network for *Ab Initio* Many-Body Methods: Development, Education and Training

Sr. Investigator(s):	Miguel Morales; Lawrence Livermore National Laboratory Jeffrey Greeley; Purdue University Luke Shulenburger; Sandia National Laboratories-Albuquerque Nichols Romero; Argonne National Laboratory David Ceperley; Illinois-Urbana Champaign, University of
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$882,000 (2014)

PROGRAM SCOPE

For many classes of materials and molecular systems we lack predictive computational quantum mechanical methods, where the properties and performance can be reliably calculated to high accuracy without empirical tuning of parameters. This project focuses on the continuum quantum Monte Carlo (QMC) method, which offers a path towards these high accuracy calculations for a broad range of electronic systems and is potentially systematically convergeable to give exact results. Localization, van der Waals interactions, and strong electronic correlations can all be treated with high fidelity. These are areas where established electronic structure methods have great difficulty. The importance of a

predictive capability cannot be overstated: it is the very foundation of viable efforts in computational materials design. The proposed research brings developers of electronic structure methods together to build a QMC framework supporting continuing theoretical development, broader scientific application, and use in changing computing environments. The outcome of this collaboration – advanced software, efficient workflows, and data repositories – will increase productivity and fundamentally alter how QMC data are produced, acquired, processed, and used by the materials and chemistry community at large. The next-generation QMC methods and software will first be applied to catalysis, defects, high-pressure materials and establish benchmark materials problems. Our work will provide direct answers to fundamental materials science questions in these areas and establish benchmark levels of accuracy that will, in turn, provide insight and targets for future developments in other electronic structure approaches.

FY 2014 HIGHLIGHTS

In FY 2014 we published an Editors' choice article, Shulenburger & Mattsson Phys. Rev. B (2013), carefully benchmarking QMC calculations for solids. The test set of solids included ionic, metallic, covalent, and van der Waals bonded materials. This article is the first to comprehensively and systematically determine the accuracy of the standard QMC approach, via careful extrapolation and convergence testing of all quantities. These calculations only became possible due to advances in DOE computational platforms and large allocations, e.g. through the INCITE program. The insights into the method help guide the future activities of this project and guide others on the practical accuracy of the current approach. We continued to perform benchmark calculations including (i) a study of the performance of different density functionals for bulk water using QMC, (ii) a study of van der Waals interaction dominated systems, ranging from noble gas solids to DNA, and (iii) high pressure hydrogen. Overall in FY 2014 we published 8 articles including two Physical Review Editors' choice. David Ceperley gave an invited talk on the project at the American Physical Society March Meeting. As part of our goal of improving accessibility of Quantum Monte Carlo (QMC) methods, in FY 2014 we made several public releases of the open source QMCPACK code, and developed and a new QMCPACK website, <http://www.qmcpack.org> . The new releases include automation tools that significantly enhance productivity for new and expert users. We organized a training workshop, held 14-18 July at Argonne Leadership Computing Facility, with 33 trainees including 1 from industry. The workshop covered fundamental aspects of QMC through to practical calculations for molecular and solid-state systems. Every member of the project was onsite for the full week to assist with training, labs, and developing new QMCPACK users. The training sessions were recorded and are published at the video sharing website YouTube.

Electronic Properties of Transition Metal Compound Nanotubes

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Wei Ku
Sr. Investigator(s): Weiguo Yin; Brookhaven National Laboratory
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$296,000 (2014)

PROGRAM SCOPE

The goal of the program is to study nanoscale physics in transitional metal compounds and in the nanotubes. The program employs density functional theory and the Wannier function toolset developed in the program, supplemented by low-energy effective model suggested by these studies for a better illustration of underlying physics. Recently, we have been focusing on three main directions: 1) effects of glide translational symmetry in Fe-based superconductors, 2) signatures of topological quantum phase transition in insulators 3) propagation and decay of local excitations, and 4) systems with simultaneously strong spin-orbit coupling and electronic interactions (e.g. the irridates). In addition to the studies of physical effects in real materials, the program also includes an important effort of developing new theoretical/numerical method to address new territories of problems not possible with current technology. A good example is our recent development of an *ab initio* Wannier function method to incorporate disordered impurities in full, a task previously impossible to achieve without dropping the essential multiple scattering processes between impurities.

FY 2014 HIGHLIGHTS

1. Develop a new method to study propagation and decay of local excitations in materials, and predicted excitonic band structures later verified by X-ray experiment. 2. Investigate various spectroscopic signatures of quantum topological phase transition in insulators. 3. Investigate the effects in electronic structure and pairing symmetry of the glide translational symmetry. 4. Study pseudogap and degeneracy lifting with fluctuating ferro-orbital order in Fe-based superconductors.

Dynamical Mean Field Theory for Oxide Heterostructures

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Peter Littlewood
Sr. Investigator(s): Andrew Millis; Columbia University
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$299,000 (2014)

PROGRAM SCOPE

The use of advanced methods for strongly correlated materials has traditionally been confined to simplified models with few parameters, and without a systematic connection to the underlying electronic structure. This glue grant aims to exploit dynamical mean field theory in a realistic context, by developing techniques for rapid solution of the many body kernel, and by connecting *ab initio* electronic structure to simplified models in a realistic and transferable way. As a linked project (following on from seed funding), we have developed models for collective phenomena in multiferroic oxides, focusing on control of structure and thermodynamic properties.

FY 2014 HIGHLIGHTS

- We have successfully used machine learning methods to replace the auxiliary solver at the heart of Dynamical Mean Field Theory (DMFT), which is the most computationally intensive part. This will aid high throughput electronic structure calculations of correlated materials.
- We are porting DMFT codes onto Argonne's Leadership Computing Facility.
- We have used related methods to explore the potential

role of oxygen defects as the progenitors of magnetism in SrTiO₃ in combination with electrostatic doping. • We have generated a new model for the electrocaloric effect, explaining why it is in general small, and offering a path to develop materials where it is enhanced.

Theory of Materials Program

Dung-Hai Lee; Lawrence Berkeley National Laboratory
Jeffrey Neaton; Lawrence Berkeley National Laboratory
Lin-Wang Wang; Lawrence Berkeley National Laboratory
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$735,000 (2014)

PROGRAM SCOPE

The goal of this program is to understand and compute material properties and behaviors, covering a range of systems that include complex materials, surfaces and interfaces, nanostructures, superconductors, and strongly correlated electron systems. Novel materials and new concepts are explored. A variety of theoretical techniques is employed, ranging from first-principles electronic structure methods and many-body perturbation theory approaches to new conceptual and computational frameworks suitable for complex materials/nanostructures and strongly interacting systems. One emphasis is to investigate realistic systems employing microscopic first-principles approaches, including many-electron effects. Model systems are also examined. Close collaboration with experimentalists is maintained. Another emphasis is to push theory beyond the Landau paradigm toward a framework suitable for very strongly correlated systems. New phenomena, new phases, and new organization principles may be discovered. Equally important is the development of computational methods suitable for increasingly complex materials and strongly correlated materials.

FY 2014 HIGHLIGHTS

This program has made a number of advances in understanding reduced dimensional systems, topological phases, superconductivity, nanostructures, molecular interfaces, as well as in theory and method development. We obtained an explicit formula for optical oscillator strength of excitons in carbon nanotubes (CNTs) and developed a theory of multiple exciton ionization in shallow doped CNTs. For 2D systems, we predicted novel and diversity of excitons in monolayer transition metal dichalcogenides that were subsequently confirmed by experiment, provided first-principles calculations of satellite structures in the spectral function of 2D electron gas systems, analyzed the effects of charge doping and constrained magnetization on the electronic properties of monolayer FeSe, and predicted the effects of doping on excitons and quasiparticle lifetimes in graphene. We moreover discovered the novel phenomenon of electron supercollimation in graphene and other 2D Dirac fermion systems using 1D disorder potentials. We showed the microscopic coexistence of spin density wave and superconductivity in underdoped NaFe_{1-x}Co_xAs and developed a general approach to calculate shallow defect levels in semiconductors. We demonstrated critical theories of phase transition between symmetry protected topological states and gapped symmetric edges of such states. We predicted theoretically and subsequently demonstrated experimentally that the spin polarization of

photoelectrons from topological insulators may be tuned and controlled using the polarization of the incident light. We performed nonadiabatic molecular dynamics simulation for hole transport in organic molecule monolayer, explained the highest rectification ratios measured in molecular devices, and obtained a hybrid functional for polarization-induced gap renormalization in molecular solids.

Condensed Matter Theory

Alexei Koshelev; Argonne National Laboratory
Olle Heinonen; Argonne National Laboratory
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,520,000 (2014)

PROGRAM SCOPE

Condensed matter theory research programs are carried out in the areas of superconductivity, magnetism, and low dimensional systems, with an emphasis on interaction with other programs at Argonne. Our long term goal is to make fundamental advances in condensed matter physics as it relates to BES mission goals. In particular, we desire to make a major impact in a number of important endeavors, including the understanding of high temperature cuprate and pnictide superconductors, other transition metal compounds with novel properties such as quantum spin liquids and charge density waves, topological properties of metallic and nanostructured magnets, quantum phase transitions in strongly correlated electron systems, and transport in quantum wires, quantum dots, and spintronic devices. We are also developing as a center for theoretical analysis of spectroscopic and imaging data, not only within the context of MSD programs, but also those at the Advanced Photon Source and Argonne's Center for Nanoscale Materials, as well as other DOE national lab programs.

FY 2014 HIGHLIGHTS

- Showed that the magnon spectrum in magnetic thin films can be manipulated through periodic topographic modifications of the thin film.
- Demonstrated that the reversal mechanism in spin-torque random access memories becomes dominated by ferromagnetic exchange for sizes 50 nm and smaller.
- Demonstrated that superconductivity smears the Lifshitz topological transition as a consequence of particle-hole mixing.
- Investigated multiband superconductors in a magnetic field and demonstrated that fluctuations are enhanced at the magnetic field scale set by the band with the largest coherence length.
- Developed a systematic approach to calculate energies of periodic and quasiperiodic arrangements of interacting particles.
- Discovered exotic collective nematic Wigner crystal and supersolid phases of bosons in frustrated 2D lattices.
- Showed that the true low-energy excitations in one-dimensional quantum liquids have fermionic statistics, regardless of the statistics of the constituent particles.
- Developed a theory of equilibration of strongly interacting electrons in quantum wires and established the crucial role played by the coupling of spins of next-nearest neighbor electrons.
- Found that cuprates are on the border between uniaxial and biaxial charge order by a Ginzburg-Landau analysis with coefficients derived from photoemission data.
- Demonstrated that inelastic neutron scattering

data on the spin liquid material Herbersmithite are consistent with antiferromagnetic coupling between copper spins on neighboring Kagome planes.

Materials Project for Functional Electronic Materials Design

Institution: Lawrence Berkeley National Laboratory

Mark Asta; Lawrence Berkeley National Laboratory
Shyue Ping Ong; California-San Diego, University of
Jeff Snyder; California Institute of Technology
Students: 9 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The Materials Project aims to accelerate materials discovery and education through advanced scientific computing and innovative design methods, scale those computations to cover all known inorganic compounds, and disseminate that information and design tools to the larger materials community. Specifically the Project will achieve this by: • Providing unprecedented data and materials design tools as well as comprehensive capabilities for scientists to share their processes and results. • Leveraging high-throughput calculations, state-of-the-art electronic structure methods as well as novel data mining algorithms for surface, defect, electronic and finite temperature property predictions for tens of thousands of materials to yield an unparalleled materials design environment. • Demonstrating the derived data and infrastructure in the design of novel functional electronic materials: photovoltaics, thermoelectrics, transparent conductors and photocatalytic materials.

FY 2014 HIGHLIGHTS

The Materials Project (www.materialsproject.org) – part of the broader Materials Genome Initiative - is an effort to compute the properties of all known inorganic materials and beyond, and offer that data to the community together with online analysis and design algorithms. The current release contains data derived from density functional theory (DFT) calculations for over 54,000 materials, each with searchable associated properties such as relaxed structure, electronic state, energy storage capability, aqueous and solid stability, and more. Furthermore, software algorithms are offered by the Materials Project and can be used by researchers for materials informatics, including both interactive web-based tools like the Phase Diagram App and the Pourbaix App, as well as open-source codebases and data access tools such as the pymatgen materials analysis library, FireWorks workflow software, and Materials API (www.github.com/materialsproject). The MP Pourbaix App operates through an in-house developed reference scheme and constitutes – by orders of magnitude - the largest available resource for solid-aqueous phase stability, comprising > 70,000 Pourbaix diagrams. Showcasing the capabilities of

the Materials Project, the team has successfully explained why the CaCO_3 polymorph aragonite is formed rather than the stable calcite under modern seawater conditions – a fact that has tremendous implications for biomineralization, paleogeochemistry, and the vulnerability of marine life to ocean acidification. The suite of easily available online data, algorithms and open-source codes has attracted 8,500 registered users with – on average – > 40,000 page, > 6,800 sessions, and > 3,000 unique visitors per month. This combined data strongly indicates that the Project is being heavily used and is becoming a unique resource in the materials science community.

Extending the Reach of Computational-Theoretical Methods to Materials at the Energy Frontier

Institution: Oak Ridge National Laboratory
Point of Contact: James Morris

Principal Investigator: Fernando Reboredo
Sr. Investigator(s): G. Malcolm Stocks; Oak Ridge National Laboratory
Markus Eisenbach; Oak Ridge National Laboratory
Jaron Krogel; Oak Ridge National Laboratory
Sokrates Pantelides; Vanderbilt University
Students: 4 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,327,000 (2014)

PROGRAM SCOPE

This program is designed to overcome materials theory challenges that are both at the frontier of basic research and beyond current theoretical and computational capabilities. Our overarching goal is to significantly improve our description and understanding of electronic correlations and magnetic interactions in an *ab initio* framework. A new effort is under way, focused in highly correlated materials and magnetic oxides. The first QMC results of defects in correlated oxides are currently under peer review. Our goal is to describe the physical, chemical, and electronic properties of magnetic and highly correlated materials with accuracy comparable to experimental characterization and in large, physically-relevant systems. This program includes both accurate *ab initio* approaches and methods development based on simpler systems or models. Models will allow us to test and develop new approaches which can be next extended to real materials. A priority is to develop, improve, and implement new theories that go well beyond the current approaches to exploit high-performance computers (HPC). We thus focus on stochastic methods such as quantum Monte Carlo (QMC) or the Wang and Landau (WL) free-energy method because of both accuracy and scalability in HPC. Many relevant properties of semiconductors, polymers, correlated, oxides, and magnets are currently beyond the accuracy obtainable with the state-of-the-art approaches based on Density Functional Theory (DFT). Accordingly, we aim to provide an alternative route using the highly accurate QMC and/or improve DFT approximations (e.g. for finite temperature) with WL. In the short term, the results provided by our research will quantify the errors of the state of the art approximations of DFT that are widely used. In addition, we aim to provide an alternative stochastic-based approach to reach the required accuracy for energy applications.

FY 2014 HIGHLIGHTS

We have generated a set of pseudopotentials for light transition metal elements Sc to Zn to be used in QMC calculations for transition-metal oxides. We found that QMC calculations require including semi-core electrons in the valence. Our pseudopotentials are moderately hard, requiring a planewave cutoff

energy of about 500 Ry and a small nonlocal cutoff radius. However, the pseudopotentials can be softened to around 300 Ry using an optimized approach without greatly impacting the overall level of accuracy. A lower energy cutoff results in significant memory savings, which in turn permits the study of larger systems with more electrons such as bulk transition metal oxides and even point defect systems with modest supercells. These pseudopotentials have allowed the calculation of magnetic coupling constants in cuprates and defect formation energies in ZnO. Calculations of other binary and ternary oxides are in progress. We derived a general scheme to calculate the magnetic exchange interaction, local anisotropy and anisotropic exchange due to spin-orbit coupling in metal and alloys. We have expanded our statistical description of magnetic systems (WL-LSMS) to include longitudinal fluctuations of the magnetic moments going beyond a rigid spin Heisenberg model (e.g. Ni). We have investigated the convergence behavior of the parallel replica exchange and implemented this algorithm on massively parallel architectures. We have developed an *ab initio* based “Enthalpy Matrix” that correctly identifies all known single-phase high-entropy alloys (HEAs) while rejecting similar elemental combinations that do not form a HEA. We have made predictions of new 5-, 6-, and 7- elemental HEAs. The absolute convergence of Full-Potential Multiple Scattering Theory electronic structure methods in terms of the underlying angular momentum expansion parameters has been demonstrated and implemented in the linear scaling LSMS method for treating large cell models complex materials.

Discontinuous Methods for Massively Parallel QMD: Li-ion Interface Dynamics from First Principles

Institution: Lawrence Livermore National Laboratory
Point of Contact: John Pask
Email: pask1@llnl.gov
Principal Investigator: John Pask
Sr. Investigator(s): Vincenzo Lordi; Lawrence Livermore National Laboratory
Erik Draeger; Lawrence Livermore National Laboratory
Chao Yang; Lawrence Berkeley National Laboratory
Lin Lin; California-Berkeley, University of
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$361,000 (2014)

Jointly funded by the Chemical Sciences, Geosciences, & Biosciences Division and Materials Sciences and Engineering Division

PROGRAM SCOPE

We develop and employ for the first time new Discontinuous Galerkin (DG) and Pole Expansion/Selected Inversion (PEXSI) electronic structure methods to accomplish quantum molecular dynamics (QMD) on an unprecedented scale; and apply the new methodologies to address fundamental questions in energy storage: the formation and evolution of the solid-electrolyte interphase (SEI) layer in Lithium-ion cells. We employ state-of-the-art massively parallel planewave codes in the initial phase of the work while the new DG and PEXSI methodologies are developed and verified. We then apply the new methodologies to much larger systems, up to 10,000 atoms, in order to reach for the first time sufficient system complexity to effectively model complete liquid-on-anode configurations. The remarkable properties of the new methodology are made possible by releasing the constraint of continuity through the DG formulation of the Kohn-Sham equations. By virtue of these properties, our initial parallel

implementation has accomplished *ab initio* calculations with over 4,000 atoms with planewave accuracy. Initial DG QMD simulations show excellent energy conservation, with energy drift < 2 meV/atom/ps. To reach the largest system sizes, we develop and employ the new PEXSI methodology, eliminating the need for diagonalization while retaining strict systematic improvability and applicability to both metals and insulators. In partnership with the SciDAC FASTMath Institute, we have completed MPI parallelization of the PEXSI code, testing on a wide range of systems, documentation, and release (<http://www.pexsi.org>). The resulting code can scale to over 100,000 processors and has now been applied to systems containing over 45,000 atoms. Current work focuses on the combination of DG and PEXSI methodologies to reach the length and time scales necessary to model mixed-phase anode-electrolyte configurations to begin to understand for the first time the chemistry and dynamics at this critical interface.

FY 2014 HIGHLIGHTS

We accomplished all FY14 project milestones and commenced work on FY15 milestones. Four journal articles were published and five more submitted. We carried out an extensive series of QMD simulations of ethylene carbonate (EC), ethyl methyl carbonate (EMC), and EC/EMC mixture solvents with LiPF₆ salt, as widely used in practice. We found that Li prefers tetrahedral coordination in all electrolytes considered, consistent with experiment for EC, and providing a prediction for EMC and EC/EMC mixture. Most significantly, we found a key correlation of solvation and mobility in all electrolytes considered: the stronger the solvation, the less the mobility. This finding has the potential to significantly impact the engineering and improvement of Li-ion battery electrolytes going forward, and with that, battery systems as a whole. Regarding the new Discontinuous Galerkin (DG) computational methodology being developed to reach the needed length and time scales to model full anode-electrolyte systems, we made a number of advances. We implemented independent grids for density and wavefunctions, yielding accurate forces for all atomic species, soft and hard, metals and nonmetals alike. We implemented molecular dynamics, obtaining excellent energy conservation. We implemented MPI parallelization of local Kohn-Sham solves to form DG basis in each element, yielding a 70-fold speedup. Regarding the new Pole Expansion and Selected Inversion (PEXSI) methodology being developed to eliminate the need for diagonalization altogether, we parallelized, tested, documented, and released a full production code (<http://www.pexsi.org>). The new MPI code scales to over 100,000 CPUs. The new PEXSI code has been incorporated into the widely used SIESTA electronic structure code, yielding a factor of 18 speedup. Finally, we implemented the new PEXSI methodology with the DG basis to reach the largest length and time scales needed to model full anode-electrolyte configurations.

High-Performance First-Principles Molecular Dynamics for Predictive Theory and Modeling

Institution:	Lawrence Livermore National Laboratory
Point of Contact:	Eric Schwegler
Email:	schwegler@llnl.gov
Principal Investigator:	Eric Schwegler
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$165,000 (2014)

PROGRAM SCOPE

First-principles molecular dynamics (FPMD) simulations are used in a wide range of applications in chemistry, materials science and nanotechnology, and provide an accurate, atomic-scale model of matter based on a quantum mechanical description. We are working to develop a high-performance software infrastructure that combines large-scale FPMD simulations with on-the-fly computation of vibrational spectra and electronic excitations. The software includes a toolkit that enables the exploration of new statistical sampling methods. This research provides a powerful predictive simulation tool that enables the direct comparison of simulated data with experimental data such as infrared and Raman spectra, X-ray and neutron diffraction spectra as well as vibrational and optical properties measured at finite temperature or during chemical processes that involve breaking and formation of bonds. The software infrastructure is readily available to the general research community in an open-source format and will accelerate the process of discovery and optimization of new materials properties.

FY 2014 HIGHLIGHTS

Theoretical analysis of phase transition mechanisms using standard atomistic simulation methods is not feasible because such transitions involve rare barrier-crossing events with mean first passage time many orders of magnitude greater than the vibrational frequency of atoms. To overcome this time-scale issue we have implemented a free energy surface exploration tool in QBox. The method involves selecting a set of suitable collective variables (CVs), that can distinguish the different phases in super cooled water, and the information required to evolve these CVs is extracted by evolving the underlying atomic system. The method involves an adiabatic time-scale separation between the electrons and the ions and also between the atomic vibrational motion and the evolution of the CVs. The replica-exchange molecular dynamics (REMD) approach has been successfully implemented within the Qbox client-server model. REMD allows exploration of the whole configuration space by running multiple trajectories at different temperatures to accelerate the sampling. The resulting trajectories contain a wealth of information that can be fed to dimension reduction techniques like diffusion maps, principle component analysis, etc. to identify the dimensions of the slow manifold involved in a phase transition. Our initial analysis of the liquid-liquid transition in water, using PBE exchange correlation functional, suggests that we need at least three order parameters to understand microscopic mechanisms associated with the proposed liquid-liquid transition in super cooled water.

Materials Theory

Funding: \$1,322,000 (2014)

PROGRAM SCOPE

This project uses state-of-the-art materials specific theoretical tools to develop understanding of materials. Working in conjunction with ORNL and external experimental efforts, we unravel the chemical and structural underpinnings of collective properties in specific materials, develop understanding of novel phenomena and materials, and devise new compounds with useful properties. The essential aspect is the use of methods that directly incorporate the chemical make-up and detailed structure of materials and so enable direct connections with experiments. Impacts of this work include microscopic understanding of materials properties with emphasis on functional materials. Our effort includes materials with exceptional (low or high) thermal conductivity, correlated magnetic materials, transparent conductors, intercalation compounds for energy storage, superconductors, and materials with unusual characteristics, such as uncommon bonding patterns. Questions that we will address are: How do interesting and useful properties arise? How can we modify materials to achieve and control properties and function? What are the chemical and structural motifs that lead to interesting and useful properties? In what materials should we expect the unexpected (i.e. where are there intense competitions between ground states that may lead to novel behavior)? The overarching goal behind this is materials discovery.

FY 2014 HIGHLIGHTS

- Predicted two new chalcogenide semiconductors, one of which is a candidate p-type transparent conductor. These were subsequently synthesized experimentally at ORNL and shown to have the predicted properties. This provides a rare example of a new bulk functional material predicted theoretically and subsequently confirmed experimentally.
- Showed that the Fe-based compound YFe_2Ge_2 is near a magnetic quantum critical point with features closely related to the Fe-pnictide superconductors, although it does not contain pnictogens or chalcogens.
- We found an extremely inhomogeneous, fractal like electronic structure and lattice distortion in metallic IrTe_2 arising from frustration of Te p-electron bonding.
- Discovered that the transparent conducting oxide BaSnO_3 has exceptional tunability in its optical properties via volumetric strain and that interfacial two dimensional electron gasses based on stannate and transition metal perovskites interfaces may be achievable.
- Identified two new silicide magnetic semiconductors.
- Found that Ta_2PdS_5 and $\text{Ta}_4\text{Pd}_3\text{Te}_{16}$ are multiband superconductors explaining the very high upper critical field and other anomalous properties.
- Refined density functionals for van der Waals interacting materials and identified strategies for further improving this class of functional.
- Calculated the thickness depend surface carrier concentration on 111 terminated SrTiO_3 .

Condensed Matter Theory

Sr. Investigator(s): Robert Konik; Brookhaven National Laboratory
Wei Ku; Brookhaven National Laboratory
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,406,000 (2014)

PROGRAM SCOPE

The goal of the program is to study systems with strong correlations and systems out of equilibrium. Such studies provide us not just with important new insights into fundamentals of condensed matter physics, but also have practical importance for discovery and development of new materials. Strong correlations emerge either as a result of strong lattice interactions or, in low dimensional systems, due to strong quantum fluctuations. Examples of such systems include Mott insulators, quantum magnets, systems close to quantum criticality, heavy fermion materials and many others. Strong correlations playing especially prominent role in out-of-equilibrium make the traditional computational methods ineffective. Our group has developed new ones based on a combination of methods of integrable field theory and numerical methods.

FY 2014 HIGHLIGHTS

(1) In collaboration with Prof. A. Chubukov (Wisconsin) we developed a theoretical description of the phase transition in the cuprates separating the pseudo gap region from the rest of the phase diagram [Phys. Rev. B 89, 184515 (2014)]. (2) In collaboration with Prof. M. Aronson's group at BNL we studied Quantum Critical Point in the non-Fermi liquid metal YFe_2Al_{10} [Proc. Nat. Academy of Sciences. pnas.1413112111.]

PROGRAM SCOPE

Materials Theory Institute (MTI) aims to attract world-leading theorists for visits of one week to six months to broaden the base and the scope of and bring new cutting-edge theory to the Materials Science Division (MSD). MTI selects topics and visitors in two categories: promising new opportunities arising from MSD research, and new directions in condensed matter and materials science arising from the broader community. MTI implements its goal through an intensive visiting programs, which bring top experts, both, distinguished scientists and outstanding young talents, to work on high impact problems and emerging topics and themes in materials theory and to bring new revolutionary science to MSD. The topics to be pursued and the respective visitors are selected by an internal Scientific Advisory Committee from competitive proposals solicited from all MSD staff and also from the outside researchers. MTI also identifies top early career and established theorists as candidates for recruitment to postdoctoral and permanent positions at Argonne. MTI holds topical workshops on the most urgent subjects related to existing MSD projects, which promise to stimulate new research directions at MSD.

FY 2014 HIGHLIGHTS

[1] We have studied the dynamical permittivity in ferroelectric film a few nanometer-thin carrying 180-degree periodic domain structure, sandwiched between two para-electric layers. The resulting

frequency-dependent permittivity demonstrates the sharp collective resonance mode at $\omega \sim 0.3 - 2$ THz. [2] Boltzmann's H-theorem stating that entropy of a physical system would tend to increase over time remains a foundation of thermodynamics. Original Boltzmann's formulation given for classical gases was resting on the molecular chaos hypothesis. Von Neumann's quantum H-theorem claimed quantum origin of irreversibility but included as a part of the proof macroscopic measurement procedure going thus beyond the strictly quantum consideration. Recent developments related entropy growth to quantum entanglement hinting the solely quantum origin of macroscopic irreversibility. In particular, progress in quantum informatics brought in several rigorous results on the conditions for the non-negative entropy gain. However, many questions of how to adapt them to the realm of physics remain. Utilizing the mathematical formalism, we show that entanglement of electrons with either electromagnetic environment or phonon bath results in the evolution of the electron density matrix that belong in the classes of evolution described in quantum informatics. Using exemplary physical systems we formulate and prove the H-theorem for a wide class of physical phenomena. [3] We studied the free-energy landscape of a minimal model for relaxor ferroelectrics. Using a variational method, which includes leading correlations beyond the mean-field approximation as well as disorder averaging at the level of a simple replica theory, we found metastable paraelectric states with a stability region that extends to zero temperature. The free energy of such states exhibits an essential singularity for weak compositional disorder pointing to their necessary occurrence.

Quantum Mesoscopic Materials and Structures

Institution: Argonne National Laboratory
Point of Contact: Michael Norman
Email: norman@anl.gov
Principal Investigator: Valerii Vinokur
Sr. Investigator(s): Andreas Glatz; Argonne National Laboratory
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$741,000 (2014)

PROGRAM SCOPE

The goal of the Quantum Mesoscopic Materials Program is to explore the phenomena of quantum coherence and entanglement in order to develop predictive models and theories for the design of new materials with desirable properties and controllable behavior on the electron, atomic, and mesoscopic levels. Our strategy is based on creation of nanoscale metamaterials, such as granular structures, Josephson and hybrid arrays, and nanopatterned structures. At the initial stage we will focus on the exemplary superconductor-insulator transition that represents a unique coherent quantum phase transition. Building on the developed understanding of a superconductor-insulator transition as a manifestly quantum transition between the two quantum coherent superconducting and superinsulating states, we will perform an intensive theoretical analysis of quantum coherent effects in the vicinity of the superconductor-insulator transition (SIT), the role of the entanglement and related phenomena in formation irreversibility and glassiness in the finite quantum systems with the localized degrees of freedom. We define our strategic priorities as: 1. Comprehensive formulation of a theory of the superconductor-to-superinsulator transition emphasizing its quantum coherent nature, the role of Coulomb effects and quantum fluctuations. 2. Entanglement effects and their role in formation irreversibility and other macroscopic properties in inherently quantum systems. 3. Fluctuation effects both in the proximity of the superconductor-insulator transition and far from the transition both deep in the insulating and the superconducting states. 4. Quantum coherent transport utilizing the duality between the Aharonov-Bohm and Aharonov-Casher effects in disordered films, quantum wires and hybrid structures. 5. Fluctuation effects in conventional (type I and type II) and critical superconductors.

FY 2014 HIGHLIGHTS

(1) We investigated realization of the so-called Bogomolny critical regime, which was originally found in Abelian Higgs models at the border of type I-type II superconductivity in the finite weakly type II superconducting samples. The Bogomolny point at $\kappa_c=1/\sqrt{2}$ is characterized by infinite degeneracy of the superconducting state with respect to vortex spatial configurations. Finite-size system stabilizes normal domains and promotes their transient dynamics in the critical regime. We report that in mesoscale samples with dimensions commensurate with ξ , a vortex droplet, comprising a single normal domain, undergoes the Rayleigh instability at $\kappa \leq \kappa_c$ and decays by emitting a sequence of single vortices. We showed that at $\kappa \leq \kappa_c$ the repulsion mediated by the vortex stray fields prevails over the vortex core attraction and causes the fission of vortex droplets. We thus reveal Abrikosov-Nielsen-Olesen vortices of Abelian-Higgs models dynamics in finite systems with boundaries, which promises access to novel effects in quantum field theory via a bench-top laboratory experiment. (2) Understanding the resulting complexity of glassy behaviors is key to gaining insight into a variety of systems in nature, including spins and magnetic moments in magnetism, electrons in metals, Cooper pairs in disordered superconductors, vortices and interfaces in superconductors and magnets, social and neural networks, and protein folding, and remains one of the major challenges in physics. We developed an analytical approach based on the method of functional equations that allows us to construct Rayleigh approximation to the ground state of a two-dimensional (2D) random Coulomb system with logarithmic interactions. (3) We found a giant inverse proximity effect that arises in small low-dimensional superconductor-normal-superconductor (S/N/S) junctions, where the proximity coherence length is larger than the coherence length of a source superconductor.

Accelerated Molecular Dynamics Methods

Institution: Los Alamos National Laboratory
Point of Contact: Toni Taylor
Email: ttaylor@lanl.gov
Principal Investigator: Arthur Voter
Sr. Investigator(s): Danny Perez; Los Alamos National Laboratory
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$446,000 (2014)

PROGRAM SCOPE

Molecular dynamics (MD) simulation, a powerful tool for probing systems in full atomistic detail, is limited to a few microseconds or less, while many activated processes in materials take place on much longer time scales. Moreover, most real systems have a complexity that makes it difficult or impossible to accurately predict their dynamical evolution using intuition or simple models. Accelerated molecular dynamics methods, developed over the last 17 years at Los Alamos, offer a way out of this dilemma. Built on solid statistical mechanical concepts, these methods follow the long-time evolution of activated processes in full, accurate detail. Simulations so far on processes such as surface diffusion and growth, bulk diffusion, radiation damage annealing, and grain-boundary sliding and nanoscale kinetics provide insights that would have been virtually impossible to obtain by any other technique. We can reach time scales of ms, s, and beyond, and we invariably observe complex, unanticipated behavior, even in situations where the dynamics were expected to be simple. We are applying the methods to assist other DOE programs at LANL, and developing the methods further to overcome key obstacles, with the goal of making them applicable to the widest possible range of problems. In particular we are developing new

algorithms for treating more complex systems and making use of massive parallelism. We are also developing user-friendly software and collaborating on applications with experts from around the world. Feedback from the collaborations in turn shows us where further development is most needed.

FY 2014 HIGHLIGHTS

- Developed a method for computing exact rate constants that is efficient enough to use with density functional theory.
- Explained mechanism for crossover to anisotropic surface-directed growth of near-surface He bubbles in plasma-irradiated tungsten as growth rate is decreased to experimental rates.
- Developed a new way to achieve unprecedented efficiency from the parareal algorithm, which parallelizes time without requiring infrequent events.
- Developed a method for performing accelerated quantum dynamics, as appropriate for, e.g., hydrogen at or below room temperature.
- Provided a formal analysis of the accuracy of kinetics in coarse-grained molecular dynamics models for solids.

Exploratory Development of Theoretical Methods

Institution: Ames Laboratory
Point of Contact: Duane Johnson
Email: ddj@ameslab.gov
Principal Investigator: Cai-Zhuang Wang
Sr. Investigator(s): Vladimir Antropov; Ames Laboratory
Viatches Dobrovitski; Ames Laboratory
Bruce Harmon; Ames Laboratory
Kai-Ming Ho; Ames Laboratory
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$639,000 (2014)

PROGRAM SCOPE

The purpose of this FWP is to generate new theories, models, and algorithms that will be beneficial to the research programs at the Ames Laboratory and to the mission of DOE. This FWP will lead the development of theoretical tools to study a broad range of problems in physics, materials science, and chemical as well as biological systems. The generality of these tools allows the cross-fertilization of ideas from one problem to problems in an entirely different area through the common link of the mathematical formulation. Such leaps across topic areas and in some cases across disciplines are characteristic of the power of a fundamental physics-based approach to the development of new theoretical methods, facilitated by the availability of general theoretical tools applicable to very different sets of problems. Current efforts of this FWP includes (1) methods for accurate calculation of correlated electron systems; (2) methods for spin dynamics and quantum control of spin; and (3) methods for computational prediction and design of complex structures and materials.

FY 2014 HIGHLIGHTS

During FY 2014 we developed a LDA+Gutzwiller (LDA+G) method and computational code for studying correlated electron systems. The LDA+Gutzwiller method has been found to have accuracy similar to LDA+DMFT, yet performs thousands of times faster! The LDA+Gutzwiller method has been applied successfully to study the electronic structure of pnictide superconductors, iso-structural transformations in Ce, and energetics and electronic structure of Pu. The team developed a new first-principles density

functional theory based Gutzwiller wave function for correlated electron systems. A correlation matrix renormalization (CMR) method was also developed to treat two-particle interactions beyond the original Gutzwiller approximation. We developed theories for itinerant magnetism including strong spin fluctuation effects. Spin fluctuation effects in iron superconductors, 3d-metals Fe and Ni, and 5f-metal Pu, were investigated. We also developed novel theoretical techniques for investigating and controlling the quantum spin dynamics of the coupled individual electronic and nuclear spins in diamond, interacting with their solid-state environment and applied these tools to nanoscale sensing. Lastly, the team detailed an adaptive genetic algorithm method for crystal structure prediction. The method enables computational prediction of complex binary and ternary crystal structures as well as interface structures with unit cells as large as 50-200 atoms.

Resonant Soft X-Ray Scattering Studies of Spontaneous and Engineered Electronic Order in Transition Metal Oxides

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Peter Abbamonte
Email: abbamont@illinois.edu
Principal Investigator: Peter Abbamonte
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 1 Undergraduate(s)
Funding: \$252,796 (2012-2015)

PROGRAM SCOPE

The purpose of this project is to understand the interplay between engineered nanoscale order, created artificially by nanofabrication techniques, and the innate electronic instabilities in transition metal oxides. The term “instability” here refers to spontaneous electronic order such as stripe phases, charge or spin density waves, orbital order, or intrinsic electronic inhomogeneity due to proximity to a quantum critical point. The long-term goal is to understand how these two types of nanoscale order cooperate to create new phenomena, with hopes of contributing eventually to a revolution in strongly correlated electronic devices. This project is integrally tied to the development of new scattering techniques for the study of important phenomena in condensed matter. Progress with this project depends on access to materials that have been artificially structured with nanofabrication techniques. For this purpose, we have developed electron beam lithography techniques, using facilities in the Frederick Seitz Materials Research Laboratory, for fabricating very large arrays of transition metal oxide quantum wires. In addition, we have ongoing collaborations with several groups at Illinois and Argonne who specialize in single crystal and thin film growth of strongly correlated materials.

FY 2014 HIGHLIGHTS

(1) Discovery of charge density wave domain walls associated with pressure-induced superconductivity in TiSe_2 : As alluded to above, unconventional superconductivity is nearly always found in the vicinity of another ordered state, such as antiferromagnetism, charge density wave (CDW), or stripe order. This suggests a fundamental connection between superconductivity and fluctuations in some other order parameter. To gain a deeper insight into this phenomenon, we used high-pressure x-ray scattering to study the CDW order in the layered dichalcogenide TiSe_2 , which was previously shown to exhibit superconductivity when the CDW is suppressed by pressure or intercalation of Cu atoms. We succeeded in suppressing the CDW fully to zero temperature, establishing for the first time the existence of a quantum critical point (QCP) at $P_c = 5.1 \pm 0.2$ GPa, which is more than 1 GPa beyond the end of the superconducting region. Unexpectedly, at $P = 3$ GPa we observed a reentrant, weakly first order, incommensurate phase, indicating the presence of a Lifshitz tricritical point somewhere above the superconducting dome. Our study suggests that superconductivity in TiSe_2 may not be connected to the QCP itself, but to the formation of CDW domain walls. This study was published in *Nature Physics*. (2) Improved measurements of the effective fine structure constant of graphene: A few years ago we published a paper claiming that graphene is not a strongly correlated electron system [J. P. Reed, *et al.*,

Science 330, 805 (2010)]. While many theorists were arguing that Coulomb interactions were nonperturbative in graphene, we argued that in most regions of phase space Coulomb interactions are screened out. We quantified this statement by characterizing the strength of interactions in terms of an effective fine structure constant, which we found to have the rather small value of 0.14. This result was met with enough skepticism that we repeated the study with ten times higher energy resolution.

Multifunctional Materials Research Using Ultrafast Optical Spectroscopy

Institution: Boston University
Point of Contact: Richard Averitt
Email: raveritt@ucsd.edu
Principal Investigator: Richard Averitt
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$194,000 (2014)

PROGRAM SCOPE

The properties of complex transition metal oxides (TMOs) arise from subtle interplay between competing degrees of freedom. The results are dramatic and include superconductivity, novel magnetic ordering, and metal insulator transitions. Advances in the synthesis, growth, and characterization of complex TMOs coupled with new experimental techniques in ultrafast optical spectroscopy have ushered in an exciting era of dynamics and control in these materials. Our experiments utilize femtosecond optical pulses to initiate and probe dynamics of the spin, lattice, orbital, and charge degrees of freedom. Major goals include determining how interaction and competition between the relevant degrees of freedom determine macroscopic functionality in TMOs and searching for hidden phases in TMOs by controlling dynamic trajectories in a complex and pliable energy landscape. We are currently investigating strained manganites ($\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$), nickelates (NdNiO_3 and EuNiO_3), and vanadates (V_2O_3 and VO_2). These materials exhibit insulator-to-metal transitions and our work is focused on interrogating and controlling the dynamic pathways of such transitions using ultrashort optical and far-infrared pulses. This work directly impacts BES grand scientific challenges including enhancing our understanding of matter far from equilibrium and the emergence of collective phenomena in condensed matter.

FY 2014 HIGHLIGHTS

During FY 2014, we have observed interesting phenomena in several complex transition metal oxides that exhibit insulator-to-metal transitions. In strained $\text{La}_{0.7}\text{Ca}_{0.3}\text{MnO}_3$, we have discovered a photo-induced metastable transition from a charge ordered insulating state to a ferromagnetic state. In V_2O_3 , the conductivity dynamics of the insulator-to-metal transition exhibit scaling and can be described in terms of nucleation and growth of the metallic volume fraction. This growth occurs ballistically at the speed of sound. Finally, in NdNiO_3 , it appears that the photoinduced insulator-to-metal transition results in conductivity dynamics that closely follows magnetic disordering of the Ni ion sublattice.

Ultrafast Infrared Nano-Spectroscopy and Nano-Imaging of Unconventional Superconductivity in Cuprate and Pnictide High- T_c Systems

Institution: California-San Diego, University of
Point of Contact: Dmitri Basov
Email: dbasov@physics.ucsd.edu

Principal Investigator: Dmitri Basov
Sr. Investigator(s): Richard Averitt; California-San Diego, University of
Michael Fogler; California-San Diego, University of
James Hone; Columbia University
Andrew Millis; Columbia University
Students: 3 Postdoctoral Fellow(s), 2 Graduate(s), 2 Undergraduate(s)
Funding: \$400,000 (2014)

PROGRAM SCOPE

High- T_c superconductivity is surpassed by few, if any, other unresolved problems in contemporary physics in its richness, complexity, impact on other fields and potential technological importance. A specific common aspect of Fe-based and Cu-based high- T_c superconductors is a propensity towards electronic and magnetic self-organization, leading to dynamic inhomogeneities at nano-to-mesoscopic length scales. The inhomogeneities have so far been documented with quasi-static probes and scanning tunneling microscopies. In contrast, ultrafast infrared/optical studies enable characterization of dynamics and fluctuations in superconductors. However, such experiments have been carried out using diffraction-limited optics and therefore probe length scales that inform us of a “mixed” response involving contributions from the multiple electronic, chemical and structural phases occurring in real materials along with nanoscale heterogeneities. As a result, the interpretation of area averaged ultrafast optics data has been complicated and often ambiguous. We propose an effort to investigate the intrinsic spatio-temporal response of pnictides and cuprates. The goal of the proposed work is to carry out pump-probe infrared (IR) spectroscopy and imaging studies with 10-nm spatial resolution and temporal resolution of tens of femtoseconds. This will be enabled through a unique THz-IR nano-spectroscopy/imaging set-up developed by Basov. Nano-scale IR measurements will be augmented with ultrafast studies of superconductivity using THz pump – THz probe experiments carried out at the group of Averitt. THz/IR nano-imaging of surface plasmons will be performed using ultrathin samples of cleavable cuprate and pnictide superconductors capped with a protective layer of boron nitride prepared in the group of Hone. Theoretical and computational studies of ultrafast electrodynamics in cuprate and pnictide materials will be carried by Millis and Fogler.

FY 2014 HIGHLIGHTS

Since the inception of the program in August 2014, our team has made significant progress with the design and numerical modeling of meta-material antennas intended to enhance photo-induced effects in cuprate high T_c superconductors. These structures are currently being fabricated at Columbia. In parallel, we dedicated significant effort to improving the signal-to-noise ratio of our pump-probe nano-infrared experiments. Novel approaches to data acquisition have allowed us to increase the signal-to-noise up to 1000-5000 nearly matching usual benchmark numbers of conventional diffraction limited measurements.

X-Ray Studies of Highly Correlated Systems

Institution: Western Michigan University
Point of Contact: Clement Burns
Email: clement.burns@wmich.edu
Principal Investigator: Clement Burns
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$100,000 (2014)

PROGRAM SCOPE

Our work involves studies of strongly correlated systems using synchrotron x-ray sources. Much of the work involves using inelastic x-ray scattering (IXS) and Resonant Inelastic X-ray Scattering (RIXS) to study electronic and vibrational excitations. A goal of our current work is to measure polarization of the scattered x-ray during RIXS. Scattering can change the energy, wavevector, and polarization of the x-ray. Currently, only the first two are measured. This is unfortunate, since polarization carries valuable information about the states involved in the scattering, including symmetry information. Specifically, we wish to develop polarization analysis for materials with strong spin-orbit coupling such as the iridates. We have previously developed a curved graphite polarization analyzer for measurements at the copper K-edge, but polarization effects are likely to be more interesting at the L- and M- edges.

FY 2014 HIGHLIGHTS

We have been creating and characterizing bent single crystal Si polarization analyzers for resonant inelastic x-ray scattering at the iridium L3-edge. Recently, we have been bending very thin Si single crystal wafers to limit the strain. The Si is bent in a double toroidal shape which is a good approximation to the logarithmic spiral which is the exact shape required to have the curved surface meet the Bragg condition. The advantage of using a good crystal is that it keeps the good energy resolution of the main analyzer. So far, we have been able to achieve resolutions of about 140 meV but only with an efficiency of about 0.5%. We have also carried out measurements and simulations to study the polarization of the incident x-ray synchrotron beam above the plane of the electron beam. We find good agreement with standard models of synchrotron radiation. Characterizing the beam polarization is necessary in order to know the ratio of the initial polarization components, and may also be useful for aligning the polarization analyzer in the polarization flipped channel. We have also carried out studies of the magnetic excitations in BaIrO₃. BaIrO₃ is an interesting 5-d transition metal system. It contains Ir atoms in both quasi 1-d zigzag chains and 2-d planes. It has a combined ferromagnetic and charge density wave (CDW) transition at 180 K, and the system displays unusual non-linear voltage characteristics that may or may not be related to the CDW. We have begun a study of the magnetic excitations in this material throughout the Brillouin zone as a function of temperature.

Electrons, Spins, and Lattice Structures of Surface-Based Nanoscale Systems

Institution: Illinois-Urbana Champaign, University of
Point of Contact: Tai Chiang
Email: chiang@mrl.uiuc.edu
Principal Investigator: Tai Chiang
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 3 Graduate(s), 2 Undergraduate(s)
Funding: \$285,359 (2014)

PROGRAM SCOPE

The proposed research focuses on the physics of surfaces, interfaces, and tailored structures that are promising for a wide range of scientific and technological advances in the quantum, nano-, and meso-scale regimes. Measurements, modeling, and computation will be performed to determine and to understand the electronic, spintronic, and atomistic behavior of selected surface-based nanoscale

systems. Electrons confined in nanoscale systems form discrete states, or quantum well states, that are sensitive to the physical dimensions, boundary conditions, and spin-orbit coupling. As a result, the electronic and spintronic properties can exhibit substantial quantum variations (or oscillations) as a function of system size and environment. The lattice structure of the system in turn responds to these changes as a result of electron-lattice coupling, possibly leading to distortions and new lattice structures with different symmetry types. These effects can be pronounced at the nanoscale because of quantum coherence, interference, entanglement, and the relative ease of atomic movement at surfaces. The resulting collective behavior involving coupled electron, spin, and lattice degrees of freedom can deviate substantially from the bulk limit, thus giving rise to ample opportunities for engineering properties and functions by tailored synthesis. The underlying physics principles are of basic importance to nanoscale and mesoscale science and technology, a prevailing national research theme. Our research is directed mainly at four areas: (1) surfaces, interfaces, and ultrathin films involving topological insulators and spin systems, (2) dichroic effects associated with angle-resolved photoemission spectroscopy, (3) coupled electronic and lattice effects on the epitaxial growth of thin films, and (4) phase transformations in oxides. The experimental work will include angle-resolved photoemission spectroscopy and x-ray diffraction and scattering.

FY 2014 HIGHLIGHTS

(1) Interfacial bonding and structure of Bi_2Te_3 topological insulator films on Si(111): Interfacial topological states are a key element of interest for topological systems, and their properties can depend sensitively on the atomic bonding configuration. We employ non-resonant and resonant surface X-ray scattering to study the interfacial and internal structure of a prototypical topological film system: Bi_2Te_3 on Si(111). The results reveal a Te buffer layer, a large interfacial spacing, and a slightly relaxed and partially strained bottom layer of an otherwise bulk-like Bi_2Te_3 film. The presence of the buffer layer indicates a nontrivial process of interface formation and a mechanism for electronic decoupling between the topological film and the Si(111) substrate. (2) Electronic size effects in three-dimensional Bi nanostructures: This research is performed in collaboration with P. J. Kowalczyk (Poland), Mahapatra and S. A. Brown (New Zealand), and X. Wang (China). We show that bismuth nanostructures form three-dimensional patterns governed by two-dimensional electronic effects. Scanning tunneling microscopy reveals that both the vertical and lateral dimensions of the structures favor certain values and that the preferred widths are different for each preferred height. Calculations demonstrate that this effect is related to the Fermi surface topology, which in turn depends sensitively on the dimensions of the structure. (3) Topological phase transition and Dirac fermion transfer in Bi_2Se_3 films: Topological surface states, while protected by time-reversal symmetry in the bulk, can be missing in films with thicknesses much greater than the decay lengths of the surface states. This novel effect is demonstrated theoretically in Bi_2Se_3 . When the spin-orbit-coupling strength is tuned through the quantum critical point, there is a wide dead zone where the film is topological but without topological surface states. This dead zone can be suppressed by interfacial bonding.

Oxide Interfaces: Emergent Structure and Dynamics

Institution: Michigan, University of
Point of Contact: Roy Clarke
Email: royc@umich.edu
Principal Investigator: Roy Clarke
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 3 Undergraduate(s)
Funding: \$176,789 (2014)

PROGRAM SCOPE

The overall goals of this program are focused on the behavior of epitaxial oxide heterostructures at atomic length scales (Ångstroms), and correspondingly short time-scales (fs-ns). We aim to achieve a better basic understanding of structural and electronic correlations and how these can be exploited for technological applications, especially energy conversion and harvesting. Topics of interest include: probing the microscopic behavior of epitaxial interfaces and buried layers; novel materials structures that emerge from ionic and electronic reconfiguration at epitaxial interfaces; ultrahigh-resolution mapping of the atomic structure of heterointerfaces using synchrotron-based x-ray surface scattering, including direct methods of phase retrieval; using ultrafast lasers to study the effects of transient strain on coherent manipulation of multi-ferroic order parameters; and investigating structural ordering and relaxation processes in real-time. Atomic-scale detail can be achieved by direct methods (COBRA), which were used to determine a new ferroelectric heterostructure based on the SrTiO₃ – LaAlO₃ interface.

FY 2014 HIGHLIGHTS

We have studied the thickness dependence of the BiFeO₃ thin film structure in the ultra-thin regime under moderate compressive strain (~ -1.4%) from (001) SrTiO₃ substrates. The samples were prepared in Schlom's MBE lab at Cornell. We found that a structural transition occurs from monoclinic to tetragonal, accompanied by a change in the octahedral tilt pattern when the film thickness is less than 20 unit cells. This definitively establishes the ultrathin-film structure as tetragonal which is important for several reasons: first, device applications normally require a single-domain state, which the lower-symmetry bulk-like monoclinic phases do not generally support; and secondly, the new tetragonal phase favors a polar alignment normal to the plane of the film, a geometry that is favorable for planar devices. The work reveals a novel "untilting" mechanism driven by the epitaxial heterointerface with SrTiO₃, which itself is untilted under ambient conditions. This in turn drives the transition to tetragonal symmetry. The work is published in APL materials. We also studied the effect of epitaxial strain on this structural transition. Samples of BiFeO₃ grown on LaAlO₃ substrates, grown by pulsed laser deposition in the group of Hans Christen at Oak Ridge National Laboratory have a significantly larger mismatch (-4.3%). Interestingly, these highly strained films grown on LaAlO₃ also show the disappearance of the monoclinic peak splitting in the ultrathin regime. The larger compressive stress apparently drives the transition thickness to smaller dimensions, indicating again that the substrate interface plays a crucial role in the formation of the tetragonal phase. We have also studied the structure of these ultrathin samples down to low temperatures (~30K). These studies are ongoing.

Dynamical Control of Nanoscale Order in Complex Oxides

Institution: Wisconsin-Madison, University of
Point of Contact: Paul Evans
Email: evans@engr.wisc.edu
Principal Investigator: Paul Evans
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$198,932 (2014)

PROGRAM SCOPE

A series of recent advances now allow materials to be designed and created in which spontaneous nanoscale order arises from a competition between atomic-scale and long-range effects. In nanoscale ferroelectrics, the competition is between structural effects associated with the creation of interfaces and the larger-scale phenomena arising from electrical polarization. Their relative importance can be tuned by varying the spatial extent and composition of the nanostructures. The development of nanoscale order is fundamentally important because it leads to new phenomena, including the formation of polarization domain patterns and local atomic arrangements that profoundly influence phase transitions and functional electronic and optical properties. We focus here on ferroelectric materials in which the balance of long-range and atomic-scale effects is manipulated via the systematic creation of atomic-scale superlattices. In particular, superlattices incorporating a very thin ferroelectric layer spontaneously form a domain pattern with a characteristic repetition length of several nanometers, with profound effects on the functional properties as well on the physics of phase transitions. The configurations of the polarization in the superlattices also include geometric arrangements that are difficult to stabilize in compositionally homogenous materials, including polarization vortices and anti-vortices. The present state-of-the-art in the experimental understanding of the nanoscale domains in ferroelectric superlattices is based on probes which either inform us only about the static state of the system (i.e. corresponding to the dynamics at the very longest times) or which lack nanoscale specificity. A rapid series of experimental developments both in synchrotron x-ray diffraction facilities and in x-ray scattering instrumentation and techniques now make it possible, however, to achieve much better specificity in the study of these phenomena.

FY 2014 HIGHLIGHTS

Our accomplishments are in three areas: 1) Equilibrium Ferroelectric Domain Dynamics: We have used coherent x-ray nanobeam scattering to show that a ferroelectric nanodomain system within a lead titanate/strontium titanate (PTO/STO) thin film heterostructure superlattice exhibits a disordered spatial pattern accompanied by fluctuations of the domain pattern at room temperature. The temporal decorrelation of domains at thermal equilibrium fits a compressed exponential time dependence similar to the thermal fluctuation of soft materials, suggesting that the fluctuation of ferroelectric nanodomains is also driven by the transition between spatially disordered metastable states. 2) Effects of Spatial Confinement on the Geometry of Ferroelectric Striped Domains: We have used a lithographic process based on focused ion beam (FIB) lithography to create nanoscale structures confining the stripe domain pattern in PTO/STO superlattices. The ferroelectric nanodomain pattern within the ridges patterned into the PTO/STO superlattices was studied using coherent microbeam x-ray diffraction. The size of the crystal has a significant effect on the domain scattering, including the distribution of in-plane directions of domain walls. 3) Large Optically Induced Strains in Multiferroics: Working with Dr. Haidan Wen and Dr. Yuelin Li at the Advanced Photon Source we have found that that intense femtosecond laser pulses can induce transient strains of up to 0.5% in multiferroic BiFeO₃ thin films. Our initial results, published in early 2013, have been followed by a systematic study of the magnitudes and time constants of the optically induced strain. Matthias Bargheer (Uni. Potsdam) has shown using laser-plasma x-ray source studies of the same samples that the strain is developed within less than 10 ps following the optical excitation, matching the APS results and published in collaboration with our group.

EARLY CAREER: Optical Manipulation and Detection of Emergent Phenomena in Topological Insulators

Institution: Massachusetts Institute of Technology
Point of Contact: Nuh Gedik
Email: gedik@MIT.edu
Principal Investigator: Nuh Gedik
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$175,000 (2014)

PROGRAM SCOPE

The goal of this project is to develop short-pulse laser-based experimental tools to probe the ultra-fast electron dynamics of topological insulators. Topological insulators exhibit a newly discovered property of matter where surface electrons have exceptional conducting properties distinct from the non-conductive nature of the bulk insulator material. This project will develop advanced optical spectroscopy along with electron spectroscopy and diffraction, all based on ultrafast laser pulses as the initial excitation source. The techniques will be developed with the goal to observe the time-resolved signature of quantum interactions and order in topological insulator and related materials.

FY 2014 HIGHLIGHTS

(1) We have implemented high harmonic generation light source for ARPES. We have successfully generated light energies in the region 20-30 eV. We have already used this light source to obtain angle resolved photoemission spectroscopy (ARPES) patterns. (2) We have used the time domain terahertz spectroscopy setup to study graphene. We have demonstrated the ability to control the way light influences the conductive properties of graphene by electrically tuning the number of electrons in the material. We showed that an intense incident light pulse can either increase or decrease the electrical conductivity of graphene, depending on how many electrons are initially in the material. By using ultrashort laser pulses, modulation of conductivity can be controlled in one trillionth of a second. This work also revealed that the conducting capacity of graphene depends on temperature in a manner distinct from that of conventional metals or semiconductors, due to the unique crystal symmetry of this two-dimensional carbon material. These results may potentially be useful for developing next-generation optoelectronic devices using graphene. (Phys. Rev. Lett. 113 , 056602 (2014))

Ultrafast Electronic and Structural Dynamics in Complex Materials

Funding: \$525,000 (2014-2016)

PROGRAM SCOPE

The goal of this project is to use light to break time reversal symmetry (TRS) to achieve experimental realization of several fascinating effects in 3D topological insulators (TIs). First, we hope to achieve a complete understanding of the nature of Floquet-Bloch states and the photoinduced TRS broken phase

in topological insulators. Then, we will use this light induced TRS broken state to realize several theoretically predicted exotic phenomena in TIs. In particular, we will search for light induced quantum anomalous hall effect, low frequency magneto-optical effects and one-dimensional chiral edge modes. This new field of Floquet physics in TIs is ripe for exploration, the importance of which extends well beyond understanding topological materials. The ability to change electronic band structure with light could fundamentally change the way we think about generating materials with novel properties.

FY 2014 HIGHLIGHTS

Observation of Floquet-Bloch states on the surface of a topological insulator. The unique electronic properties of the surface electrons in a topological insulator are protected by time-reversal symmetry. Using time- and angle-resolved photoemission spectroscopy, we show that an intense ultrashort mid-infrared pulse with energy below the bulk band gap hybridizes with the surface Dirac fermions of a topological insulator to form Floquet-Bloch bands. These photon dressed surface bands exhibit polarization-dependent band gaps at avoided crossings. Circularly polarized photons induce an additional gap at the Dirac point, which is a signature of broken time-reversal symmetry on the surface. These observations establish the Floquet-Bloch bands in solids and pave the way for optical manipulation of topological quantum states of matter. 'Observation of Floquet-Bloch States on the Surface of a Topological Insulator' Y.H. Wang, H. Steinberg, P. Jarillo-Herrero and N. Gedik Science 342, 453 (2013).

Dynamic Visualization and Control of Emergent Phases in Complex Oxide Heterostructures

PROGRAM SCOPE

Our project aims to address two of the grand challenges of materials research put forth by the BES, namely to uncover hidden phases in transition metal oxides by controlling dynamic trajectories in a complex energy landscape by preferentially exciting specific degrees of freedom, while developing the experimental and theoretical tools to control matter away from equilibrium. We propose an interdisciplinary team to explore the physics of transient and metastable states in complex oxide films and heterostructures at ultrafast time scales studying two broad classes of phenomena: strongly electron correlated oxides exhibiting metal-insulator transitions, and "hidden phases" in ferroelectrics and multiferroics. Fundamental research goals that will be addressed by the team are to: (a) Establish

materials design principles beyond the ground state paradigm to control and tailor material responses at ultrafast time scales. (b) Identify phase competition mechanisms to stabilize phase coexistence and engineer enhanced susceptibilities. (c) Use spatio-temporal methods to gain new insights into creation and destruction of phases that arise from strongly competing interactions. In order to probe transient states, the team has assembled experts in a new generation of ultrafast and ultrabright light sources in terahertz, infrared and hard X-ray free electron lasers, as well as pioneers in the development of nanoscale diffraction, spectroscopy, and ultrafast multimodal microscopy techniques such as ultrafast infrared near-field nanospectroscopy. The team consists of experienced users and resident scientists at national X-ray user facilities including the Linac Coherent Light Source (LCLS) and the Advanced Photon Source (APS). They are complemented by material growers, who utilize state-of-the-art hybrid and laser molecular beam epitaxy with unit cell level control, and theorists who bring materials-by-design density functional and non-equilibrium dynamical mean field theory.

FY 2014 HIGHLIGHTS

We have discovered a hidden ferromagnetic state in (La, Ca) MnO_3 films in paramagnetic insulator state through optical excitation at 1.55eV and THz time domain spectroscopy (Averitt, Basov). We are setting up optical-pump THz-probe and optical pump x-ray probing studies of strained manganites and strained vanadate films (Averitt, Wen, Freeland, Chakhalian). We are performing ultrafast nanospectroscopic microscopy on VO_2 thin films (Basov). Ultra-fast, pump-probe studies of BiFeO_3 films reveal metastable excited states under ultra-fast, high electric pulses (Martin, Wen, Freeland collaboration with A. Lindenberg, Stanford). We have discovered metastable phases in BaTiO_3 (Gopalan) and are performing optical/THz pump – X-ray probing of titanates and vanadates (Gopalan, Wen, Freeland, Martin, Engel-Herbert). In strained Nickelate films, we have discovered that structural and electronic orders can be disengaged (Chakhalian, Freeland, Averitt). Using DFT (Rondinelli), we have determined ground state structure of LaSrMnO_3 under epitaxial strain constraint. The next step is to compare the electronic/magnetic properties to those determined in experiment. Vibrational frequencies for CaTiO_3 and LaTiO_3 have been computed. The coupling constants connecting the mode displacements describing IR-active and TiO_6 Raman modes have been computed. We are exploring the dependence of rotation amplitude, correlation, and A-cation size on the strength of the interaction. Already, we find that the interaction is strongly dependent on the d electron count. The electronic structure of the metastable states has also been computed and is being explored in more detail. We are developing the theoretical machinery needed to do time dependent dynamical mean field theory (Millis).

Synchrotron X-ray Based Electronic Structure Study of Correlated Quantum Materials and Topological Insulators

PROGRAM SCOPE

Novel electronic phases, excitation modes, and phase transitions in quantum materials are topics at the forefront of modern fundamental condensed-matter physics. Research in these areas has led to new

superconductors and thermoelectric and spintronic materials, which have uses in future electronic, information and energy technologies. At Princeton, the P.I. leads the ARPES and x-ray spectroscopy work that combines synchrotron x-ray based techniques of photoemission spectroscopy and x-ray scattering to gain critical insights about the complex electronic structure of novel quantum materials. The main goal of this program is to investigate the ternary and quaternary-complex topological insulators and iron pnictide high T_c superconductors towards discovering new physics and functionality (both bulk and MBE thin film geometries). Physics topics that are being covered include systematic study of Topological Phase Transition and dynamics of 3D Dirac Fermions and exotic symmetry breaking phenomena. In addition, some exploratory investigation into non-topological insulator spin-orbit materials featuring novel surface phenomena and/or correlated phenomena such as novel Dirac modes and the Weyl Fermions are underway.

FY 2014 HIGHLIGHTS

The 3D topological Dirac semimetal systems with strong spin-orbit coupling can host many exotic Hall-like phenomena and Weyl fermion transport. Using high-resolution ARPES, we performed electronic studies of Cd_3As_2 and Na_3Bi which have been predicted to be the parent material, from which many topological phases can be derived. We experimentally identified their 3D topological metallic nature. Our discovery of the Dirac-like bulk topological semimetal phase in Cd_3As_2 and Na_3Bi opens the door for exploring higher dimensional relativistic physics. [S.-Y. Xu, C. Liu et.al., Observation of Fermi arc surface states in a topological semimetal; *Science* 10.1126/science.1256742 (2014) and Observation of a 3D topological Dirac semimetal phase in high-mobility Cd_3As_2 ; M. Neupane et.al., *Nature Commun.* 5, 4786 (2014) and *Nature Commun.* 5, 3841 (2014).] Superconductivity involving topological Dirac electrons has recently been proposed as a platform between concepts in high-energy and condensed-matter physics. It has been predicted that supersymmetry and Majorana fermions, both of which remain elusive in particle physics, may be realized through emergent particles in these particular superconducting systems. Using artificially fabricated topological-insulator–superconductor heterostructures, we presented direct spectroscopic evidence for the existence of Cooper pairing in a weakly interacting half Dirac gas. Our studies revealed that two dimensional topological superconductivity in a helical Dirac gas is distinctly different from that in an ordinary two-dimensional superconductor in terms of the spin degrees of freedom of electrons. Our demonstration and momentum-space imaging of Cooper pairing in a half-Dirac-gas two-dimensional topological superconductor serve as a critically important platform for future testing of fundamental physics predictions such as emergent supersymmetry and topological quantum criticality. [S.-Y. Xu et.al., *Nature Physics* 10, 943 (2014)]

Understanding Valley Spin Coupling and Two-Dimensional Exciton Gases in Layered Materials at Extreme Magnetic Fields

Institution:	South Florida, University of
Point of Contact:	Denis Karaiskaj

Students:	3 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding:	\$455,727 (2014)

PROGRAM SCOPE

The advent of graphene has generated a wealth of interest in other materials that can be made two-dimensional (2D). Atomically thin group VI transition metal dichalcogenides (TMDs) have emerged as one of the most interesting and important classes of 2D materials beyond graphene. When reduced to a monoatomic layer thickness, they exhibit drastic changes in the electronic properties, exhibiting a crossover from an indirect gap in the bulk to a direct band gap semiconductor. Also, as is common for lower-dimensional materials, many-body interactions are found to be significant, forming strongly bound excitons and trions. Although these quasiparticles have been observed, their properties are not well studied. These materials are important for numerous applications, central to the DOE's mission. Most electronic devices exploit the electric charge of electrons, but it is also possible to build devices that rely on other properties of electrons. Spintronic devices, for example, make use of the spin of electrons. 'Valleytronics' is a more recent development that relies on the fact that the conduction or valence bands of some materials have two or more degenerate minima/maxima at different positions in momentum space. Group VI TMDs are a promising material for valleytronics. In large magnetic fields monoatomic layers III-VI chalcogenides, undoped or doped behave similar to two-dimensional electron gases formed in modulation doped systems or graphene. The formation of Landau levels in high magnetic fields and the confinement of electrons and holes have led to the observation integer and fractional quantum Hall effects. Inspired by fascinating and not yet understood effects observed in modulation doped systems, we will investigate these effects in this novel class of two-dimensional materials at extremely high magnetic fields. At these extreme magnetic fields we will apply the most advanced ultrafast techniques including multidimensional Fourier-transform spectroscopy.

EARLY CAREER: Generation, Imaging, and Control of Ultrafast Electrical Currents and Radiation

Institution: Maryland, University of
Point of Contact: Ki-Yong Kim
Email: kykim@umd.edu
Principal Investigator: Ki-Yong Kim
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 1 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The PI investigates the physics of ultrafast electrical current and electromagnetic radiation generation/control in two systems: (a) centrosymmetric gaseous plasmas and (b) symmetry broken gaseous plasmas and solid-vacuum boundaries. In these systems, the PI uses ultrashort optical laser pulses to produce and control ultrafast electrical currents, as well as, to study the current evolution, screening, and decoherence with accompanying electromagnetic radiation. In particular, coherent broadband terahertz (THz) emission, expected from fast arising current surge, is of great interest and can be a useful tool for studying the underlying physics of ultrafast currents. Moreover, concurrent or delayed second or third harmonic radiation can provide phase-sensitive nature of current generation

and two-dimensional (2D) imaging of time-varying current density distribution at micrometer-scales. Specifically, in (a), the PI investigates the generation mechanism of ultrafast current via two-color photoionization, recently proposed by the PI, by directly measuring the photoelectron spectrum and linking it with far-field THz and harmonic generation. In terms of producing THz radiation as a potential source, the PI tests the feasibility of achieving an unprecedented millijoule level of THz radiation with a multi-terawatt laser system. Such radiation will allow the observation of extreme nonlinear THz phenomena in a university laboratory. Moreover, our high-energy (multi-microjoule), broadband (>20 THz) THz generation scheme at 1 kHz has potential for studying THz-driven nonlinear optics and spectroscopy.

FY 2014 HIGHLIGHTS

(1) Microscopic mechanism of terahertz generation in two-color photoionization: The primary research goal is to verify the microscopic mechanism of terahertz (THz) generation in two-color photoionization. Although such a source is widely used for many applications, the details of the mechanism are still on debate. Here we have confirmed that the optimal relative phase for THz generation is ~ 90 degrees, not significantly affected by gas species, laser intensities, and intensity ratios between two-color laser fields. These results are in accordance with the semi-classical plasma current model. We have also observed a strong correlation between microscopic photocurrents and resulting THz radiation. This verifies plasma currents as a microscopic source for far-field THz radiation in two-color laser-produced plasmas. In addition, our method of phase measurements can be readily applied to other two-color coherent control systems such as photocurrent production in semiconductors and on metal surfaces, as well as high-harmonic generation and dissociation of molecules in intense two-color laser fields. (2) High-average, high-peak power THz field generation: We have demonstrated strong-field (>8 MV/cm), high-peak-power (12 MW) THz generation with a bandwidth of >20 THz via two-color laser filamentation. Moderate average power (1.4 mW) is also achieved by using a cryogenically-cooled Ti:sapphire amplifier capable of producing 30 fs, 15 mJ pulses at a 1 kHz repetition rate. For maximal THz generation and transmission, we have used a combination of a thin dichroic waveplate and a large Brewster-angled silicon filter. In particular, we have used a microbolometer camera for real-time THz beam profiling and imaging. This cost-effective THz camera along with our intense THz source can be a useful tool for nonlinear THz studies including broadband THz spectroscopy and imaging.

Real-Time X-Ray Studies of Surface and Thin Film Processes

Institution: Boston University
Point of Contact: Karl Ludwig
Email: ludwig@buphy.bu.edu
Principal Investigator: Karl Ludwig
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$89,585 (2014)

PROGRAM SCOPE

Surface growth processes are at the core of many of our most widely used technologies today and increasing interest in the “digital design” of future materials for enhanced functionality can only come to fruition if we understand and learn how to control materials synthesis at surfaces and interfaces. The development of increasingly powerful x-ray sources and the new techniques they enable can have a major impact on our understanding and ability to control growth. In particular we are developing

coherent grazing-incidence small-angle x-ray scattering (co-GISAXS) as a powerful new tool for investigating surface and thin film growth dynamics. Coherent x-ray scattering offers the unique promise of being able to elucidate the dynamics, rather than just the spatially-average kinetics, of surface growth processes. As an example, if we consider the typical growth of an amorphous or polycrystalline thin film, the spectrum of surface fluctuations grows during deposition until a steady state is reached. Dynamic processes of deposition and local relaxation continue on the surface but there is no longer any ensemble-averaged kinetics. However it is the dynamic balance between roughening and smoothing processes that is determining the final nanoscale morphology of the growing film. Temporal information about these processes is not accessible in traditional time-resolved x-ray scattering but it is now possible to determine their nature for the first time using the new co-GISAXS technique.

FY 2014 HIGHLIGHTS

We have continued to make major progress in developing coherent grazing-incidence small-angle x-ray scattering (co-GISAXS) as a powerful new tool for investigating surface and thin film growth dynamics. For our first experiments we investigated room-temperature growth of a-WSi₂ and a-Si films. Data were collected both during the initial phase of film growth and during the later stages, when the spectrum of surface height fluctuations reached a dynamic steady state. The scattering growth to a dynamic steady state saturates first at high wavenumbers. The two-time correlation function at a given wavevector shows growing correlation times until a steady state, constant correlation time is reached. In this late stage there is no longer any ensemble-averaged kinetics, and hence there is no temporal information to be obtained from a conventional scattering experiment. However local dynamics of deposition and relaxation continues and it is these processes which are determining the final nanoscale morphology of the growing film. For conditions in which significant scattering signal comes from the bulk of the film, oscillations are seen in the autocorrelation function indicating a very interesting heterodyning process. In heterodyne processes there is a beating of the sample scattering against a reference signal. Here the reference signal appears to be coming from the internal nano- and micro-structure of the film. Autocorrelation functions of the coherent scattered intensity show compressed exponential behavior with exponents of 1-2 that vary systematically with wavenumber. The correlation times decrease as a power law with increasing wavenumber and the power law exponent is the dynamic scaling exponent z . These exponents are predicted by different theoretical models of the surface evolution and thus the co-GISAXS studies allow direct comparison with competing theoretical predictions.

HPCAT -- An Integrated High-Pressure Facility at the Advanced Photon Source

Institution:	Carnegie Institution of Washington
Point of Contact:	Ho-Kwang Mao
Email:	hmao@carnegiescience.edu
Principal Investigator:	Ho-Kwang Mao
Sr. Investigator(s):	Guoyin Shen; Carnegie Institution of Washington Russell Hemley; Carnegie Institution of Washington
Students:	4 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$1,213,315 (2014)

PROGRAM SCOPE

The primary goal of this project is to advance high-pressure materials science using the high energy x-ray source at the Advanced Photon Source. At HPCAT, a number of high-pressure synchrotron techniques has been developed and widely used for the research in discovering new materials and characterizing

novel properties of materials at extreme conditions. HPCAT has played pioneering roles in enabling many of these new capabilities and in establishing new ways of conducting experiments. A broad range of pressure conditions, including both static and dynamic, together with extreme conditions of temperature, radiation, and deviatoric stress, has been integrated with x-ray diffraction, x-ray scattering and spectroscopy, and x-ray imaging techniques. The integrated HPCAT facility allows for extreme condition studies in: (1) structural determinations at various scales from amorphous, nano-, polycrystalline, single crystal, to microstructures of composite materials, (2) measurements of phonon dynamics, charge dynamics, and electronic and spin states of metals, alloys, oxides, nitrides, hydrides, new superconductors, and new superhard or other super-durable materials, (3) *in situ* measurements with high spatial resolution (1-3 microns) and high temporal resolution (down to 100 ps). The powerful, integrated probes at HPCAT and other APS beamlines enable us to tackle a number of grand challenges in high pressure materials science. Some are century-old questions that have finally become within our grasp; some have global impacts that will alter various fields; some are surprising, novel phenomena that will rewrite conventional wisdom. The current objectives of this project are on the four thrust areas: (a) hydrogen and alkali metals, (b) magnetic and superconducting materials, (c) high pressure melting and polyamorphism in liquids, and (d) enabling high pressure x-ray techniques.

FY 2014 HIGHLIGHTS

In the FY 2014, a multigrain diffraction technique has been developed, which has shown to be promising for detail crystallographic information for samples at extreme conditions and holds great potentials for future high pressure crystallography. A new focusing device providing 1-2 micron x-ray beam has been successfully commissioned for megabar x-ray spectroscopy experiments. The developed fast radiographic imaging enables determinations of ultra-low viscosities of liquids and fluids. A new x-ray method based on phase contrast imaging has been successfully used for identifying liquid-liquid immiscibility. Fast (un)loading devices have been coupled with the time resolved x-ray techniques for studying phase transition kinetics and metastability under high strain rates. A new reliable melting criterion has been developed for measuring melting curves of metals. These new capabilities, together with the other already established techniques, are used for studying materials behavior at extreme conditions. Among others, new superconductors were found in metallic and metal oxides. Interesting electronic structures tuned by pressure have been monitored by x-ray spectroscopy. Novel chemistry of the elements has been revealed at high pressures. Liquid-liquid phase transitions have been observed by x-ray diffraction and x-ray imaging. Universal power law has been established for metallic glasses. HPCAT continues to stay among the most productive sector at the Advanced Photon Source in terms of the number publications in “high-impact” journals as well as the total number of publications.

Ultrafast Magnetization Dynamics and Spin Transfer Probes by Coherent Soft X-Rays

Institution: Colorado, University of
Point of Contact: Margaret Murnane
Email: murnane@jila.colorado.edu
Principal Investigator: Margaret Murnane
Sr. Investigator(s): Henry Kapteyn; Colorado, University of
Thomas Silva; National Institute of Standards and Technology
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$475,000 (2014)

PROGRAM SCOPE

A detailed understanding of nanoscale magnetization dynamics for 3d metals has become critical for spintronics-based memories as a low-power, non-volatile, ultrafast replacement for DRAM and SRAM in ubiquitous computing applications. However, we only have a crude understanding of magnetization dynamics of the transition metals because a comprehensive, self-consistent, microscopic model for metals that rigorously includes the spin, electronic, photonic and phonon-degrees of freedom and their interactions does not yet exist. While the fundamental length- and time-scales for magnetic phenomena are nanometers (exchange length) and femtoseconds (exchange splitting), tools that enable the exploration of dynamics at these scales have only recently become available. Our joint JILA-NIST program is exploring the fastest and smallest dynamics in magnetic materials by use of high harmonic generation (HHG) sources.

FY 2014 HIGHLIGHTS

Using HHG sources, we made several advances in uncovering new understanding of spin dynamics on the fastest timescales.[1-3] First, we solved a controversy regarding the microscopic mechanisms contributing to ultrafast demagnetization.[2] Two theoretical mechanisms had been proposed to explain ultrafast laser-induced magnetization dynamics: non-local quasi-ballistic spin-currents and local spin-flip scattering. Spin-currents would remove spin angular momentum from a given layer, whereas local spin-flip scattering results in a direct transfer of angular momentum between spins and lattice. Our data conclusively showed that both spin-currents and spin-flip scattering contribute with similar efficiency to ultrafast demagnetization in these multilayers.[2] Second, in work in collaboration with Oren Cohen's group at Technion, we demonstrated the first bright, phase-matched, extreme UV circularly-polarized HHG and used this new light source for magnetic circular dichroism (MCD) measurements at the M-shell absorption edges of Ni.[3] For decades it was assumed that HHG from atoms was brightest when both the driving laser and HHG fields were linearly polarized. While the use of passive optical components can convert from linear- to circular-polarization, these are far too inefficient to be practical. Using combined blue and red driving lasers with opposite polarity, we showed that circularly-polarized HHG is unique and robust, producing high photon flux. Fundamental Studies of the Structural Response of Disordered Materials to High P and T

Institution: New York-Stony Brook, State University of
Point of Contact: John Parise
Email: John.parise@stonybrook.edu
Principal Investigator: John Parise
Sr. Investigator(s): Richard Weber; Materials Development Inc
Chris Benmore; Argonne National Laboratory
Lawrie Skinner; New York-Stony Brook, State University of
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$176,342 (2014)

PROGRAM SCOPE

Understanding and controlling oxide melts is important to technologies where materials are processed via the liquid phase. Increasingly, solutions proposed to a number of technological challenges in the energy sector involve the synthesis and/or use of disordered materials, including liquids, melts, nano- and glassy materials, at extreme conditions. Examples include materials under high radiation fluxes advanced nano-materials for energy storage and conversion clathrates and other materials in contact with sequestered carbon - supercritical CO₂ in reservoirs or the deep ocean, for example, and high energy density materials. Understanding how the atomic arrangements in this class of materials respond to changes in pressure (p), temperature (T) gas loading and high chemical gradients is therefore fundamental to 1) understanding the behavior of these materials under their operating conditions, and 2) deriving general principles applicable to such classes of materials that 3) can be applied to vary conditions of manufacture that 'steer' toward the desired product. Addressing our energy-related problems will therefore involve learning how to vary reaction pathways, including those at extreme conditions, in order to obtain precise information on changes in structural arrangements *in situ*. We combine development of sample cells for *in situ* x-ray and neutron (XN) scattering of key classes of materials under their operating conditions, with innovative data analysis and modeling in order to characterize materials with intrinsic disorder, such as are encountered in nano-, melt, glassy and gas adduct materials. We do this in collaboration with partners in industry (Richard Weber's group at Materials Development Inc., who develops levitation apparatus with the aid of a DOE SBIR grant) at the APS (Chris Benmore) NSLS-II (Eric Dooryhee) and SNS (Jeorg Neuefeind).

FY 2014 HIGHLIGHTS

Our recent PRL publication reveals a general trend that oxide melts and glasses have lower coordination than their crystalline counterparts. Melts with low cation field strength, such as ZrO₂, and UO₂ are found to have a particularly large coordination drop on melting. Our PNAS paper provides a Pressure-Temperature map for predicting the density and pressure where coordination increase occurs in oxide glasses and melts. Our Nature communications paper provides a structural explanation for the viscosity minimum in silicates melts. This unusual behavior, where silicates initially become less viscous (thin) under pressure, is relevant to processes within Earth's mantle. We also collaborated on a recent Nature paper studying liquid water at extremely low temperatures (-40 °C). This is relevant to the debates about the amorphous and liquid phase transitions in water at these conditions, relevant to conditions in clouds and the behavior of water in interstellar space, which is expected to be amorphous. Our most recent Science article reports measurements of the structure of molten UO₂ for the first time; UO₂ is important technologically and to anthropological climate change since it is the fuel used in most nuclear power reactors, yet relatively little is known about the melt due to the very high temperatures (3200 K) and radiation controls required. Alongside this we have collected data on iron oxides and iron silicate melts, combined with control of the oxidation state. Understanding these melts is relevant to the deep Earth, steel production and slag waste. Many of the measurements we perform are difficult, with complex sample environments that can potentially compromise data. We are working closely with the XPD beamline team at NSLS-II to apply modulation Enhanced Diffraction (MED) to our systems.

Element Specific Atomic Arrangement of Binary and Ternary Alloy Nanosized Catalysts in As Prepared and Active State

Institution: Central Michigan University
Point of Contact: Valeri Petkov
Email: petko1vg@cmich.edu

Principal Investigator: Valeri Petkov
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 4 Graduate(s), 0 Undergraduate(s)
Funding: \$201,119 (2014)

PROGRAM SCOPE

Project aims at: i) synthesizing a series of technologically important binary and ternary nanoalloy catalysts ii) determining their atomic-scale structure and how it evolves under realistic reaction conditions by *ex situ* and *in situ* high-energy x-ray diffraction (XRD), including element specific resonant XRD, coupled to atomic pair distribution functions (PDF)s analysis and 3D structure modeling, iii) revealing synthesis – atomic structure – catalytic properties relationships in the nanoalloys iv) using the unique knowledge obtained as a feedback loop for streamlining their synthesis with respect to the catalytic properties targeted for optimization thus drafting a roadmap to producing nanoalloy catalysts by rational design. Outcomes: Besides advancing the frontiers of nanocatalysis, the project will push forward high-energy synchrotron XRD and atomic PDFs analysis, in particular resonant XRD, provide new hardware (e.g. reaction chambers) for in-situ high-energy XRD studies of catalytic reactions and perfect 3D structure modeling of nanometer-size materials, such as nanoalloy catalysts, of DOE interest.

FY 2014 HIGHLIGHTS

Major impact of the studies within fiscal year 2014: i) A prime example of a roadmap to synthesis of nanoalloy catalysts by rational design was demonstrated (paper # 5 of the list below) ii) An approach to solving the atomic structure of nanoalloys was put forward (paper # 2 of the list below). iii) A fuel cell reaction chamber was designed and used for *in situ* studies on the structural evolution of cathode catalysts during heavy operation. The chamber may be reproduced or just borrowed and used by other groups interested in similar studies. iv) Unique resonant XRD studies on the structural characteristics of core-shell interface in nanoalloys were carried out. v) Two more research groups, one from Argonne and the other from University of Mississippi, were introduced to resonant high-energy XRD thus helping the community using this technique grow. Indeed, Sector 1 at APS would like to host resonant high-energy XRD experiments on a more regular basis. Sector 6 at APS expressed similar interest. Forthcoming experiments (Pd and Ru K edges) will show which way resonant XRD aimed at atomic PDFs studies at Sector 6 will go. Seven papers published: [1] ACS Catal., 2014, 4, 1859; [2] Nanoscale, 2014, 6, 10048; [3] Phys.Chem.Chem.Phys., 2014, 16, 18866; [4] Chem. Commun., 2014, 50, 6005; [5] J. Am. Chem. Soc. 2014, 136, 7140; [6] RSC Advances, 2014, 4, 42654; [7] Catal. Sci. Technol., 2014, 4, 3570. Two more papers were submitted for publication and 13 presentations (talks plus posters) made.

Nanoscale X-Ray Imaging and Dynamics of Electronic Magnetic Materials

Institution: California-San Diego, University of
Point of Contact: Oleg Shpyrko
Email: oleg.shpyrko@gmail.com
Principal Investigator: Oleg Shpyrko
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$185,000 (2014)

PROGRAM SCOPE

This proposal is aimed at development and application of several Coherent X-ray Scattering Tools. Our group has made several important developments in Coherent X-ray Diffraction Imaging (CXDI) techniques and have applied them to both stand-alone, isolated nanostructures (nanowires, nanoparticles), and extended objects, such as magnetic thin films (GdFe), as well as applied these methods for in-situ studies of energy storage materials.

FY 2014 HIGHLIGHTS

We have recently developed CXDI technique and applied it to study in-situ ionic diffusion within a single grain of a Lithium Ion battery cathode. By mapping out displacement field and electron density for the same grain in three dimensions, we were able to study how ion distribution is modified during charge and discharge processes. We were also able to see formation of dislocations and their dynamics within Lithium oxide material. We have applied CXDI to studies of curvature-induced strain and stacking faults in metal nanoparticles. We have also recently done the first X-ray Photon-Correlation Spectroscopy experiments at the Free Electron Laser Facility (LCLS) at SLAC. Finally, we have performed ultrafast pump-probe studies of Charge Density Wave in Antiferromagnetic Chromium (associated with formation of Spin Density Wave). All of these results have either been published or submitted over the fiscal year 2014.

EARLY CAREER: Photon-Electron Interactions in Dirac Quantum Materials

Institution: Washington, University of
Point of Contact: Xiaodong Xu
Email: xuxd@uw.edu
Principal Investigator: Xiaodong Xu
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$150,000 (2014)

PROGRAM SCOPE

The objective of this proposal is to understand and control electron, photon, and phonon interactions in new classes of Dirac quantum materials, such as graphene and atomically thin transition metal dichalcogenides (TMDs), for new energy harvesting technologies. These materials have unusual physical properties which allow us to probe unprecedented quantum phenomena otherwise not assessable in other material systems. Graphene is a gapless Dirac material with linear energy momentum dispersion for low energy carriers. It has unusual quantum Hall effects with large Landau level spacing, which enables us to investigate non-equilibrium carrier dynamics in the quantum Hall (QH) regime. Monolayer TMDs have a honeycomb lattice structure like graphene. This fact gives them analogous Dirac-like electronic valleys at the corners (K-points) of the hexagonal Brillouin zone. A key difference from graphene is that TMDs possess inversion asymmetry, which gives rise to direct band gaps in the visible regime and non-trivial Berry-phase related physics. But more profoundly, $\pm K$ valleys have circularly polarized optical selection rules, providing the first solid state system for dynamic control of the valley degree of freedom. A second important difference, arising from the transition metal, is large spin-orbit coupling which spin-splits the valence band by 150 - 450 meV.

FY 2014 HIGHLIGHTS

In the current funding period, we made the following progress. (1) In bilayer WSe_2 , we discovered a new coupling effect between spin, valley, and layer pseudospins. Here, both spin and valley degrees of freedom are associated with magnetic moments. The layer degree of freedom is associated with electrical polarization, which corresponds to electrons either in the upper or bottom layers. We showed the electrical control of spin splitting without the applied magnetic fields. Further, we demonstrate the optical generation of valley quantum coherence using interlayer trion states. (2) We designed a monolayer WSe_2 p-n junction and observe bright electroluminescence from the p-n junction area. We identified that the light emission is from the radiative combination of excitons and trions localized at valleys. These excitons are created by strong Coulomb interaction between electrically injected electrons and holes. (3) We demonstrated hetero-epitaxy growth of seamless lateral heterostructures in an atomic plane by physical vapor transport method. Remarkably, each large crystal exhibits two concentric regions with different optical contrast. We identified that the inside and outside triangles are $MoSe_2$ and WSe_2 , respectively. High-resolution transmission electron microscopy image showed that all the atoms lie on a single honeycomb lattice. There are no dislocations or grain boundaries, and negligible distortion of the lattice near the interface, i.e., perfect lateral epitaxy. We showed that the photoluminescence from the heterojunctions is brighter than the bulk, highlighting the interesting optical properties of a 1D heterojunction.

Ultrafast Control of Emerging Electronic Phenomena in 2D Quantum Materials

Di Xiao; Pittsburgh, University of
Students: 3 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$370,000 (2014)

PROGRAM SCOPE

The objective of this proposal is to combine both theoretical and experimental efforts to investigate valley dynamics and Berry phase effects on ultrafast timescales in novel two-dimensional (2D) quantum materials - monolayer transition metal dichalcogenides (TMDs). Monolayer TMDs are a new class of direct bandgap semiconductors at the truly two-dimensional limit. Their energy bands consist of two degenerate but inequivalent valleys located at the corners of the hexagonal Brillouin zone. Due to the broken inversion symmetry, their low-energy electron dynamics can be described as a pair of Dirac fermions with opposite masses. This leads to a number of valley-contrasting Berry phase phenomena and, consequently, the first solid system for dynamical control of valley degrees of freedom. To achieve the objective, we plan to employ state-of-the-art ultrafast technologies, including femtosecond optical pump-probe spectroscopy, an intense THz apparatus and advanced x-ray facilities at the Advanced Photon Source (APS), and the ultrafast x-ray facility at Linac Coherent Light Source (LCLS). Part of our proposed work will represent the first ultrafast x-ray study of atomically thin TMDs. Below are the two inter-related tasks. In the first task, we will investigate the dynamics of valley excitons and control of their Berry phase by optical pumping and subsequent manipulation by an intense THz optical field. In the second task, we will investigate the effects of structural deformation on valley quantum dynamics as

well as Berry phase related quantities, which represents control of valley contrasting physical properties by manipulating the time-dependent basis of the electronic wave function.

FY 2014 HIGHLIGHTS

We have started the project from Sept, 2014. In the first period of this project, we focused on the characterization of x-ray response of monolayer transition metal dichalcogenides and their heterostructures. The x-ray experiment is performed at Argonne national lab by Haidan Wen (a Co-PI of the project). We successfully characterized the structural properties of monolayer WSe_2 and identified the fluctuations of the separation between monolayer and sapphire substrates. We have also applied full-field X-ray diffraction microscopy to image the $MoSe_2$ - WSe_2 heterostructures. These initial works are important steps towards the investigation of structural dynamics of monolayer structures using ultrafast x-ray techniques.

Towards Understanding and Control of Nano-Scale Fluctuations in Strongly Correlated Electron Systems

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Simon Billinge
Sr. Investigator(s): Emil Bozin; Brookhaven National Laboratory
Students: 5 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$1,163,000 (2014)

PROGRAM SCOPE

To advance our understanding of the role of nanometer sized inhomogeneities, nano-phase-separation, and nano-scale stripe features, generically referred to here as “fluctuations”, in determining the properties of strongly correlated electron systems. The approach is to develop state of the art diffraction approaches to study nanometer scale structures, principally around the atomic pair distribution function (PDF) technique, and then to apply these to study fluctuations in electronic systems. Another critical aspect of the project is to integrate scattering with complementary techniques. Nanoscale fluctuations are difficult to study but crucial to understanding the emergent properties of complex materials such as high- T_c superconductivity in oxides, chalcogenides, colossal magnetoresistance and relaxor ferroelectricity - precisely the phenomena that make correlated electron systems so exciting. Techniques include x-ray and neutron diffraction, scanning tunneling microscopy and spectroscopy, electron microscopy and spectroscopy and oxide MBE synthesis. The varied information provided by these techniques; real and reciprocal space, static and dynamic, surface and bulk, will allow us to construct a more coherent view of the fluctuations and their role in the strongly correlated physics of these materials. Once the role of fluctuations in determining these properties is understood it will become possible to explore approaches to control the fluctuations to yield desired properties.

FY 2014 HIGHLIGHTS

EARLY CAREER: Probing the Magnetic Excitations in Complex Oxide Interfaces and Heterostructures

Institution: Brookhaven National Laboratory
Point of Contact: Peter Johnson
Email: pdj@bnl.gov
Principal Investigator: Mark Dean
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Heterostructures of transition metal oxides exhibit numerous novel properties that emerge at the interface of such unconventional materials. The microscopic origin of these properties is poorly understood. This program aims to measure the charge, magnetic, and orbital excitations at these interfaces. These excitations provide detailed quantitative information about the parameters at transition metal oxide interfaces and by studying these parameters we aim to understand and eventually control these novel emergent phenomena. In order to do this, we use advanced x-ray scattering methods at synchrotrons such as the National Synchrotron Light Source (NSLS) II at Brookhaven National Laboratory, as well at numerous national and international facilities. We are working to further enhance our abilities to probe these excitations by developing instrumentation to measure the polarization, as well as the energy loss, of the scattered x-ray photons. The goal of the program is to obtain a detailed understanding of the role of interfacial effects such as charge transfer, strain, orbital reconstruction and exchange bias in determining magnetic interactions. This is a vital step towards exploiting these effects to obtain the desired properties for next generation functional devices.

FY 2014 HIGHLIGHTS

This program started on July 15, two and a half months before the end of FY 2014. In this time we established a collaboration with Anand Bhattacharya at Argonne National Laboratory to synthesize and characterize nickelate-based heterostructures. Successful beamtime proposals were awarded time at the Advanced Light Source and the Swiss Light Source for performing Ni M- and L-edge resonant inelastic x-ray scattering (RIXS) experiments on these films. A Bruker D8 Discover diffractometer was procured by the X-Ray Group in order to characterize thin film heterostructures and a postdoctoral researcher was hired to start in November 2014. The PI also prepared a Partner User Proposal for the Soft Inelastic X-Ray (SIX) beamline at NSLS-II. We completed the conceptual design of the x-ray polarimeter for analyzing the polarization of the scattered x-ray photons during a RIXS experiment. We also finalized the parameters for the x-ray multilayer mirrors that form part of this apparatus.

PROGRAM SCOPE

Our efforts are centered on joint theoretical and experimental activities to uncover the origins of phase transitions, non-equilibrium behavior and emergent properties in strongly correlated electron systems with the goal of understanding and potentially controlling emergent phenomena at their natural time and length scales, under equilibrium, non-equilibrium and/or extreme conditions. We explore how quantum mechanics acts at nano- to microscopic length scales and atto- to femto-second time scales, thus enabling the design and optimization of new materials with desirable properties. This is accomplished through the use of high-resolution x-ray spectroscopy and ultrafast pump-probe techniques, with the development of a variety of theoretical approaches to x-ray spectroscopy and non-equilibrium dynamics. Our work is focused on the new capabilities offered at the Linac Coherent Light Source to study novel x-ray spectroscopies in both the time and frequency domains, in equilibrium and in response to tailored light pulse stimuli. We combined that work with other x-ray and optical based activities at other light sources and local laboratories, and utilize DOE tier I computational facilities to carry out numerical investigations. The techniques developed are important to the fundamental understanding of non-equilibrium physical processes and the origin of emergence but also open the ability to control novel properties in materials for energy and other technology applications, resulting in substantial advances of great benefit to DOE.

FY 2014 HIGHLIGHTS

(1) Revealing the asymmetry in collective excitations between electron- and hole-doped cuprates. We used state-of-the-art RIXS instruments to perform momentum-dependent measurements on electron-doped high temperature superconducting cuprates. Surprisingly, upon electron doping, the energy scale of magnetic excitations increases. Furthermore, we also discovered an unexpected branch of collective modes, hinting at the existence of a distinct quantum phase and an associated quantum critical point. Both behaviors of collective modes are distinct from those in hole-doped compounds, demonstrating a notable asymmetry in collective excitations on both sides of cuprate phase diagram. Yet, despite their differences, the persistence of magnetic excitations and the existence of a distinct quantum phase appear to be universal in both hole- and electron-doped cuprates. (2) Low energy excitations from resonant inelastic x-ray scattering (RIXS) at the L-edge in cuprates. We demonstrated that L-edge RIXS can indeed provide a good proxy for measuring the spin dynamical structure factor which complements information obtained from inelastic neutron scattering. Utilizing two numerical techniques, we showed how one can naturally understand the evolution of the spin excitation spectrum with doping and that even in heavily hole-doped compounds these excitations persist at high-energies along the anti-ferromagnetic zone boundary. Our results reconcile recent RIXS experiments with previous investigations using inelastic neutron and Raman techniques; and in addition, we predicted a striking asymmetry between hole- and electron-doped materials, which was recently confirmed in two separate experiments, one by members of the present FWP (the preceding achievement).

Magnetization and Dynamics

Students: 2 Postdoctoral Fellow(s), 7 Graduate(s), 0 Undergraduate(s)
Funding: \$1,355,000 (2014)

PROGRAM SCOPE

The Magnetization and Dynamics FWP focuses on the emergence of mesoscopic spin and charge order in the far from equilibrium states that occur when solid-state devices used for instance in information technology are operated near their speed limits given by the fundamental laws of physics. It aims at addressing the grand scientific challenges related to these areas by developing a fundamental understanding of the evolution of materials properties determined by the flow of energy and angular momentum as the magnetic and charge state is switched by external stimuli. It employs the unique x-ray capabilities at SLAC to access the nm length scale on the complementary fs (LCLS) and few-ps (SSRL) timescales for probing: (1) all-optical magnetic switching in metallic alloys, and (2) electric field driven metal-insulator transitions in strongly correlated materials. The latter makes use of intense THz fields generated by fs lasers and the relativistic electron beams available at SLAC. (3) It finally aims at developing a new generation of non-linear x-ray techniques such as stimulated inelastic x-ray scattering to uniquely probe the electronic and spin interactions in emergent mesoscopic phases.

FY 2014 HIGHLIGHTS

- Investigated all-optical magnetic switching in FeCoGd alloys using elastic resonant magnetic scattering at LCLS, SXR
- Investigated the magnetic domain sizes for the latest generation of magnetic hard disc drives with elastic resonant magnetic scattering at SSRL
- Studied the ultrafast demagnetization of Fe films following fs laser excitation with ultra-violet radiation from the Flash free electron laser
- Investigated the magnetic domain sizes written by fs laser illumination of FeCoTb alloys at SSRL
- Investigated the insulator-metal transition in VO₂ in thermal equilibrium at ALS
- Probed the evolution of the electronic excitations across the metal-insulator transition with Resonant Inelastic X-ray Scattering (RIXS) at the Swiss Light Source
- Investigated the THz driven insulator-metal transition using x-ray scattering techniques at LCLS
- Stimulated inelastic x-ray scattering studies in solid state samples performed at the LCLS AMO beamline
- Studied the laser-induced non-equilibrium phase transition in FeRd films at LCLS, SXR
- Studied the orbital and spin moments of 5 to 11 nm Fe₃O₄ nanoparticles at SSRL.

PROGRAM SCOPE

This program is focused on revealing the underlying equilibrium excitations, reactions, and dynamics that control the properties and evolution of materials for energy. Through innovative use of the Advanced Photon Source (APS) and the Linac Coherent Light Source (LCLS), we are developing and utilizing novel x-ray experimental techniques that will allow the study of phase transitions, synthesis and catalytic processes not only as statistical averages, but as events resolved in both time and space. We explore the competing interactions underlying high T_c superconductivity in order to understand their fundamental physics. We are developing Bragg coherent diffraction imaging techniques, for example “Bragg Projection Ptychography”, and using them to study thin films. We are extending coherent imaging techniques to surfaces and using them to understanding dynamics in the reactive environments of crystal growth and catalysis. Finally, we are performing the first atomic resolution x-ray photon correlation spectroscopy measurements on simple liquids to observe their diffusive and vibrational modes near the glass transition temperature. Throughout this research, we strive to develop a fundamental understanding of materials physics while also laying a solid foundation for in-situ materials science at the DOE Scientific User Facilities. The in-situ techniques enabled by the latest x-ray sources are important components in the transition of materials development from an empirical technology to a control science—a crucial transition if we are to meet the need for new, exceptional materials for energy applications.

FY 2014 HIGHLIGHTS

We developed a new Bragg ptychography technique that reconstructs 3D structural images of a crystal from a set of 2D diffraction patterns measured at a single angle. By integrating concepts from medical computed tomography and coherent diffraction imaging, our new technique can rapidly image a broad range of nanoscale crystals under real-world conditions. We imaged the step structure of buried platinum surfaces (e.g. in an electrochemical cell). The results demonstrated the capability of techniques we’ve developed to apply reflection x-ray ptychography to the study atomic level step structures of interfaces. Using Bragg projection ptychography, we independently imaged nanoscale structural features of a nanoelectronic device prototype at two different Bragg conditions and developed a new analysis approach of the reconstructed images that enabled comparison of experimental distributions of crystal strain and rotation with linear elastic predictions. We performed *in situ* x-ray scattering measurements of SrCoO_{2.5} (001) epitaxial thin films, observing that oxygen is removed from the film in carbon monoxide and is replenished in oxygen. This indicates that carbon monoxide oxidation takes place on this material via the Mars-van Krevelen mechanism. The activity-stability relationship during reaction is then strongly dependent on both the surface exchange coefficient and oxygen diffusivity. We performed the first split-pulse ultra-fast x-ray photon correlation spectroscopy measurements of the q-dependent dynamics in a colloidal liquid. This measurement was made possible by systematic studies of

the performance of detectors at LCLS and by a focused effort to improve the performance of the hard x-ray split and delay instrument at LCLS.

Funding: \$1,158,000 (2014)

PROGRAM SCOPE

The central objective of this program is to carry out basic studies of the structural, electronic and magnetic properties of strongly correlated electron systems using advanced x-ray scattering techniques. Particular emphasis is placed on electronic and magnetic structure and phase behavior, on collective excitations and on the investigation of electronic surface and interfacial phenomena. The proposed research has a long term goal of understanding and ultimately controlling the properties of these materials. The program seeks to address questions on the mechanisms of high-temperature superconductivity, the role of intrinsic perturbations in strongly correlated systems and to understand the dynamics over of these systems over a wide range of time and energy scales. Inelastic x-ray scattering and hard and soft x-ray resonant scattering experiments will be carried out as part of a broader effort within the Condensed Matter Physics and Materials Science Department (CMPMSD) and more generally at Brookhaven National Laboratory (BNL) to address these questions. To carry out these objectives, the X-ray Scattering Group also develops instrumentation, and maintains and operates two beamlines at the National Synchrotron Light Source (NSLS) and is involved in the development and use of two sectors at the Advanced Photon Source, and three of the six project beamlines at the NSLS-II.

FY 2014 HIGHLIGHTS

The ubiquity and importance of short-range charge correlations in the cuprate phase diagram has recently become clear. We have used soft x-ray resonant scattering to show that these correlations in the so-called “214” system of $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ and in the “123” system $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$ have order parameters of a similar size, despite having different wave-vectors [1]. Further, we have observed rotated charge stripe ordering for the first time in orthorhombic $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ and showed that again this ordering has a similar integrated intensity [2]. These results lend strong support to the idea that there is a common motif to the charge order in all cuprate families. Our ultra-fast experiments on $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$, show that this charge order is melted with a mid-IR photon pump on a time scale of a few hundred femtoseconds [3]. This is much faster than the response of the LTT structural distortion, which in equilibrium is tied to the charge order. This is significant because similar mid-infrared pumps have previously been shown to induce superconductivity in non-superconducting, stripe ordered $\text{La}_{1.675}\text{Eu}_{0.2}\text{Sr}_{0.125}\text{CuO}_4$ and to increase the strength of the superconducting condensate in $\text{La}_{1.875}\text{Ba}_{0.125}\text{CuO}_4$ [4]. Our results are consistent with a picture where, in equilibrium, the charge order inhibits the 3D phase coherence between the 2D planes (even though these have strong superconducting correlations). The mid-IR pump then destroys charge order and allows the formation of 3D phase-coherent superconductivity [4]. Using inelastic scattering, we have also looked for renormalization of the spin correlations as a result of the charge correlations. No such effects were observed [5]. [1] Thampy, *et al.*, Phys. Rev. B 88, 024505 (2013). [2]

Sr. Investigator(s): Robert Kaindl; Lawrence Berkeley National Laboratory
Joseph Orenstein; Lawrence Berkeley National Laboratory
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$969,000 (2014)

PROGRAM SCOPE

Program is focused around the application of ultrafast techniques to understand and control novel properties and emergent phenomena in complex materials, by: a) resolving in energy, spin and momentum the ultrafast dynamics that results from intrinsic many-body interactions, b) by generating new phases and states that do not occur spontaneously and ultimately, c) by controlling their structural and electronic order via ultrashort light pulses.

FY 2014 HIGHLIGHTS

Our work “Ultrafast Charge Localization in a Stripe-phase Nickelate” was published in Nature Comm. 4, 2643 (2013). As the first ultrafast mid-IR study of a stripe-phase correlated system, it clarifies the initial steps of stripe formation – governed by rapid hole localization and correlated electron-phonon coupling. Understanding stripe dynamics is important for clarifying the role of fluctuating charge order in high- T_c superconductors and other correlated oxides. Optimization and testing of the new extreme ultra-violet time and angle resolved photo-emission spectroscopy (XUV trARPES) setup for initial pump-probe studies of correlated materials, was performed. A paper describing this innovative system is under review in Nature Comm (arXiv:1408.6827). Implementation of reflection-mode THz spectroscopy over an ultrabroadband frequency range was applied to study Cooper pairing and gap dynamics in the high- T_c superconductor Bi-2212, providing important impetus for the imminent XUV trARPES studies of these materials. Similar Ultrafast time-domain THz studies were applied to study the Ni-O bending mode in La-Sr-Ni oxide revealing an intriguing two-component response composed of picosecond phonon splitting (stripe formation) and fast electronic dynamics (pseudogap). This method allows direct access to the charge order amplitude. These new results prelude planned trARPES studies of charge-density wave dynamics. Ultrafast time-resolved ARPES studies of high T_c superconductor reveal a softening of the electron-boson interaction in concomitance with a softening/closure of the superconducting gap. The effect is negligible in the normal state and for a metallic compound, suggesting that the electron-boson interaction might be a booster for pairing in cuprates.

Funding: \$2,207,000 (2014)

PROGRAM SCOPE

The overarching goal of this FWP is to understand, and ultimately control, emergent behavior in strongly correlated quantum materials, emphasizing the development and use of novel probes of matter, including scanning probes. During FY 2014 our effort has been largely directed toward experimental and theoretical studies of the electronic structure of intertwined phases in cuprate and ferro-pnictide high-temperature superconductors, and toward probes of the edge/surface states of 3D topological insulators and 3D topological semimetals. Extensive efforts were also devoted to the development of in-situ thin film synthesis coupled with photoemission experiments, with initial focus on FeSe superconductors on SrTiO₃ and MoSe₂ on graphene. This FWP is also developing or modifying several important instruments, such as an upgrade of a synchrotron beamline end station and a new type of time resolved UV laser based photo-emission, including a new modality of spin resolved photoemission.

FY 2014 HIGHLIGHTS

(1) FWP researchers have studied the interplay between the pseudogap and superconductivity in high-T_c cuprate superconductors. The comprehensive ARPES study over a wide temperature and doping range in Bi2212 has revealed an unforeseen antagonistic singularity at T_c in the spectral weight as conclusive evidence for the competition between order parameters for the density-wave-like pseudogap and superconductivity. Theoretical simulations have been performed which confirm the observed singularity is due to this competition. Furthermore, including electron-phonon coupling in the simulation reproduces evolution of the spectral weight and lineshape at the same time on a quantitative level at different dopings/temperatures. The observation of the spectroscopic singularity at finite temperatures over a wide doping range provides new insights into the nature of the competitive interplay between the two intertwined orders and the complex phase diagram near the pseudogap critical point. As a complement, FWP researchers have found a signature for the charge density wave using resonant inelastic x-ray scattering. Such a result is an important step towards defining the crucial parameters for high-T_c superconductivity, and ultimately towards a microscopic understanding and application. (2) FWP researchers have investigated the phase competition in iron-based superconductors. Through systematic studies of the doping and temperature dependence in a model system, including both experimental and theoretical efforts, direct spectroscopic evidence for the microscopic coexistence and competition between superconductivity and magnetic order has been revealed for the first time, providing important insights into the emergence of superconductivity among complex quantum phases. In addition, efforts have been made to elucidate the relationship between the structural phase transition and the spin-density-wave transition in iron-based superconductors, an important issue in understanding phase competition.

Funding: \$150,000 (2014)

PROGRAM SCOPE

The overarching goal of this project is to develop a theoretical framework for understanding and controlling the states that emerge from strong electronic correlations and coupling to bosonic degrees of freedom in strongly correlated electronic materials. The competition between these interactions establishes a delicate balance between emergent states including magnetism, heavy fermion behavior, and superconductivity. However, understanding the microscopic mechanisms governing the emergence of these states remains a challenge. Recently, ultrafast optical spectroscopy has been recognized as a conceptually new approach to tackle this problem. We use a theory-driven, coupled theoretical/experimental approach to explore quasiparticle excitation and relaxation/recombination processes in complex materials. Our theoretical studies focused on developing novel approaches to modeling quasiparticle dynamics in strongly correlated electron materials, including superconductors, heavy fermions, and polaronic materials. We also pursued a series of theory-driven experiments. Specifically, we investigated heavy fermion materials to understand quasiparticle relaxation and recombination in the presence of multiple gaps in the electronic structure, most notably the hybridization gap; multiferroics, as well as heterostructures of materials with competing magnetic/ferroelectric orders, to investigate the role of competition and coexistence of multiple orders; and complex oxides and manganites to study polaron formation and their coupling to other quasiparticles.

FY 2014 HIGHLIGHTS

The design of multilayered complex oxide heterostructures to enhance a specific functionality is an important emerging area in condensed matter physics. Thus, we have also demonstrated that optically pumping carriers across the interface between thin films of a ferroelectric insulator, $\text{Ba}_{0.1}\text{Sr}_{0.9}\text{TiO}_3$ (BSTO), and a ferromagnetic manganite metal can significantly enhance the ferroelectric polarization. This enhancement was detected using second harmonic generation which is proportional to the ferroelectric polarization in BSTO. We find that the photoinduced ferroelectric state remains stable at low temperatures for over one day. This occurs through screening of the internal electric field by the photoexcited carriers, leading to a larger, more stable ferroelectric polarization. These results suggest that ferroelectric/manganite bilayers offer a new avenue for optically increasing and stabilizing ferroelectric order. Recently, we have examined the dynamics at faster timescales using femtosecond time-resolved second harmonic generation, revealing that magneto-electric coupling in BSTO is induced within tens of ps after photoexciting the manganite layer.

Principal Investigator: Ivan Bazarov

Sr. Investigator(s):

Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)

Funding: \$150,000 (2014)

PROGRAM SCOPE

High brightness electron source R&D is supported by the referenced proposal. That includes manufacturing of a new electron analyzer instrument for studies of the more efficient photocathode materials, experimental and theoretical studies of space charge phenomena that set the limit to the performance of high-brightness accelerators using a test photo injector gun setup. In addition to advancing the area of photoemission-based electron sources and the profound impact it has for the next generation X-ray synchrotron radiation facilities, training of graduate and undergraduate students is an essential part of the project. This is consistent with the growing demand for accelerator physicists in the United States and the world.

FY 2014 HIGHLIGHTS

We have extended the Cornell Monte-Carlo simulation tool for photocathode physics to layered semiconductor structures. This new result was published in Physical Review Letters 112 (2014) 097601 and opens new opportunities for designing superior photocathode structures with very low angle spread in the electrons. A new stand-alone transverse energy measurement system was implemented to allow studies of the intrinsic photocathode emittances at cryogenic temperatures along with the improvements to a comprehensive vacuum chamber, which integrates growth, activation, and characterization of photocathodes in vacuum. The world's brightest beam was demonstrated in 2013 with the help of the photocathodes developed within this award. Superb longevity of the sodium potassium antimonide photocathode was experimentally demonstrated. This result was published in Applied Physics Letters 103 (2013) 103504. A method for advanced laser shaping was implemented, which allows creation of arbitrary electron shapes to minimize the adverse effects on beam brightness from non-linear space charge forces inside the electron bunch. The laser shaping method was theoretically analyzed for its efficiency and then used to create electron bursts in the Cornell high-voltage electron source. This new result was published in Applied Physics Letters 105 (2014) 171109.

Optoelectronic Picosecond Detection of Synchrotron X-rays

Institution: Purdue University
Point of Contact: Stephen Durbin
Email: durbin@purdue.edu
Principal Investigator: Stephen Durbin
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$313,504 (2014-2016)

PROGRAM SCOPE

The outcome of this research project is a time-resolving x-ray detector that will permit the observation of fundamental physical processes in materials that happen as fast as only one “picosecond,” a billionth of a billionth of a second. This is a natural time scale for many important energy processes at the molecular level that are not easily accessible at the powerful x-ray synchrotron sources where many advanced x-ray studies are currently done. This new detector takes advantage of ultrafast laser pulses to read out the electrical signals generated by x-rays in custom-designed semiconductor devices, produced with state-of-the-art fabrication techniques. Techniques previously developed for optoelectronic applications using semiconductor stripline waveguide circuits will be adapted to synchrotron x-ray pulse excitation. This will include all-optical detection, where the striplines sit directly on optoelectronic crystals that modulate laser pulse polarizations as a function of electric field. This will be accomplished using resources at Purdue University’s Birck Nanotechnology Center as well as Argonne’s Advanced Photon Source. The finished detector will be applied to the science of ultrafast dynamics in complex materials, using laser pump x-ray probe techniques at the Advanced Photon Source. The finished detector will be used to address important questions about ultrafast dynamics, such as non-thermal melting in semiconductors like GaAs and InSb, energy flow carried by vibrations in silicon, and insulator-metal phase transitions in vanadium dioxide and other complex oxides. The successful implementation of this optoelectronic x-ray detector will provide picosecond capabilities to any synchrotron facility around the world, a breakthrough enabling picosecond science to be done “inside” the much longer synchrotron x-ray pulse.

FY 2014 HIGHLIGHTS

We have discovered how fundamental interactions between an x-ray photon and the semiconductor gallium arsenide critically determine the electronic response of the stripline detectors. We found that point defects must be introduced to reduce photocarrier lifetimes, as was well-known from laser studies of similar materials, but for the first time we established that the same point defects produce very different responses from x-rays than optical photons. X-rays produce ballistic photoelectrons and Auger electrons, and we find that these also interact with point defects in ways that were not previously considered. Comparison of detector pulses excited by x-ray pulses versus laser pulses reveal that defects such as the EL2 antisite defect, where an arsenium atom occupies a gallium site and binds a localized electron, in gallium arsenide suppress the creation of electron-hole pairs from x-rays, diverting the energy into other channels. This points the way to more efficient approaches to picosecond detection of x-ray pulses, using optical detection in optoelectronic materials such as lanthanum tantalate, where electric fields are measured directly as opposed to electrical currents. In addition to this fundamental insight, there are two other highlights to report. First, our studies of point defects in gallium arsenide show that x-ray pulses excite metastable states leading to transient energy storage in the EL2 point defects, which can then be interrogated with optical pulses. Second, we have developed an entirely new

approach to measuring the delay time between x-ray and optical pulses with picosecond resolution using frequency domain techniques, which can improve the accuracy of synchrotron-based laser pump x-ray probe experiments.

Versatile, Reprogrammable Area Pixel Array Detector for Time-Resolved Synchrotron X-ray Applications

Institution: Cornell University
Point of Contact: Sol Gruner
Email: smg26@cornell.edu
Principal Investigator: Sol Gruner
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 2 Graduate(s), 0 Undergraduate(s)
Funding: \$2,850,000 (2013-2015)

PROGRAM SCOPE

It is widely acknowledged that many, if not most, experiments at modern synchrotron radiation sources are limited more by detector capabilities than by the source. This is especially true for time-resolved studies. Examples span many disciplines and include, but are not limited to, material processing; understanding how materials fail; time-resolved protein interactions (e.g., enzymes, membrane proteins, gene regulation); depositions and growth of technologically significant complex films; turbulence in liquids; etc. The goal of this project is to develop a series of silicon-based Pixel Array Detectors (PADs) for challenging time-resolved and structural x-ray synchrotron radiation applications in which flexible data processing hardware are integral to the detector. The front-end detector hardware is comprised of a pixelated semiconductor detector layer that is connected pixel-by-pixel to Application Specific Integrated Circuits (ASICs). Each detector being developed has pixel circuitry tailored for specific categories of experiments for which currently available detectors are inadequate. Thus, the availability of the novel designs that are being developed will considerably expand the scope of experiments that can be performed at synchrotron radiation sources. Since the design and fabrication of custom, large ASICs suitable for area detectors is inherently expensive, it is imperative that each PAD design build on the lessons of earlier work and, in so far as possible, utilize integrated circuit parts that have already been proven to work. Building on prior work of our detector development group, we have been (1) performing R&D on novel PAD designs, (2) adapting pixel circuits developed in the past to new controller hardware to realize usable detectors as rapidly as possible, and (3) demonstrating the resultant detectors by performance of important and novel experimental applications at synchrotron radiation sources.

FY 2014 HIGHLIGHTS

With respect to the approach in the previous paragraph, three PADs under development are a Mixed-Mode PAD (MM-PAD) for ultra-wide dynamic range x-ray imaging, a Keck-PAD for capture of x-ray “movies” at rates of 10 million frames per second, and a MM-PAD variant (called the HDR-PAD) designed for use at x-ray free electron lasers. Highlights include demonstration of the following: (1) The MM-PAD was used to perform 3-dimensional radiographic reconstructions of objects from inherently noisy x-ray images. This is significant because it allows successful radiography in cases where data were formerly thought to be useless. (2) The MM-PAD was used to perform superior x-ray microscopy via the technique of coherent x-ray imaging. This extends the range of x-ray microscopy for examination of nanomaterials. (3) In a first demonstration, a prototype Keck-PAD was to obtain atomic level structural data on the response of metal alloys under conditions of rapid impact by a projectile. The entire

sequence of images lasted only microseconds. This capability will considerably extend time-resolved x-ray studies that have hitherto been unfeasible, and will be especially important in developing impact resistant materials.

Theoretical and Simulation Studies of Seeding Methods

Institution: SLAC National Accelerator Laboratory
Point of Contact: Claudio Pellegrini
Email: claudiop@slac.stanford.edu
Principal Investigator: Claudio Pellegrini
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 11 Graduate(s), 0 Undergraduate(s)
Funding: \$450,000 (2013-2014)

PROGRAM SCOPE

The main goal of our program is to extend the X-ray FEL capability for exploration of atomic and molecular science, by increasing its peak power by over one order of magnitude. The increase in peak power from the present level of 10-50 GW to 1 TW or more, while maintain good transverse coherence properties, is of critical importance for single particle coherent diffraction imaging, as discussed at a workshop at SLAC in the spring 2014. This peak power level would also enhance the research in nonlinear science. The peak power is increased by seeding or self-seeding the FEL to generate a photon pulse with a narrow energy spread, and an almost flat energy distribution. After reaching saturation at peak power of typically 30 GW, the radiation intensity is further increased by tapering, reducing the undulator magnetic field to adjust it to the electron beam energy to preserve the resonant condition. With this method the energy transfer from the electron to the photon beam increases from about 0.1%, typical value at saturation, to about 5% or more. Another application of high efficiency tapered FELs is lithography. This application requires a high average power FEL, about 10kW or more, operating at a wavelength of about 13 nm. The large efficiency of tapered FELs, combined with a high repetition rate superconducting linac, allows the generation of large average power without the need of an energy recirculating linac, using a much lower electron beam average current, with benefits like a smaller repetition rate for a critical component like the electron gun, and a simpler radiation protection system. Several industrial groups are now considering high average power FELs for the next generation of microchips fabrication facilities. For X-ray FELs dedicated to research the larger efficiency, combined with an optical system to split the photon beam in several less intense beams, can be used to operate simultaneously more than one experimental station, reducing the cost.

FY 2014 HIGHLIGHTS

During 2014 we studied the effect of the transverse electron distribution on the output power of a tapered undulator [C. Emma, J. Wu, K. Fang, S. Chen, S. Serkez, and C. Pellegrini, Terawatt x-ray free-electron-laser optimization by transverse electron distribution shaping, Phys. Rev. ST AB, 17, 110701 (2014)], showing that a uniform or parabolic transverse distribution is more efficient than a Gaussian distribution. We studied for the first time the transverse coherence properties of the radiation from a tapered FEL, using the autocorrelation function approach [C. Emma, C. Pellegrini, J. Wu, K. Fang, S. Chen, S. Serkez, Radiation Properties of Tapered Hard X-ray Free-electron Lasers, in Proc. 2014 FEL Conf. Basel (2014)] and a transverse mode decomposition approach [S.D. Chen, K. Fang, X. Huang, C. Pellegrini, J. Wu, C. Emma, S.D. Chen, S. Serkez, Mode Decomposition of a tapered Free-electron Laser, in Proceedings of FEL2014, Basel, Switzerland]. Good transverse coherence is critically important for

coherent diffraction imaging. Our results show that a tapered FEL maintains good transverse coherence and can be used for imaging experiments. More recently we studied step-wise tapering versus continuous tapering and the effect of reducing the undulator period to decrease the undulator length, and thus its cost [C. Emma, J. Wu, P. Emma, Z. Huang, and C. Pellegrini, Tapering studies for Terawatt level X-ray FELs with a superconducting undulator, in course of publication]. We show that, while continuous tapering is most effective, stepwise tapering, easier to realize, also has good efficiency if the step is of the order of the gain length or shorter. We also show that using a step-wise, short period, less than 2 cm, tapered undulator, and standard LCLS beam parameters, it is feasible to reach peak power in excess of 1 TW at photon energies between 5 and 10 keV.

DOE National Laboratories

EARLY CAREER: Diagonalization Solvers for Electronic Collective Phenomena in Nanoscience

Institution: Oak Ridge National Laboratory
Point of Contact: Gonzalo Alvarez-Campot
Email: gz1@ornl.gov
Principal Investigator: Gonzalo Alvarez-Campot
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The objective of this project is to study collective phenomena at the electronic level, using the Density Matrix Renormalization Group (DMRG) algorithm, and to develop and make available the corresponding computational codes. The proposed research will be carried out for realistic models of relevance for practical applications of strongly correlated electronic materials. We aim to understand three aspects: the real time evolution in electron transport, the temperature dependence of electronic properties in nanostructures, and the multiscale nature of the emerging orders in strongly correlated systems.

FY 2014 HIGHLIGHTS

We have completed work on the second aim of this project, the study, use, and implementation of temperature-dependent DMRG. The PI has published a paper on minimally entangled typical thermal states or METTS for fermionic systems, and has made available the corresponding codes to the scientific community, as planned in the original FWP. Work on time-dependent DMRG applied to the study of spin-charge separation and similar 1D phenomena in nanostructures has been published in Physical Review. The PI was invited to give a talk at the 2014 March meeting of the APS, and took the opportunity to promote our nanocenter, and to showcase codes and results obtained from work done under this award.

EARLY CAREER: Research and Development of Detection Systems for Neutron Imaging

Institution: Oak Ridge National Laboratory
Point of Contact: Philip Bingham
Email: binghampr@ornl.gov
Principal Investigator: Philip Bingham
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$2,500,000 (2010-2014)

PROGRAM SCOPE

Neutron radiography (NR) is typically performed in a direct imaging mode (magnification of 1) using scintillator based detectors capable of resolutions in the 50-100 micron range. Neutron optics are not currently feasible for focusing to improve resolution beyond the detector resolutions, so NR systems are designed to place the object as close as possible to the detector resulting in a magnification of one. Such a system design limits the imaging resolution to that of the detector. For magnification with such a pinhole system, the source size is limited to the desired resolution. At the HFIR CG-1D instrument, a common source size is 12mm in diameter, so a magnified setup that achieves 10 micron resolution with a single pinhole would increase exposure time by a factor of 1,440,000. This research effort is focused on development of a Coded Source Neutron Imaging (CSNI) system using magnification to improve resolution without the loss of neutrons associated with a pinhole source. For this system, a mask is positioned between the object and source to produce a source pattern having a known code. The Modified Uniformly Redundant Array (MURA) was previously developed for coded aperture imaging with a 50% open pattern and is being employed for this effort. A coded source mask is a pattern of small apertures with diameters equal to the desired system resolution. In a CSNI system, the recorded image is an overlay of individual radiographs taken by each small aperture in the MURA pattern. Direct deconvolution is traditionally used for reconstruction by correlating the measured projection with a reconstruction kernel specific to the MURA pattern. In this effort, an iterative reconstruction algorithm using a system model that accounts for divergence and source non-uniformities not handled by direct methods is being developed. Key challenges of the effort are manufacturing of the coded mask and development of an iterative reconstruction algorithm.

FY 2014 HIGHLIGHTS

(1) Coded aperture masks have been produced by patterning Gadolinium (Gd) on quartz wafers. Since the quartz wafers are optically clear, mirrored versions of the wafers are being manufactured that will be aligned to double the thickness of the Gd layer in the mask. 10 micron mask resolutions have been repeatedly produced with 9 micron thick Gd and initial tests for 5 micron masks at 4.5 micron Gd thickness have produced usable masks. (2) Quantitative testing of coded source imaging at HFIR CG-1D has been performed using a resolution target manufactured along with the coded apertures. Direct deconvolution reconstructions have shown resolutions down to 20 microns with magnifications above 20x such that the resolution target is placed over 5 meters away from the detector. (3) A methodology and algorithm for measurement of beam nonuniformity and variations in the nonuniformity for each pinhole in the aperture has been developed that captures a few images with larger pinholes and interpolates to model the source distribution for each mask hole. (4) Iterative reconstruction code has been modified to incorporate complex source distribution model.

Detector R&D

Institution:	Lawrence Berkeley National Laboratory
Point of Contact:	Peter Denes
Email:	pdenes@lbl.gov
Principal Investigator:	Peter Denes
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding:	\$800,000 (2014)

PROGRAM SCOPE

The goal of this detector R&D effort is to innovate soft X-ray detection solutions (the overwhelming majority of X-ray detector development in the world today is for hard X-ray detectors) that maximize the scientific reach of the ALS, and to collaboratively improve the state of the art in X-ray detection at other storage ring and FEL-based light sources. Detectors we have developed are in use at ALS, APS and LCLS; and are being prepared for use at NSLS-II and EuXFEL, and potentially several other light sources world-wide. Current R&D efforts are focused on a fine-pitched Charge-Coupled Device (CCD) detector for high resolution Resonant Inelastic X-ray Scattering (RIXS), and increasing frame rates by use of a fully column parallel CCD. In addition, we have demonstrated very thin contacts, essential for high efficiency soft X-ray detection, and are bringing on line an ultra-thin contact process using molecular beam epitaxy (MBE). Lastly, we are leveraging other work in CMOS active pixel sensors and detector thinning to produce CMOS-based soft X-ray detectors.

FY 2014 HIGHLIGHTS

In FY14, we developed a complete electronics and mechanics system for high resolution RIXS. We have also started to deploy CCD detectors with <10 nm thick contacts. For the thinnest contacts, on a larger variety of detectors, we have installed and qualified an MBE-based system, with first detectors expected in FY15. Lastly, we have designed new, high speed clocking electronics for the fully column parallel CCD capable of 10s of kHz frame rates.

EARLY CAREER: Generation and Characterization of Ultra-short Electron Beams for X-ray Free Electron Lasers

Institution:	SLAC National Accelerator Laboratory
Point of Contact:	Yuantao Ding
Email:	ding@slac.stanford.edu
Principal Investigator:	Yuantao Ding
Sr. Investigator(s):	
Students:	1 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding:	\$2,500,000 (2010-2014)

PROGRAM SCOPE

This 5-year project starting from 2010 is to innovate and develop new methods for generating and characterizing femtosecond time-scale electron bunch and x-ray pulses at free-electron laser (FEL) facilities. The x-ray FEL, such as the Linac Coherent Light source (LCLS) at the SLAC National Accelerator Laboratory, has provided a unique tool in many research fields since 2009 with typical pulse durations between 10s to 100s femtoseconds. The x-ray FEL user community is also interested in even shorter x-ray pulses, like a few femtoseconds or attoseconds scale, that would enable many new ultrafast studies such as time-resolved electronic dynamics, with widespread applications in physics, chemistry and biology. Generating ultra-short pulses is a formidable challenge requiring theoretical and experimental breakthroughs to develop new concepts for future design and upgrade of x-ray FEL facilities. An additional challenge is to develop methods to measure the length of ultra-short pulses below 1 fs. The project focuses on two topics: (1) develop new techniques and instruments to characterize femtosecond-scale electron and x-ray pulses; (2) investigate and improve short pulse operation based on the developed diagnostics, and explore new methods to push the short pulse limit down to sub-femtosecond scale.

FY 2014 HIGHLIGHTS

Substantial progress has been made during FY 2014. A recently developed X-band transverse deflector has been ready at the LCLS providing a time resolution below 1 fs rms for soft x-ray FELs (Nature Communications 5, 3762 (2014)). We performed extensive studies with this new tool to understand the lasing process and short pulse generation such as low-charge mode and emittance spoiling-foil scheme. This enables direct time-domain measurement shot by shot for user experiments and demonstrates flexible control of the x-ray pulse duration using the foil scheme. A benchmark study for the deflector method has been performed using a high-resolution spectrometer with excellent agreement has been achieved. With the help of this new diagnostic tool, we have also explored new schemes for short pulse generation, such as a two-bunch operation mode and a new nonlinear compression scheme for attosecond pulse generation.

EARLY CAREER: Large Dynamic Range Beam Diagnostics and Beam Dynamics Studies for High Current Electron LINACs

Institution: Jefferson Lab
Point of Contact: Pavel Evtushenko
Email: pavel.evtushenko@jlab.org
Principal Investigator: Pavel Evtushenko
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The goals of this program are to develop new instruments for electron beam diagnostics and use these instruments for beam measurements and studies of beam dynamics that were not possible so far. The main emphasis of the diagnostics development is the significant increase in the dynamics range of the measurements from about 10^3 to about 10^6 . The ultimate goal of the beam dynamics studies is to measure distribution of the beam in transverse and longitudinal phase space with such large dynamic range (LDR). The motivation for this work is the following. On one hand, pulsed, normal conducting, but low average current LINACs provide exceptionally bright beams for the new generation of synchrotron light facilities – the X-ray Free Electron Lasers (FEL). The FEL community is actively working towards extending capabilities of X-ray FELs to high current, high average brightness operation, for instance as the LCLS-II projects intends to do. It is envisioned to accomplish this using Constant-Wave (CW) Superconducting Radio Frequency (SRF) LINACs and increasing the average beam current by many orders of magnitude, while operating with present peak beam brightness. With such large increase in the average beam current and beam power a very small ($\sim 10^{-6}$) fraction of the beam, if not managed and transported properly, can lead to fast degradation of expansive components of the FEL or even to accelerator components destruction, or will prevent required high current operation. When designing, constructing and commissioning such new facilities it is necessary to measure and take in to account fractions of the beam as small as 10^{-6} . This is a non-trivial task. On the other hand, the FEL facility and CEBAF at Jefferson Lab operated with the CW electron beam and large average beam current. This provides the opportunity for the instrumentation development and testing with beam as well as development of experimental techniques, which can be used to understand beam evolution with the LDR.

FY 2014 HIGHLIGHTS

In the past year we made significant progress in improving the dynamic range of the electron beam diagnostics under development. We have completed physics design as well as mechanical design of a novel non-intercepting diagnostic system based on a Thomson laser scattering. This diagnostic is intended for beam measurements with a CW electron beam. It is intended for a transverse beam profile measurements with sub picosecond time resolution, and for longitudinal phase space measurements as well. Working towards first experimental demonstration of such system, we have identified an appropriate laser system, which was purchased, installed and commissioned at the facility where the demonstration will take place. The main direction of our effort on transverse beam profile measurements is beam imaging i.e. 2D transverse beam profile measurements. Diffraction is the main challenges for large dynamic range imaging. Working on this problem we have implemented a new numerical code for simulation of optical field propagation. It is based on quasi-discrete Hankel transform. Its advantage over other codes is that it allows simulations of systems with significantly larger aperture and requires a significantly smaller amount of computer memory. In turn this allows us to complete such calculations without a supercomputer. We have used the code to design an amplitude apodized imaging system where diffraction effects are reduced by several orders of magnitude. Then we have manufactured and bench tested such amplitude apodized optical system experimentally demonstrating significant reduction of the diffraction effects, although not quite as strong as simulations were predicting, which requires further studies. We are also working on an alternative to the beam imaging transverse beam profile measurements technique, which does not require an optical system and therefore is not affected by diffraction. This technique is an improvement of existing wire-scanner diagnostic.

EARLY CAREER: High Repetition Rate Ultra-Fast Electron Diffraction Development

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Daniele Filippetto
Email: dfilippetto@lbl.gov
Principal Investigator: Daniele Filippetto
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Ultrafast phenomena have been one of the main research topics during the last decade. Thanks to the combination of ultra-fast pulses and pump-probe techniques, the observation of transient effects with atomic resolution is becoming a reality. Scientists are pursuing the dream of molecular and atomic movies that will clarify the connections between the structure and the function of biological systems, and enhance our understanding of chemical and biochemical reactions, following transformation pathways. We are pursuing the use of the Advanced Photocathode Experiment (APEX) photo-gun as novel source for time-resolved electron diffraction studies. The electron source has been designed, built and successfully tested at LBNL. It combines, unique in its genre, the high accelerating field needed for bright beams, MeV electron energy essential for time resolution in gas-phase experiments and studies of bulk processes, together with continuous (CW) operations. Ultra-short electron pulses can be delivered with a maximum repetition rate of around 186 MHz at the sample, enabling new science and

new experimental techniques. As an example, structural transitions of complex isolated molecules in gas phase could be imaged with sup-picosecond time resolution.

FY 2014 HIGHLIGHTS

This research program started July 1, 2015. In these first months, most of the effort was directed to the study and design of a beamline optimized for ultrafast electron diffraction experiments, delivering high brightness beams with a large parameter space to the sample chamber. Aberrations, space charge, and electron-electron scattering have been taken into account in simulating the results by using many different codes. The flexibility in time duration and energy spread was ensured by the use of A CW rf-buncher after the electron gun and by a low energy achromatic dog-leg. Beam compression down to 100 femtoseconds has been simulated, with 1 million particles per bunch, and down to 25 femtoseconds with collimating 70% of the charge. The beamline has been designed and the hardware is on order. Installation up to the sample chamber is expected to start in early spring 2015. Work on the laser system has started, stabilizing in time, energy and pointing, taking advantage of the high repetition rate for suppressing the noise up to high frequencies. The pointing jitter at the cathode was decreased down to 5 microns root mean square, and work on the time jitter is ongoing.

Demonstration of the Viability of SCU Technology for an FEL-Type Undulator

Institution:	Argonne National Laboratory
Point of Contact:	Efim Gluskin
Email:	gluskin@aps.anl.gov
Principal Investigator:	Efim Gluskin
Sr. Investigator(s):	Yury Ivanyushenkov; Argonne National Laboratory
Students:	0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding:	\$200,000 (2014)

PROGRAM SCOPE

This project is part of a larger scope project, in collaboration with SLAC, ANL, and LBNL, to demonstrate the viability of superconducting undulator (SCU) technology for FELs, by building, measuring, testing, and correcting two 1.5-m long prototype SCU's using two different technologies. The first technology is based on conductors of NbTi, the chosen technology at ANL, and the second is Nb₃Sn, the choice at LBNL. The specific scope of work is to design and oversee the integration of a universal magnetic mounting system that allows two completely different superconducting magnets to be consecutively tested in a single, multipurpose cryostat. The funding is utilized for engineering and physics support during the development period. The ANL deliverable is the design of the universal mounting system and vacuum chamber that allows two different undulator magnets to be consecutively installed and tested in the ANL-designed cryostat that houses the entire SCU. ANL engineers and physicists optimized the design of the existing cryostat and cold mass to add the flexibility of accommodation of various types of undulatory and beam vacuum systems.

FY 2014 HIGHLIGHTS

A universal magnetic mounting system has been designed and is currently under fabrication to support the LCLS SCU Project. The system will support the operation, testing, measurement, and tuning of two distinct SCU magnets: a NbTi-based magnet fabricated by the ANL, and a Nb₃Sn-based magnet built by the LBNL. The system is an extension of proven SCU technology at ANL and is compatible with an

existing cryocooler-based SCU cryostat design. The magnetic mounting system has been further modularized to allow independent fabrication and assembly of two completely different superconducting magnet prototypes on separate, interchangeable 'cold mass' frame systems. These systems can be quickly exchanged following a magnet test with minimal disturbance to the cryostat itself. Building two separate and independent frame systems permits parallel fabrication and assembly of each magnet design. Each system supports the specific needs of the magnet, including cooling connections, beam vacuum chamber systems, current leads, tuning/shimming systems, and support/alignment systems. The systems share common suspension points to the overall cryostat and are designed for maximum heat loads that do not exceed the available cooling power of the cryostat. The beam vacuum chamber for each frame system is based on a common extrusion profile but is tailored to the magnet. This provides compatibility with particular features of each magnet design while preserving identical thermal transition interface points at the cryostat ends.

EARLY CAREER: High Performance Toolkit for Photon Science

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Alexander Hexemer
Email: ahexemer@lbl.gov
Principal Investigator: Alexander Hexemer
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Light sources are Basic Energy Science facilities that serve thousands of researchers per year. These facilities are currently generating scientific data faster than can be analyzed using the computational methods of the past, so that scientific discovery is limited by the inability to rapidly analyze large data sets. The high performance toolkit will accelerate the rate of scientific discovery by enhancing the rate at which data can be analyzed. The main focus will be to develop and expand tools for analyzing large volumes of light source data. All tools in the toolkit will be optimized for parallelization on multiple central processing units (CPU), graphical processor units (GPU), and hybrid CPU/GPU multicore architectures. This will decrease analysis times by several orders of magnitude while simultaneously permitting larger data sets to be processed. The initial focus will be in the development of tools for scattering, in particular for grazing incidence small angle X-ray scattering and small angle X-ray scattering. An easy-to-use graphical user interface will be developed for the toolkit that can be easily accessed by a broad scientific audience.

FY 2014 HIGHLIGHTS

The main focus over last year has been the development of the toolkit for real-time applications at a synchrotron. Currently, scientists visiting synchrotrons most commonly copy their collected data onto portable hard drives, only to look at the data in detail after their time has already ended. The scientists have no means of adjusting or evaluating the experiment during the beamtime. However, creating instant feedback will supply the experimenter with knowledge to adjust their experiments and hence optimize the beamtime without having to wait usually several months for the next beamtime. In order to move into this regime, our developments over the last year focused on new and high performance algorithms to fit small angle X-ray scattering and grazing incidence small angle X-ray scattering data. These developments are now part of the "Center for Applied Mathematics for Energy Research

Applications: CAMERA.” The new developments were demonstrated as part of a larger effort to illustrate the concept of a “super facility” and evaluate the current state of the art for real-time analysis. The concept of a Super Facility is the seamless integration of multiple, complementary DOE Office of Science User Facilities into a virtual facility that presents a fundamentally greater capability for users. The multiple DOE User Facilities involved in the Demonstration were ALS (BES), NERSC (ASCR), OLCF (ASCR), ESnet (ASCR) and several other efforts: Globus Online (ANL) and SPOT (LBNL-CRD). We illustrated the ability for researchers, doing time-resolved work at a scattering beamline, to see near real-time analysis of their samples, running a large scale simulation on Titan at OLCF orchestrated and presented, without user interaction, using SPOT. Thus, enabling researchers, for the first time, to understand their samples sufficiently during beamtime and to adjust the experiment to maximize their scientific results.

Superconducting Spectrometers for Next Generation Light Sources: Making Every Photon Count

Institution: SLAC National Accelerator Laboratory
Point of Contact: Kent Irwin
Email: kdirwin@slac.stanford.edu
Principal Investigator: Kent Irwin
Sr. Investigator(s): Antonino Miceli; Argonne National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$832,400 (2014)

PROGRAM SCOPE

SLAC, ANL, and NIST are developing superconducting x-ray spectrometers for DOE light source applications. The higher efficiency provided by the Transition-Edge Sensors (TES) x-ray spectrometers will enable important new science at both free-electron and synchrotron facilities. Superconducting spectrometers can increase the solid angle by more than two orders of magnitude over gratings, providing new capabilities to measure metals with L emissions in the soft x-ray regime, including Ti, V, Cr, Mn, Fe, Co, Ni, and Cu, which are critical components to systems as diverse as the Photosystem II part of the photosynthetic pathway and advanced magnetic-information storage devices. This new capability will broadly impact x-ray emission and x-ray absorption spectroscopy in the soft-, tender-, and hard x-ray regimes. Scanning-nanoprobe-imaging beamlines will also benefit greatly from superconducting spectrometer arrays, resolving essentially all elemental x-ray fluorescence overlaps and also provide a wealth of chemical detail in x-ray emission spectra in acquisition times much smaller than previous instrumentation. The US leads the world in the development of superconducting x-ray spectrometers. Capitalizing on this lead enables unique capabilities and instrumentation that will provide a competitive advantage for US light sources. This program unleashes the true potential of this technology at the next generation of free-electron laser facilities and in synchrotron light sources.

FY 2014 HIGHLIGHTS

While this is a new program that has just begun, significant progress has already occurred. During the first few months of this work, we have (1) Designed soft x-ray pixels with a higher response time. We are proceeding to fabricate and test them. If successful, these pixels will be a significant step towards operating superconducting spectrometers on next generation free-electron light sources with higher anticipated frame rates. (2) For the first time, we have designed, fabricated, and tested microwave SQUID multiplexer chips with a much higher per-pixel bandwidth than previously achieved. This accomplishment is a significant step towards larger and faster superconducting spectrometer arrays for

both FEL and synchrotron facilities. (3) We have initiated a study of a comprehensive range of science experiments at both LCLS-II and the APS. This study will establish performance metrics for superconducting spectrometer instruments to study a wide range of high-impact science problems at both facilities.

Oscillator-Type X-Ray Free Electron Laser to Realize the Full Potential of X-Ray Lasers for Materials Sciences and Fundamental Physics

Institution: Argonne National Laboratory
Point of Contact: Kim Kwang-Je
Email: kwangje@aps.anl.gov
Principal Investigator: Kwang-Je Kim
Sr. Investigator(s): Yuri Shvydko; Argonne National Laboratory
Deming Shu; Argonne National Laboratory
Students: 0 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$400,000 (2014)

PROGRAM SCOPE

The X-ray free-electron laser oscillator (XFEL) is a device that combines the brightness of an FEL with the stability of a storage ring and the energy bandwidth of a high-resolution monochromator. The fully coherent, ultra-high spectral purity of hard x-ray pulses from an XFEL will drastically expand the reach of techniques developed at third-generation sources, offering the prospect of solving problems such as the physics of high T_c superconductivity. The XFELs and high-gain amplifiers will complement each other—together they will realize the fullest potential of FEL-based photon sciences. If an XFEL operates at one of the higher harmonic frequencies, the electron energy need not be very high, and one can significantly reduce the construction and operating costs of the CW superconducting accelerator. Thus, XFEL operation appears to be feasible at the future LCLS-II facility with the planned 4 GeV CW superconducting Radio-Frequency (RF) linac and a part of the Hard X-ray (HXR) undulator. Furthermore, the successive XFEL pulses can in principle be phase-locked to each other by stabilizing the cavity roundtrip time to within a small fraction of the wavelength, by referencing the output to an absolute external reference, such as the narrow nuclear resonance line of ^{57}Fe . A mode-locked XFEL with its x-ray spectral comb can serve as a powerful new tool for x-ray metrology and fundamental physics. The R&D goal of this proposal are: to establish the tolerance limits for errors and jitters, to assess the possibility of operating a harmonic XFEL at the LCLS-II in collaboration with SLAC National Accelerator lab scientists, to perform a feasibility study of inter-pulse mode-locking of XFEL for x-ray spectral comb generation, and to complete an experimental study of radiation damage issues of diamond crystals which serve as the near-normal incidence reflectors of the x-ray cavity. We plan to hold a two-day workshop exploring the scientific opportunities offered by an XFEL.

FY 2014 HIGHLIGHTS

(1) Progress in diamond crystal durability test: A beam time is allocated at the APS 34 ID-E for 2015-1 run to irradiate a diamond sample with the insertion device (ID) beam focused to 0.5 micron spot size generating power density comparable to the XFEL environment. The sample chamber is being constructed. A postdoc offer is in progress to work on the diamond durability experiment. (2) In collaboration with the SLAC LCLS group: A concrete scheme of an XFEL at ESA (End Station A) building was considered. A zigzag optical cavity will fit in this building either with 2 MHz operation of the accelerator, or with 1 MHz operation. Be-CRLs (compound refractive lenses), rather than the large and heavy K-T mirrors, are determined to be a low loss, compact option as the focusing elements. The

spectral flux in meV from an XFEL at LCLS II will be three orders of magnitudes higher than that can be obtained by nonlinear harmonic generation of high-gain operation of LCLS II assuming a superconducting undulator for the latter. Scientifically, an XFEL at LCLS II could provide unique tools to address the question of the underlying physics of the emergent phenomena in strongly correlated electron systems with the obvious example: high T_c superconductivity. This will be an essential extension of the LCLS II capability.

EARLY CAREER: High Resolution Spectroscopic X-ray Detectors using Superconducting Sensors

Institution: Argonne National Laboratory
Point of Contact: Antonino Miceli
Email: amiceli@anl.gov
Principal Investigator: Antonino Miceli
Sr. Investigator(s): Thomas Cecil; Argonne National Laboratory
Lisa Gades; Argonne National Laboratory
Timothy Madden; Argonne National Laboratory
Students: 0 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$2,500,000 (2010-2014)

PROGRAM SCOPE

This detector R&D program intends to develop the next-generation of energy dispersive detectors using superconducting technology. Currently, we are focusing on developing a superconducting technology called microwave kinetic inductance detectors (MKIDs), which is a resonator-based technology. This detector R&D is targeted for high resolution x-ray spectroscopic applications, such as x-ray emission and absorption spectroscopy, but also has the potential to impact techniques such as Compton scattering and energy-dispersive diffraction at high energies. The overall goal is to develop broadband energy-dispersive detectors with energy resolutions < 5 eV at 10 keV with count rates comparable to silicon drift diodes. For example, this detector could make possible x-ray emission spectroscopy at scanning nanoprobe. For superconducting detectors, the ability to multiplex is crucial to reach high count rates and large solid-angles (i.e., many pixels). MKIDs can be multiplexed in a straightforward manner and can reach pixel counts of about 10,000. An Early Career Award (4/2010 - 4/2015) has made this R&D possible. The goal of the Early Career Award is to determine whether or not MKIDs themselves can be used as the sensor or whether it is better to couple MKIDs to another technology (e.g., resonator readout SQUID/TES arrays) in collaboration with other groups.

FY 2014 HIGHLIGHTS

We have published a paper using kinetic inductance detectors in quasi-thermal equilibrium. However, improvements in the noise performance are necessary. To this end, we have developed a fabrication process to etch sloped sidewalls in silicon nitride in order to grow the capacitor on bare silicon. The multiple pixel readout using the Robotic Autonomous Crawling Hexapod (RoACH) electronics continues with firmware development to allow using Fast Fourier Transforms (FFTs) to sweep the resonator and firmware for pulse thresholding the data. We are able to acquire triggered pulse data from up to 256 resonators. We are developing a new method of pulse processing using a multivariate analysis which assumes no prior knowledge of the data. In particular, we use principal component analysis (PCA) to reduce and noise-filter the data, followed by cluster analysis to classify similar pulses. PCA provides an orthogonalized, decomposed representation of the data by their degree of covariance and thus significance. By selecting the first few components according to their degree of covariance, and

rebuilding the data matrix, main features remain and noise is filtered. PCA is a non-parametric analysis which is in contrast to more traditional pulse processing methods (e.g., optimal filters), which are parametric methods and assume some prior knowledge of the dataset (e.g., known signal shape). These parametric methods maximize the signal to noise under the conditions that the pulse shape and noise are stationary, and the pulse shape is linear. However in real detectors, these conditions are not always satisfied. Our goal is to improve on the optimal filter with a PCA-based method. This method is applied to a simulated data set as well as a data set from an x-ray thermal kinetic inductance detector and an x-ray TES detector. We demonstrated that the PCA is able to fit pulses with severe position dependence. We continue to develop this method in order to treat data which have variable pulse shapes with energy (i.e., non-linear pulses).

EARLY CAREER: Inorganic Nanocomposite Electrodes for Electrochemical Energy Storage and Energy Conservation

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Delia Milliron
Email: milliron@che.utexas.edu
Principal Investigator: Delia Milliron
Sr. Investigator(s): Jeffrey Neaton; Lawrence Berkeley National Laboratory
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$2,500,000 (2010-2014)

PROGRAM SCOPE

Dr. Milliron proposes to develop a combinatorial approach to solution-processed inorganic nanocomposite materials as a new route to the complex physical properties required for efficient energy storage and conservation devices. Inorganic nanocomposites have recently emerged as a means of controlling the properties of electronic materials through morphology as well as composition to give rise to combinations of properties not generally found in homogeneous, single-phase materials. For example, electrodes for batteries and electrochromic window coatings must efficiently conduct both electrons and ions to achieve high power and efficient coloration, respectively. The Milliron group has recently demonstrated a new method for preparing inorganic nanocomposites from solution-processible colloidal nanoparticle and molecular building blocks in a combinatorial manner. Here, we propose to apply this general approach to the fabrication of well-controlled, chemically and morphologically tunable inorganic nanocomposites for electrochemical energy applications. First, silver chalcogenide nanoparticles are investigated as model mixed ionic and electronic conductors. These are embedded in a semiconducting matrix and the interfacial area is systematically varied to reveal the contribution of interfaces to the overall ionic and electronic transport behavior. These properties suggest design rules to guide the development of highly efficient mixed conductors for energy applications. Going beyond transport, this nanocomposite platform will be further developed to resolve fundamental questions in order to guide the development of advanced battery and electrochromic device electrodes. Nanocomposite battery electrodes will be fabricated and electrochemically characterized in an effort to uncover the source of rapid degradation in charge capacity which currently limits practical application of ultrahigh energy density conversion materials, such as tin and germanium compounds.

Accelerator R&D for a Soft X-Ray FEL: Echo-Enhanced Harmonic Generation

Institution: SLAC National Accelerator Laboratory
Point of Contact: Tor Raubenheimer
Email: tor@slac.stanford.edu
Principal Investigator: Tor Raubenheimer
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$1,000,000 (2014)

PROGRAM SCOPE

The Echo Enabled Harmonic Generation (EEHG) technique is a promising approach for external seeding of a soft x-ray Free Electron Laser. External seeding offers the promise of x-ray pulse shaping and control analogous to that demonstrated with optical lasers. The EEHG technique relies on beam manipulation rather than laser manipulation to up-shift the frequency of the external seed which should provide more stable and easily controlled output pulses. EEHG has been demonstrated at harmonic numbers as high as 7. This program will study the EEHG approach at harmonic numbers as high as 75 in a phased approach to gain maximal understanding to the technique and the fundamental physics. In parallel, this program will study approaches to generating the necessary external laser seed which must have excellent control of the laser spectral phase and the laser wavefront. The benefit will be a much better understanding of the external seeding approaches and, if successful, these two elements could be combined in a facility to provide an external seed of <3 nm.

FY 2014 HIGHLIGHTS

In FY14, the program made a very clear comparison between the EEHG (Echo) and High-Gain Harmonic Generation approaches at the 15th harmonic showing the improved beam and radiation stability that Echo will achieve. The program then began the upgrade program to reach higher harmonics. Along these lines, the VISA undulator segment was shipped from Brookhaven National Laboratory, refurbished at SLAC, and then installed in the NLCTA tunnel. Commissioning of the VISA undulator will begin in early FY15 and measurements of the 30th and 75th harmonics will be made in mid- and then late FY15, respectively.

EARLY CAREER: Combining Scanning Probe Microscopy and Synchrotron Radiation for Nanoscale Imaging with Chemical, Electronic and Magnetic Contrast

Institution: Argonne National Laboratory
Point of Contact: Volker Rose
Email: vrose@aps.anl.gov
Principal Investigator: Volker Rose
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

The objective of this research is to develop a novel high-resolution microscopy technique, synchrotron x-ray scanning tunneling microscopy (SX-STM), for imaging of nanoscale materials with chemical, electronic, and magnetic contrast. SX-STM will combine the sub-nanometer spatial resolution of scanning probe microscopy with the chemical, electronic, and magnetic sensitivity of synchrotron radiation. The development will drastically increase the spatial resolution of current state-of-the-art x-ray microscopy from only tens of nanometers down to atomic resolution. The technique will enable fundamentally new methods of characterization, which will be applied to the study of energy materials, nanoscale magnetic systems, and site-specific heterogeneous catalysis. A better understanding of these phenomena at the nanoscale has great potential to improve the conversion efficiency of quantum energy devices, lead to advances in future data storage applications, and yield more efficient catalytic reactions.

FY 2014 HIGHLIGHTS

Using our novel and patented topo filter as well as new method to fabricate specialized smart tips we have achieved record-breaking elemental contrast of Ni islands on a Cu substrate at the ultimate limit of single atomic height and a lateral spatial resolution of 2 nm. We were able to conclude that electron tunneling causes the high spatial resolution and not photoejection as previously believed. The topo filter allows separating topographic information from chemical and magnetic data that are otherwise convoluted in the SX-STM signal. In this way we have achieved stable tunneling conditions even during high brilliance x-ray radiation of the sample. Further, we have used molecular beam epitaxy and focused ion beam milling to fabricate metal-insulator-metal smart tips that focus signal detection to the apex and provide therewith highly localized information. We have successfully extended the materials that can be used for smart tip fabrication, starting from Pt-Ir to W, Fe, and Gd. Methods for the growth of insulator-metal films with painted contacts have been developed. In order to enable measurements at photon energies in which air absorption would become restrictive we have developed and built a

custom high-speed ultra-high vacuum compatible optical beam chopper. It delivers a modulated tip and sample current that is used for lock-in analysis. A custom ultra-stiff x-y-z-r manipulator equipped with LHe flow cryostat was developed. It provides cooling capabilities for a new microscope that we have built. It will be the world's first low-temperature SX-STM. We have built a vacuum suitcase to transfer samples between the microscopy chamber and a separate preparation chamber in order to maximize actual measurement time at the synchrotron. An *in situ* nanopositioning system with 5 degrees of freedom was designed. It enables alignment of a focusing x-ray capillary or zone plate. The focusing element drastically enhances the flux density for SX-STM experiments.

High Repetition Rate Photoinjector

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Fernando Sannibale
Email: fsannibale@lbl.gov
Principal Investigator: Fernando Sannibale
Sr. Investigator(s):
Students: 2 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)
Funding: \$3,494,000 (2014)

PROGRAM SCOPE

The project 'High Repetition Rate Photoinjector' (a.k.a. Advanced Photo-injector EXperiment or APEX) at the Lawrence Berkeley National Laboratory is dedicated to the development of a new concept high repetition rate high-brightness electron source for free electron laser applications. The successful development of such source will critically impact the performance of future 4th generation light sources when MHz-class repetition rates are required. The core of the system is the Very High-Frequency (VHF)-Gun, a normal-conducting continuous wave (CW) RF gun where electrons are generated by laser-induced photo-emission on high quantum efficiency (QE) cathodes and accelerated up to an energy of 750 keV. The gun cavity resonates at 186 MHz, the 7th sub-harmonic of 1.3 GHz. The low frequency makes the resonator size large enough to lower the power density on the cavity walls at a level that conventional cooling techniques can be used to run in CW mode. A second advantage of the low frequency is the long wavelength that allows for large apertures on the cavity walls with negligible field distortion. Such apertures provide the vacuum conductance necessary to achieve the low pressures required to operate the sensitive QE cathodes with acceptable lifetime. A last advantage of such a scheme is that it is based on mature and reliable RF and mechanical technology, an important characteristic to achieve the reliability required to operate in a user facility. The APEX project was initiated at the end of 2009 to develop over 6 years the VHF-gun and test its capability of operating in an injector delivering the necessary performance. APEX is organized in 3 stages (Phase 0, I and II), with the first 2 dedicated to the development and testing of the gun, cathode testing and electron beam characterization at the gun energy. In Phase II, a linac is added to the VHF-Gun to accelerate the beam up to 30 MeV reducing space charge forces to perform a reliable characterization of the gun brightness performance.

FY 2014 HIGHLIGHTS

(1) Tests of the high QE cesium telluride cathodes were completed and requirements were satisfied by large margin. The cathodes were tested at 1 MHz repetition rate with charges per bunches ranging from few tens of pC to beyond 300 pC. QE and QE lifetime were measured over many days at the nominal gun power. Minimal requirements for those quantities (based on LCLS-II needs) were demonstrated by a

large margin. In general, QEs above 10% and QE lifetime of more than 30 days were measured. Such results represent the successful demonstration of one of the main milestones of the APEX program. (2) In high repetition rate FEL and ERL applications, containing the level of dark current emitted by the gun is fundamental to avoid radiation damage of downstream accelerator components and/or quenching of superconducting RF structures. Dark current was characterized at APEX and the results showed a figure (350nA) that already meets the LCLS-II requirements of less than 400 nA. The tests also allowed defining a multistep strategy to further reduce dark current. A paper reporting such results has been recently accepted for publication on Phys. Rev. Special Topics, Accel. and Beams. (3) Phase-I beamline with its diagnostic system for the 6D characterization of the beam phase space was completely installed. Phase-I commissioning initiated in June 2014 but was interrupted in August due to a failure in one of the coaxial lines that feed the power to the gun. The event caused the rupture of a RF window and the gun contamination. The recovery from the failure is now being completed and the beam tests will restart after the RF conditioning of the cavity. (4) Phase II activity achievements included, finalizing the design of the RF distribution network and of the buncher, initiating the fabrication of the linac accelerating sections, performing most of the acceptance test of the RF system that feeds the power to the linac and to the deflecting cavity, assigning the bid for the buncher RF source.

Advanced Photon Detector Development for Synchrotron Radiation Applications

Institution: Brookhaven National Laboratory
Point of Contact: Peter Siddons
Email: siddons@bnl.gov
Principal Investigator: Peter Siddons
Sr. Investigator(s):
Students: 1 Postdoctoral Fellow(s), 0 Graduate(s), 1 Undergraduate(s)
Funding: \$600,000 (2014)

PROGRAM SCOPE

The project conducts research and development of advanced x-ray detectors for synchrotron radiation applications. It includes custom detectors for x-ray correlation spectroscopy experiments and for high-energy x-ray diffraction.

FY 2014 HIGHLIGHTS

Successful demonstration of the first 3D-integrated x-ray detector and its application to x-ray correlation spectroscopy experiments. Capture of events at a 153 ns resolution was demonstrated, and correlation measurements to well below 1 ms (limited only by the available beam intensity) were made. A new 64-element germanium detector was fabricated and integrated with BNL-designed application specific integrated circuits (ASICs) to form a 1D position-sensitive spectroscopic detector ideally suited to time- and position-dependent structural changes, for example in an operating battery.

Photocathodes for High Repetition Rate Light Sources

Institution: Brookhaven National Laboratory
Point of Contact: John Smedley
Email: smedley@bnl.gov
Principal Investigator: John Smedley
Sr. Investigator(s): Howard Padmore; Lawrence Berkeley National Laboratory
Students: 3 Postdoctoral Fellow(s), 1 Graduate(s), 0 Undergraduate(s)

Funding: \$621,500 (2014)

PROGRAM SCOPE

The focus of this program is on photocathodes for high repetition rate Free Electron Lasers (FELs) and Energy Recovery Linacs (ERLs), including testing in a variety of photoguns. Teams from BNL and LBNL lead this work, which involves collaborators from ANL and Helmholtz Zentrum Berlin (HZB). This work follows on from a successful previous project that developed and applied the tools of modern materials science to understand and optimize cathode performance. The program is concentrated in three areas: a) Physics and chemistry of alkali-antimonide cathodes (BNL – LBNL) b) Development and testing of a diamond amplifier for photocathodes (BNL) c) Tests of both cathodes in copper RF photoguns (LBNL)

FY 2014 HIGHLIGHTS

For most of 2014, our focus has been on optimizing Alkali antimonide cathodes to produce smoother surfaces. Our previous work had demonstrated that these cathodes have a significant roughness (25 nm RMS roughness, with a 100 nm spatial period, for a 50 nm thick film), even when grown on an atomically smooth surface. Our previous work also demonstrated a correlation between the applied electric field and the emittance of the electrons emitted from the cathode (this measurement was made with a custom device that was invented at LBNL as part of this work). The observed roughness explains this correlation; this in turn suggests that the growth process must be modified to achieve cathodes with less roughness, while still maintaining high quantum efficiency. We have identified the source of this roughness to be the dissolution and recrystallization of the crystalline antimony precursor layer upon deposition of potassium. We have varied our deposition process to avoid the production of crystalline antimony - instead using a multilayered approach. This produced a cathode with 60% of the ideal Quantum Efficiency (QE), but almost an order of magnitude (3.3 nm vs 25 nm) reduction in roughness. This development will continue in 2015 to explore both co-deposited films and sputtered film - the production of a viable sputter target for this material was another significant accomplishment of this program in 2014.

Ultrafast Science Enabled by Femtosecond MeV Electron Diffraction

Institution: SLAC National Accelerator Laboratory
Point of Contact: Xijie Wang
Email: wangxj@slac.stanford.edu
Principal Investigator: Xijie Wang
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 2 Graduate(s), 1 Undergraduate(s)
Funding: \$574,000 (2014)

PROGRAM SCOPE

SLAC is working on an Ultrafast Electron Diffraction (UED) R&D program with the goal of providing MeV-, 100-femtosecond-scale electron pulses to support an ultrafast science program. The UED R&D will be carried out using the existing infrastructure at the ASTA accelerator test bunker at SLAC. It will be the first UED implementation to break the 100-fs time resolution barrier, and it will have an order of magnitude higher repetition rate (120 Hz vs. 10 Hz) than other existing UED implementations. The first experimental results are expected in early September 2014.

FY 2014 HIGHLIGHTS

ASTA UED was successfully commissioned in early September of 2014. Single-shot diffraction patterns were obtained for Au and Bi films. This is the first step towards establishing sub-100 fs ultrafast electron diffraction for probing the nuclear motion in photo-chemistry and materials science.

EARLY CAREER: Visualizing and Controlling Energy Excitation and Transport in Mesoscale Organic and Inorganic Material Composites

Institution: Lawrence Berkeley National Laboratory
Point of Contact: Alexander Weber-Bargioni
Email: AFWeber-Bargioni@lbl.gov
Principal Investigator: Alexander Weber-Bargioni
Sr. Investigator(s):
Students: 3 Postdoctoral Fellow(s), 0 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Energy is created in matter from light via quantum excitations: electron excitations, phonons, bound electron-hole pairs (excitons), and collective excitations (plasmons). Since the advent of quantum mechanics these 'creation' processes have been studied and are relatively well understood. To utilize the energy however we need to understand how this energy can be propagated from its point of origin, at the molecular level, to mesoscopic, microscopic and macroscopic distances, where it can be harnessed. It is the study of these transport processes that are at the core of this proposal.

Harnessing and deliberately directing energy created by material excitations is yet to be demonstrated at meaningful length scales for energy device architectures. Of specific interest are excitons that constitute the core of light-matter interactions and mediate all opto-electronic conversion processes in nano building units, such as molecules or nano crystals. Understanding and controlling the exciton transport through nano building block assemblies has profound implications on light harvesting and emitting materials, the synthesis of novel mesoscale structures with specific optoelectronic functionalities, nano electronics, and photo-induced biological processes.

A unique microscopy technique has been developed in my laboratory to visualize energy transport within structured nano building block assemblies: A nano optical light source (plasmonic antennae) excites a tiny area of the nano building block assembly. In parallel a scanning probe tip scans over the sample, mapping the material response due to the local excitation. Using the combination of local excitation and local probe technique resolves exciton diffusion with sup 10 nm spatial resolution.

We plan to explore: 1) exciton diffusion length and dynamics in organic and perovskite based photovoltaic materials in dependence of their local morphology (e.g crystallinity); and 2) measure the spatial extend of exciton transport via Foerster Resonance Energy Transfer in mono disperse and poly disperse inorganic nano building block assemblies.

FY 2014 HIGHLIGHTS

We were able to make advances on three fronts: 1. Mapping optoelectronic processes in state of the art perovskite photovoltaic materials; 2. Mapping exciton transport through CdSe quantum dot arrays and polymer thin films; 3. Manipulating excitons to engineer the currently smallest light switch. [1] In collaboration with the Joint Center for Artificial Photo syntheses we characterized high efficient perovskite PV devices (>16%) and discovered an enormous local heterogeneity between different grains

using state of the art near field optics. The most exciting finding is that these devices already include a few individual grains that operate close to the Shockley Queisser limit (32%). This insight will lead to a systematic and fast optimization process of this material class. [2] Using the techniques proposed in the proposal we were able to find an exciton diffusion length in CdSe Quantum dots of >100nm and determine how to manipulate the diffusion length which is the base for the potential development of novel PV light absorbers. For the most popular organic P3HT polymer materials we determined a diffusion length of 20nm and more importantly that the diffusion length can be manipulated via strong field gradients. The latter result might open up the approach for exciton transport manipulation and lead to novel approaches in information technology. [3] We demonstrated how to manipulate Förster Resonance Energy Transfer mediated energy transfer between individual PbSe Quantum Dots and gated layers of graphene. The main outcome is that the luminescence can be turned on and off from individual quantum dots with enormous speeds taking advantage of the high mobility of graphene and in ambient conditions. This is extremely interesting for miniaturizing light modulators for the information industry, where the smallest light modulators are currently tens of micrometers large and are reduced here to individual 4 nm quantum dots (Nano Lett., 2014, 14 (12), pp 7115–7119).

EARLY CAREER: Generation of Coherent Stable Terawatt-level Hard X-Ray Free Electron Laser Pulses with Femtosecond Duration

Institution: SLAC National Accelerator Laboratory
Point of Contact: Juhao Wu
Email: jhwu@slac.stanford.edu
Principal Investigator: Juhao Wu
Sr. Investigator(s):
Students: 0 Postdoctoral Fellow(s), 3 Graduate(s), 0 Undergraduate(s)
Funding: \$500,000 (2014)

PROGRAM SCOPE

Terawatt (TW) peak power Free Electron Laser (FEL) can enable the single molecule imaging and study of nanometer or even finer structure. The goal of this project is to study the feasibility to generate tunable, fully coherent TW peak power hard x-ray FEL pulses with more than $1.0E+13$ photons/pulse in 10 femtoseconds duration. This will be more than one-order of magnitude higher peak power than existing hard x-ray FEL facilities like LINAC Coherent Light Source (LCLS) provide. A promising way to generate such high power FEL pulses is to amplify a coherent seed through a highly tapered undulator. The seed must be predominantly coherent with stable intensity and a large signal-to-noise ratio. We propose an improved Self-Amplified Spontaneous Emission (iSASE) scheme to generate such a seed [1, 2]. Other seeding schemes, such as self-seeding, are also studied and compared to iSASE. Self-seeding has been demonstrated at LCLS, which not only proved the reduction of frequency bandwidth, but also requests further improvements to increase the taper efficiency. Approaches to overcome these challenges will be studied. For an iSASE, phase shifters are interlaced between undulators sections to mix the phase and amplitude of the FEL radiation coherent spikes. This increases the cooperation length, and gradually narrows the spectrum of the FEL. With such an iSASE scheme, a coherent seed, with stable intensity and large signal-to-noise ratio, can then be efficiently and stably amplified to TW-level in a highly tapered undulator. Such an iSASE seed is intrinsically tunable, much like SASE, in contrast to other seeding schemes which tend to have limited tuning range. This project aims at a thorough study to generate tunable, fully coherent stable TW-level hard x-ray pulses having a few femtoseconds duration, both in theory and experimentation. [1] J. Wu, A. Marinelli, and C. Pellegrini, Proc. FEL2012, p. 237, Nara, Japan. [2] J. Wu *et al.*, Proc. IPAC2013, p. 2068, Shanghai, China.

FY 2014 HIGHLIGHTS

(1) In an iSASE FEL, undulator sections are interlaced with phase shifters. To systematically study and optimize iSASE, a simulation package was developed in April, 2014. Since an iSASE seed starts from the random shot noise in the electron bunch, a statistic analysis is necessary. The iSASE scheme is studied with 1000 simulation sets, which are generated with a random start from shot noise, and also include random phase shifter error. The results enabled us to observe the statistic nature, and quantify the statistical fluctuation of the iSASE seed power and bandwidth. (2) The critical add-on for an iSASE FEL is to introduce phase shifters and interlace them with undulator sections to enhance the slippage between the FEL and the electron bunch. To connect my Early Career Research Project to SLAC's most important project LCLS-II, based on the LCLS-II base line, phase shifters are designed to show that an iSASE can be configured for LCLS-II. (3) For a tapered FEL, the power can increase by a factor of 100; we ask whether the FEL still has a high transverse coherence. A study on the mode content was carried out and the analysis revealed that the fundamental Gaussian mode contributes more than 95% of the total power even in the deep tapered region. This ensures that a deeply tapered FEL is highly coherent. (4) To benchmark our theoretical finding and numerical simulation result, we study tapered FEL experimentally on LCLS, both for SASE and Self-seeding FEL. Tapered FEL optimization is an intrinsically difficult task. An on-line optimization for a tapered FEL was implemented. For both SASE and Self-seeding FEL, the on-line optimizer successfully brought a random started LCLS to the optimized configuration within 20 minutes. Journal papers: [1] Phys. Rev. ST Accel. V. PRINCIPAL INVESTIGATORS AND SR. INVESTIGATORS INDEX

Abbamonte, Peter.....II-159, II-515, II-582
Abbott, Nicholas.....II-1
Abergel, Rebecca J.....I-372, I-379
Abu-Omar, Mahdi.....I-53, I-78
Adams, Michael.....I-438
Adams, Philip.....II-119
Ade, Harald.....II-208
Adzic, Radoslav.....I-151
Ager, Joel.....I-603, II-416, II-417
Agostini, Pierre.....I-10
Agra-Kooijman, Dena.....II-235
Agrawal, Rakesh.....I-603, II-416
Ahmed, Musahid.....I-250, I-255, I-282
Aichele, Clinton.....II-113
Aikens, Christine.....I-166
Aizenberg, Joanna.....II-2
Akinc, Mufit.....II-43
Alam, Ashraf.....I-603, II-416
Alberi, Kirstin.....II-409, II-420
Albrecht-Schmitt, Thomas.....I-353
Alexander, Millard.....I-258
Alexandratos, Spiro.....I-353
Ali, Naushad.....II-356
Alivisatos, Paul.....II-258, II-274
Allen, Heather.....I-291
Allen, Philip.....II-480
Allen, Wesley.....I-167
Allison, John.....II-275
Altman, Eric.....I-53
Alvarez-Campot, Gonzalo.....III-5
Ames, James.....I-409
An, Ke.....II-473
Analytis, James.....II-200
Andersen, Richard A.....I-379
Anderson, Iver.....II-475
Anderson, Peter.....II-295
Andraka, Bohdan.....II-120
Andreev, Anton.....II-480
Andrei, Eva.....II-120
Anovitz, Lawrence M.....I-351
Antonio, Mark.....I-380
Antropov, Vladimir.....II-580
Appel, Aaron.....I-156
Appenzeller, Joerg.....II-425
Armentrout, Peter.....I-354
Armitage, N. Peter.....II-326
Armstrong, Neal.....I-542
Arnold, John.....I-379
Arnold, Michael.....II-429
Aronson, Igor.....II-39, II-565
Aronson, Meigan.....II-187
Arslan, Ilke.....I-85
Asbury, John.....I-542
Ashoori, Raymond.....II-122
Aspuru-Guzik, Alan.....I-168
Asta, Mark.....II-320, II-571
Asthagiri, Aravind.....I-117, I-149
Atwater, Harry.....II-357
Autrey, Tom.....I-156
Autschbach, Jochen.....I-356
Averback, Robert.....II-277
Averitt, Richard.....II-583, II-584, II-590
Azadi, Parastoo.....I-447
Bachand, George.....II-40
Bagus, Paul.....I-292, I-343
Bakac, Andreja.....I-160
Baker, Ian.....II-276
Balakirev, Feodor.....II-192
Balashov, Sergei.....I-411
Balatsky, Alexander.....II-562
Balaz, Milan.....II-115
Balazs, Anna.....II-2, II-3, II-4
Balbuena, Perla.....I-54
Baldo, Marc.....II-209
Balents, Leon.....II-482
Balicas, Luis.....II-123
Balke, Nina.....II-410
Balsara, Nitash.....II-90
Baneyx, Francois.....II-28
Bansil, Arun.....II-483
Baranger, Harold.....II-484
Bard, Allen.....I-543
Bardeen, Christopher.....I-150
Barlow, Robert.....I-287
Barnes, Michael.....I-502
Bart, Suzanne.....I-357
Bartels, David.....I-549
Bartelt, Norm.....II-97
Bartlett, Bart.....I-55
Bartynski, Robert.....I-56
Baruah, Tunna.....I-169
Baskin, Tobias.....I-439

Basov, Dmitri.....II-124, II-584, II-590
 Bass, Jay.....I-293
 Batista, Cristian.....II-192
 Batista, Enrique.....I-378, II-420
 Batista, Victor.....I-401, I-547
 Batson, Philip.....II-49
 Batzill, Matthias.....I-57
 Batzle, Michael.....I-327
 Bauer, Eric.....I-374, II-353
 Bauer, Stephen.....I-342
 Bawendi, Moungi.....II-125
 Bazarov, Ivan.....III-1
 Beach, Geoff.....II-126
 Beck, Warren.....I-384
 Becker, Andreas.....I-1
 Becker, Udo.....I-358
 Bedzyk, Michael.....I-135, II-26
 Bei, Hongbin.....II-316, II-414
 Belfort, Georges.....I-503
 Belkacem, Ali.....I-43, I-50
 Bell, Alexis.....I-154
 Bellaiche, Laurent.....II-485
 Bellan, Josette.....I-259
 Bellon, Pascal.....II-277
 Ben-Itzhak, Itzhak.....I-2
 Benmore, Chris.....II-597
 Benning, Christoph.....I-385
 Bent, Stacey.....II-430
 Beratan, David.....II-358
 Berezovsky, Jesse.....II-50
 Bergman, Leah.....II-383
 Bergman, Robert.....I-154
 Bernabe, Yves.....I-303
 Bernholc, Jerry.....II-486
 Berrah, Nora.....I-3
 Berry, John.....I-58
 Berryman, James.....I-349
 Bertozzi, Carolyn.....II-206
 Bertrand, Guy.....I-58
 Betley, Theodore.....I-59
 Beyerlein, Irene.....II-321
 Bhan, Aditya.....I-61
 Bhatt, Ravindra.....II-487
 Bhattacharya, Anand.....II-188, II-413
 Bieler, Thomas.....II-278
 Billinge, Simon.....II-602
 Bingham, Philip.....III-5
 Bird, Jonathan.....II-127
 Birge, Norman.....II-128
 Birgeneau, Robert.....II-200
 Biswas, Rana.....II-204
 Blancaflor, Elison.....I-443
 Blank, David.....I-551
 Blankenship, Robert.....I-386
 Blanquart, Guillaume.....I-260
 Bligaard, Thomas.....I-152, I-157
 Bluhm, Hendrik.....I-250
 Blum, Suzanne.....I-62
 Blumberg, Girsh.....II-129
 Boatner, Lynn.....II-203
 Bobev, Svilen.....II-210
 Bocarsly, Andrew.....I-544
 Bocian, David.....I-564
 Bockrath, Marc.....II-152
 Boehlert, Carl.....II-278
 Boehme, Christoph.....II-359
 Boerio-Goates, Juliana.....I-524
 Boettcher, Shannon.....I-545
 Bohn, Paul.....I-504
 Bollinger, Anthony.....II-468
 Boncella, James.....I-378
 Bondarev, Igor.....II-488
 Bonesteel, Nicholas.....II-489
 Bonnell, Linda.....I-319
 Booth, Corwin.....I-379
 Borisevich, Albina.....II-91
 Boriskina, Svetlana V.....II-361
 Borja, Ronaldo.....I-294
 Bose, Arijit.....II-106
 Bourret, Edith.....II-200
 Bowen, Kit.....I-181
 Bower, Allan.....II-106
 Bowers, Geoffrey.....I-295
 Bowman, Craig.....I-266
 Bowman, Joel M.....I-170
 Bowman-James, Kristin.....I-505
 Boyce, Brad.....II-313
 Bozin, Emil.....II-602
 Bozovic, Ivan.....II-468
 Braley, Jenifer.....I-359
 Brantley, Susan.....I-296
 Bratko, Dusan.....I-197
 Braun, Paul.....II-244
 Bren, Kara.....I-546
 Brenner, Igal.....II-411
 Bricker, Terry.....I-387

Bridges, Craig.....II-261
 Brinker, C. Jeffrey.....I-63, II-41
 Brinson, Catherine.....II-280
 Britt, R. David.....I-388, I-409
 Broadbelt, Linda.....I-135
 Broderick, Joan.....I-440
 Broholm, Collin.....II-326
 Brongersma, Mark.....II-368
 Brown, Donald.....I-441
 Browse, John.....I-442
 Brudvig, Gary.....I-389, I-547
 Bruemmer, Stephen.....II-314
 Bruening, Merlin.....I-506
 Brus, Louis.....I-548
 Brutchey, Richard.....II-211
 Bryant, Donald.....I-390, II-16
 Buchanan, Kristen.....II-130
 Bucksbaum, Philip.....I-44
 Budai, John.....II-345
 Budakian, Raffi.....II-163
 Bud'ko, Serguei.....II-189
 Budnick, Josphep.....II-183
 Bulatov, Vasily.....II-317
 Bullock, Morris.....I-156
 Bunel, Emilio.....I-153
 Buonassisi, Tonio.....I-603, II-416
 Burke, Kieron.....II-490, II-554
 Burlingame, Alma.....I-492
 Burnap, Robert.....I-391
 Burns, Clement.....II-584
 Burns, Peter.....I-360
 Bustamante, Carlos.....I-433, II-412
 Butler, Laurie.....I-261
 Butov, Leonid.....II-131
 Bylaska, Eric.....I-343, I-373
 Cabelli, Diane.....I-602
 Cabrini, Stefano.....II-426
 Cahill, Christopher.....I-361
 Cai, Wei.....II-280
 Callis, Judy.....I-392
 Camaioni, Don.....I-156
 Camden, Jon.....II-51
 Camillone III, Nicholas.....I-254
 Campbell, Charles.....I-64, I-157
 Campbell, Geoffrey.....II-92
 Campuzano, Juan-Carlos.....II-606
 Canfield, Paul.....II-189
 Canning, Andrew.....II-494
